Cortisol biosynthesis. One of the earliest molecular markers of the developing interrenal tissue is the localized expression of the fushi tarazu factor 1β (*ff1b*), a transcription factor, and homolog of the mammalian steroidogenic factor 1. The initial expression of *ff1b* occurs at 22 hpf and is required for interrenal cell differentiation. It is also responsible for the initiation of P450scc expression at 24 hpf, which is the rate-limiting enzyme in steroidogenesis. StAR is also initially detected in the primordial interrenals at 24 hpf, followed by 3β-hydroxysteroid dehydrogenase (3β-HSD) (28 hpf) and MC2R (32 hpf). The expression of 11β-hydroxylase, which catalyzes the final step of cortisol synthesis, increases by 48 hpf, around the time of hatch. This is immediately followed by a rise in basal whole-body cortisol levels.

Interrenal development over the first 48 hpf occurs independently from higher signals such as ACTH. This is demonstrated by MC2R knockdown morphants or mutants that lack corticotropic cells (and therefore ACTH), which maintains both normal interrenal tissue development and the expression of steroidogenic enzymes. However, by 5 days post-fertilization (dpf), a lack of ACTH signaling results in the loss of steroid synthesizing capacity as genes involved in steroidogenesis are undetectable at this time. This indicates that

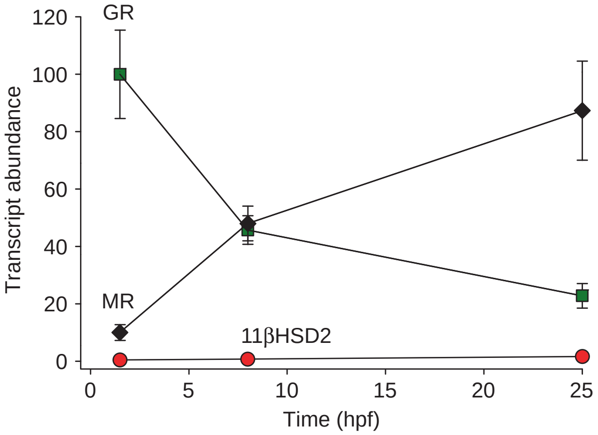

Figure 4 Glucocorticoid receptor (GR), mineralocorticoid receptor (MR), and 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) expression (arbitrary units) in zebrafish embryos. The paucity of 11βHSD2 transcripts suggests that cortisol has access to MR during embryonic development, which is steadily increasing in transcript number.

interrenal function is autonomous over the first 2 dpf, but control is transferred to higher levels by 5 dpf.

ACTH and CRF in the pituitary and hypothalamus, respectively, are expressed by 48 hpf, and the interrenals are beginning to produce cortisol. The brain appears to be poised to activate cortisol production in response to a stress. However, salinity and handling stressors do not stimulate a cortisol stress response at this point in time.

Glucocorticoid and mineralocorticoid receptors. The initial abundance of maternally derived GR transcripts in the mature oocyte is unstable and is rapidly degraded (**Figure 4**). This suggests that GR signaling may not be critical during early embryonic development. By hatch, GR transcript numbers have rebounded and remain elevated. GR signaling may be critical at this time for metabolic energy repartitioning during the onset of feeding and growth.

In contrast to GR, MR transcripts increase steadily from fertilization to feeding (**Figure 4**). In addition, there are very few 11βHSD2 transcripts in the embryo, which would suggest that cortisol is not deactivated and may be a ligand for MR. The embryo has continuous access to cortisol, from the maternal deposit during the early stages, or from *de novo* synthesis beginning around hatch.

The lack of a cortisol stress response during embryogenesis suggests that GR and MR signaling may be regulating basic aspects of development such as metabolism or osmoregulation as in adults. In mammals, GR regulates fetal carbohydrate metabolism, based on observations in GR knockout animals that display altered expression of key gluconeogenic enzymes.

Summary. The HPI axis appears to be fully expressed and the interrenal cells are producing cortisol by hatch. However, there is no cortisol stress response during early embryogenesis. Whether the cortisol response is delayed simply due to developmental constraints or is intentional to protect against elevated cortisol signaling during sensitive stages (similar to the stress hypo-responsive period in postnatal mammals) is unknown.

Hatching – Embryo to Larva Transition

Hatching begins at 48 hpf in zebrafish and this coincides with further increases in the expression of CRF, StAR, 11β-hydroxylase, 11βHSD2, and the rebound of GR. At hatch, whole-body cortisol levels are beginning to rise as synthesis is initiated. In spite of these developments, cortisol levels in zebrafish are unresponsive to salinity or handling stressors. It appears that development of the sensory inputs to the hypothalamus, critical for stress perception and CRF release, is the limiting step delaying the activation of the cortisol stress response during development.

The stress response is first observed at 3 dpf (72 hpf), where cortisol levels in freshwater reared larvae are elevated after exposure to increased salinity (seawater). Although this is the earliest indication of a functional HPI axis, a handling stress (swirling around in a glass vial) at this same stage does not elicit an increase in cortisol. One hypothesis to explain this difference is that handling and osmotic challenges activate different signaling pathways, which have reached different degrees of functional development by 3 dpf. The HPI axis appears to be fully functional and receptive to different types of stressors at 4 dpf (approaching the onset of exogenous feeding). At this time both an osmotic challenge and handling stress elicit an increase in cortisol levels.

Stress Axis Development in Other Teleosts

Common Carp

The common carp and zebrafish are both cyprinids and have similar developmental rates and times to hatch (2–3 dpf). However, the cortisol stress response develops at an earlier stage in carp: basal cortisol and ACTH levels increase well before hatch, and also increase in response to stressor exposure before hatching. The evolutionary pressures that would lead to an accelerated development of HPI axis in carp are unknown.

Rainbow Trout, Atlantic Salmon, and Yellow Perch

Relative to hatching time, the temporal development of basal and stress-induced cortisol levels in rainbow trout, Atlantic salmon, and yellow perch are very similar to zebrafish. Cortisol levels are at a minimum around

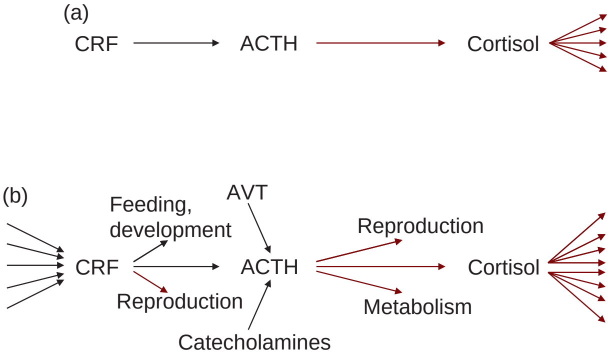

Figure 5 The HPI-axis signaling pathway: (a) simplified and (b) with some of the known signaling pathways, modulators, and functions of the HPI axis.

hatching (hatching times: zebrafish – 2–3 dpf; perch – 10 dpf; salmonids – 4 wpf), and then begin to increase. However, stress-induced elevations of cortisol are not observed until after hatching (1 week post-hatch in perch and 2 weeks post-hatch in salmonids).

Early exposure to stressors can alter the activation of the stress response later on in life. For example, rainbow trout embryos and larvae exposed to a stressor have a depressed cortisol response as juveniles (5 months post-fertilization). This dampening of the stress response is also observed in juvenile rainbow trout that were exposed to waterborne cortisol immediately after fertilization for approximately 2 days. This illustrates that the development and programming of the HPI axis is sensitive to stressor exposure, and long-lasting effects can be imprinted early on during development. However, determining the physiological consequences of these changes in the stress response is still required, and is essential in furthering our understanding of the development of the HPI axis.

Conclusion

There is clearly a good understanding of the molecular ontogeny of the HPI axis in teleosts, or more specifically, the CRF-ACTH-cortisol axis (**Figure 5**(**a**)). However, this is an extremely simplified view of a complex system that possesses multiple paths of regulation and function (**Figure 5**(**b**)). To date, the majority of experiments have focused on the regulation of stress axis genes in terms of transcript abundance under various conditions. However, there are several genetic and epigenetic mechanisms that influence these parameters. Characterizing these molecular mechanisms is useful not only to understand gene regulation but also to identify novel pathways, which can be used as bio-indicators of exposure to stressful stimuli. In addition, perhaps one of the more significant issues that currently remains unresolved is determining the basic functions of the stress axis components such as CRF, ACTH, GR, and MR during embryogenesis, given that there is no active stress response during this time.

Model species such as zebrafish have occupied a pivotal position in the study of physiological and molecular pathways of the HPI axis. However, teleosts are a large group with diverse developmental patterns, so it would be presumptuous to believe that the mechanisms are similar between different species, especially in light of the accelerated HPI-axis development in carp and the unique situation of single gene systems for CRF, ACTH, and GR in zebrafish. Hence, studies conducted in nonmodel species that are of importance to aquaculture, environmental conservation, and management are necessary.

Glossary

Adenohypophysis The anterior part of the pituitary composed of the pas distalis and pars intermedia, derived from the roof of the embryonic mouth.

Antigen A substance capable of reacting specifically with an antibody to induce an immune response.

Antiserum Serum containing an antibody or antibodies.

Axon The long extension of a nerve cell that carries spikes (action potentials, or neural impulses) to distant target cells away from the cell body where the nucleus lies (also called the nerve fiber).

Bony fish The majority of extant fishes – class Osteichthyes.

Connective tissue This tissue binds and supports the body.

Diencephalon The more caudal of the two divisions of the forebrain. Caudal part of the prosencephalon (forebrain) associated with the third ventricle. The general subdivisions are (from dorsal to ventral): epithalamus, dorsal thalamus, subthalamus, and hypothalamus.

Diverticulum (pl. diverticula) A pouch opening from a hollow organ.

Ectodermal cell Cell of the outermost layer of an early animal embryo.

Electrolyte A solute that has an ionic charge.

Epithelial cells These cells cover a surface or line a cavity.

Hypothalamus Region at the floor of the forebrain (diencephalon) that controls several vegetative physiological processes, including food intake and secretion of hormones from the pituitary gland

Infundibulum The neural stalk connecting the median eminence to the pars nervosa.

Median eminence A downward extension of the hypothalamus.

Melanophores Stellate connective tissue cells containing melanin granules in their cytoplasm.

Mesenchyme Embryonic connective tissue composed of stellate cells, wandering cells, and capillaries in an amorphous intercellular substance.

Negative feedback It tends to stabilize a process by reducing its rate when its effects are too great.

Neurohypophysis The portion of the pituitary that is derived from the downgrowth of nervous tissue from the diencephalon.

Neurosecretion The production of hormones within the body of nerve cells and their release from axon tips.

Pars distalis The anterior endocrine part of the pituitary derived from the ectoderm lining the roof of the mouth; it secretes a number of hormones.

Pars intermedia Part of the pituitary lying between the pars distals and pars nervosa; it is derived from the pars distalis.

Pituicytes Elongated cells of unecertain function in the neurohypophysis; their long processes course between neurosecretory axons.

Portal vessel A blood vessel connecting two capillary beds.

Releasing factor A hypothalamic neurosecretion that stimulates the liberation of a specific hormone from the adenohypophysis.

Saccus vasculosus A thin vesicle of unknown function on the floor of the diencephalon of most fishes.

Septum (pl. septa) A membrane between body spaces.

Sympathetic nervous system The division of the autonomic nervous system involved with the fight-or-flight reaction. Autonomic pathways from the thoracic and lumbar segments of the (mammalian) spinal cord.

Transporting epithelium (pl. epithelia) It a acts as a selective barrier to the diffusion of substances.

Vascular plexus A network of blood vessels.

Anatomy

An intimacy develops among vertebrate embryos between a mass of ectodermal cells that migrate upward from the roof of the mouth and the infundibulum, a stalk of nerve fibers that grows downward from the hypothalamus in the floor of the diencephalon. The tissue mass formed by this union becomes permeated with vascular mesenchyme that develops into a capsule besides providing the vascular connective tissue that supports and nourishes the organ. This is the beginning of the hypophysis or pituitary gland, the master gland of the endocrine system.

The pituitary secretes several hormones that control diverse activities in the body. It is two glands in one: the adenophypopophysis or anterior pituitary, which develops from the cells that budded upward from the roof of the mouth, and the neurohypophysis, or pars nervosa, derived from the bundles of nerve cell processes (axons) that grew down from the hypothalamus. This stalk of nerve fibers persists throughout life and the pituitary gland remains attached to the brain, thereby enabling the nervous system to exert its control over the endocrine system. In elasmobranchs and teleosts, the neurohypophysis also includes an outgrowth of the infundibulum, the nonglandular saccus vasculosus of uncertain function.

The proximity of the neurohypophysis to the adenohypophysis enhances integration of pituitary function by easing the passage of materials between them. This transfer may be facilitated by a portal system involving capillaries draining the neurohypophysis that pass to a capillary bed in the adenohypophysis.

The adenohypophysis of fish is subdivided into two parts: the pars distalis and the pars intermedia. Although there are variations in the arrangement of these parts, the pituitary of the puffer (*Fugu stictonatus*) is a good example of the structure of this gland in bony fish (**Figure 1**). The pars distalis is further subdivided into the anterior rostral pars distalis and the posterior proximal pars distalis, which lie below the neurohypophysis. Groups of cells with a variety of functions comprise the regions of the adenohypophysis. Finger-like ramifications of the pars nervosa invade the adenohypophysis, especially the pars intermedia (**Figure 2**).

The pars nervosa of bony fish is a neurosecretory organ where droplets of secretion, produced in the bodies of nerve cells located within the hypothalamus (**Figures 3** and **4**), travel down inside the axons of these cells (**Figure 5**) to be released into the vascular connective tissue of the pars nervosa; the axon terminals do not penetrate the adenohypophysis. The association between the neurohypophysis and adenohypophysis of teleosts is especially intimate (**Figure 6**) and a portal system is absent in most. Pituicytes, which lurk among the nerve fibers, are probably not secretory and have an unknown function. They may be derived from the cells of the vascular mesenchyme, which invaded the region during its development.

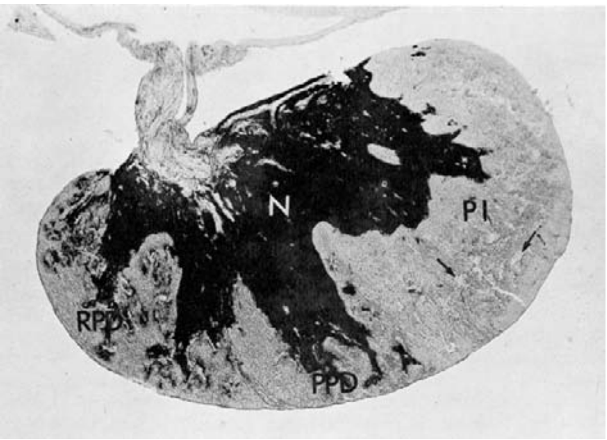

Figure 1 Median sagittal section of the hypophysis of a juvenile puffer, *Fugu stictonotus*, showing the neurohypophysis (N) and three parts of the adenohypophysis: the rostral pars distalis (RPD), proximal pars distalis (PPD), and pars intermedia (PI). Figure 5 Electron micrograph of a cross section of a trunk of neurosecretory axons in the pars nervosa of the loach (teleost), *Misgurnus fossilis*. BM, basal lamina; M, mitochondria; NF, neurofilaments; NSG, neurosecretory granules to neurosecretory droplets; NT, neurotubules; SV, synaptic vesicles. 21 400×. From Jasinski and Kilarski (1970) Fine structure of pars neuro-intermedia the loach, *Misgurnus fossilis* L. *Zellforschung* 105: 259–275, figure 7.

has been omitted from the diagram. The pars distalis lacks arteries in elasmobranchs and is supplied by a portal system that collects blood from the median eminence and hypothalamus. The diverticula of the pars nervosa have a vessel-free outer surface that contains as much neurosecretory material as the parts facing the pars intermedia.

The pars distalis of the lamprey is embedded in connective tissue which separates it from the pars intermedia and the neurohypophysis (**Figure 8(a)**). The neurohypophysis of lampreys is only a slight thickening of the floor of the third ventricle. A vascular plexus intervenes between the pars intermedia and the neurohypophysis.

The pituitary of the hagfish is a simple strucure (**Figure 8(b)**). Its adenohypophysis shows no clear distinction between a pars distalis and a pars intermedia and consists of follicles and clusters of cells embedded in connective tissue below a hollow evagination of the hypothalamus that constitutes the neurohypophysis. The thin septum of connective tissue separating the neurohypophysis and adenohypophysis may be sufficiently thin to permit diffusion of materials.

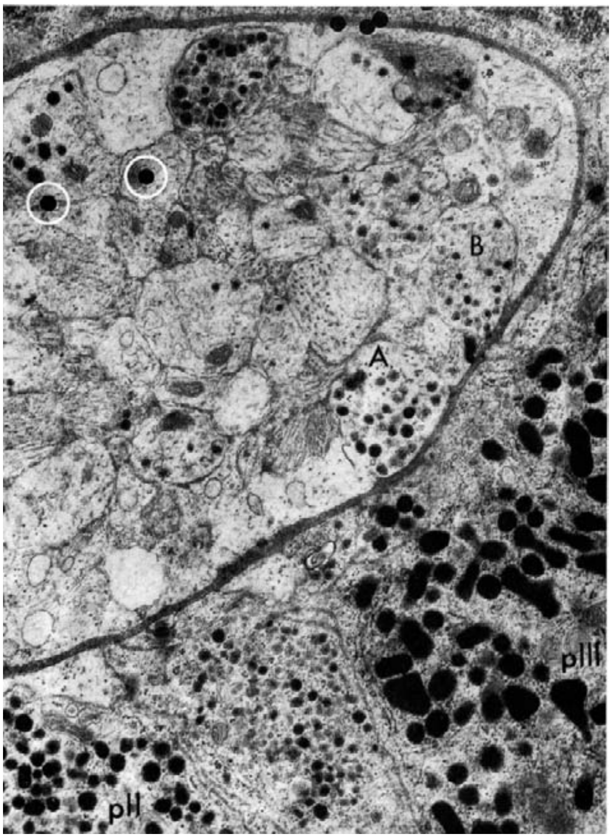

Figure 6 Electron micrograph of an evagination of the neurohypophysis extending between cells of the pars distalis. It contains two types of axons, A and B. Axonal tips (pII and pIII) penetrate between cells of the pars distalis. A limiting membrane separates the two regions. White circles are drawn around grains of latex. 10 900×. From Jasinski (1974) Fine structure of the anterior neurohypophysis of the pond-loach, *Misgurnus fossilis* L., with reference to the neurosecretory innervation of intrinsic cells of the pars distalis. *Acta Anatomica* 87: 193–208, figure 2.

The means by which neurosecretions reach the adenohypophysis are variable in the vertebrates (**Figure 9**). Portal vessels of higher vertebrates collect blood from capillaries in the neurohypophysis and carry it to capillaries in the adenohypophysis. There is no portal system in most teleosts, and extensions of the neurohypophysis intrude upon the adenohypophysis, allowing their neurosecretions to diffuse to the adenohypophysis; direct innervation by processes from the pars nervosa may also take place. A portal system occurs in the hypophysis of elasmobranchs carrying neurosecretions from the neurohypophysis to the adenohypophysis. Simple diffusion of neurosecretory material occurs in the agnatha.

Hormones of the Adenohypophysis

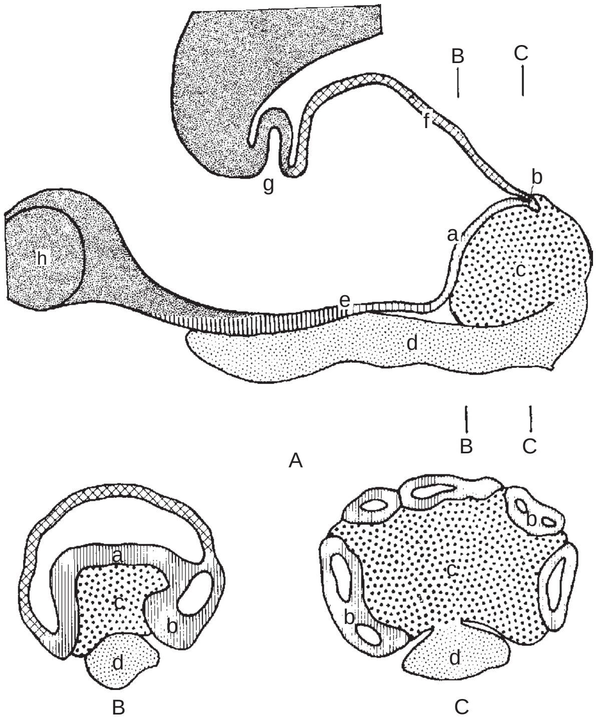

Figure 7 Diagrams of sections of the hypophysis of the dogfish shark, *Etmopterus spinax*. A is a median sagittal section; B and C are transverse sections taken at the levels shown in A. The ventral lobe of the pars distalis, which extends ventrally from the large anterior lobe, has been omitted. a, pars nervosa; b, diverticula of the pars nervosa; c, pars intermedia; d, pars distalis; e, median eminence and infundibular stem; f, saccus vasculosus; g, posterior recess; h, optic chiasma. From Meurling (1963) Nerves of the neuro-intermediate lobe of *Etmopterus spinax* (Elasmobranchi). *Zeitschrift für Zellforschung* 61: 182–201, figure 1.

Immunocytochemistry has been used extensively to determine the distribution of cells in the pituitary gland (**Figure 10**). Antisera to many hormones, often mammalian, have been used to identify and localize the different cell types. Secretory cells of the teleost fish are distributed in well-defined zones. **Figure 11** summarizes these findings for the pituitary of the Atlantic croaker *Micropogonias undulatus* – the literature abounds with similar findings. The rostral pars distalis contains corticotropes (adrenocorticotropic hormone (ACTH) cells) and prolactin (PRL) cells (PRL cells); the proximal pars distalis contains growth hormone cells (GH cells), gonadotropes (gonadotropic hormone (GTH) cells), and thyrotropes (thyroid-stimulating hormone (TSH) cells); there is evidence that cells that stain with lead hematoxylin (PbH+ cells) in the pars intermedia secrete melanophore-stimulating hormone (MSH) and that cells that are positive for the periodic acid-Schiff stain (PAS+ cells) secrete somatolactin (SL), a hormone that particpates in ion regulation.

Heavy metals have been attached to antigens in order to visualize secretory cells with the electron microscope. **Figure 12** is an electron micrograph of a section of the cytoplasm of a prolactin cell from the

Figure 9 Brain pituitary relations in vertebrates. In agnathans, a thin neurohypophysis lies adjacent to a thin layer of glandular epithelial cells, permitting direct diffusion between these two structures. Many neurohypophysial axonal extensions penetrate the adenohypophysis of teleosts and either directtly innervate the adenohyphysial cells or end near these cells allowing the diffusion of neurosecretions. In higher vertebrates, portal vessels collect blood from capillaries in the neurohypophysis and carry it to the adenohypophysis. Cartilaginous fish (lower left) show many short vessels between the neurohypohysis and adenpohyphysis. pituitary of *Tilapia mossambicus* labeled with immunogold. Granules in the cytoplasm containing the hormone prolactin have picked up the labeled antigen and appear as black spots.

By a system of negative feedback in teleosts, ACTH causes the adrenal gland to release corticosteroids. PRL acts on transporting epithelia in the gills, kidney, urinary bladder, skin, and gut, thereby maintaining electrolyte and water balance in the body fluids of freshwater fish; its function in animals in seawater is unclear. GH promotes growth. GTH stimulates maturation of the gonads; two forms may be distinguished:

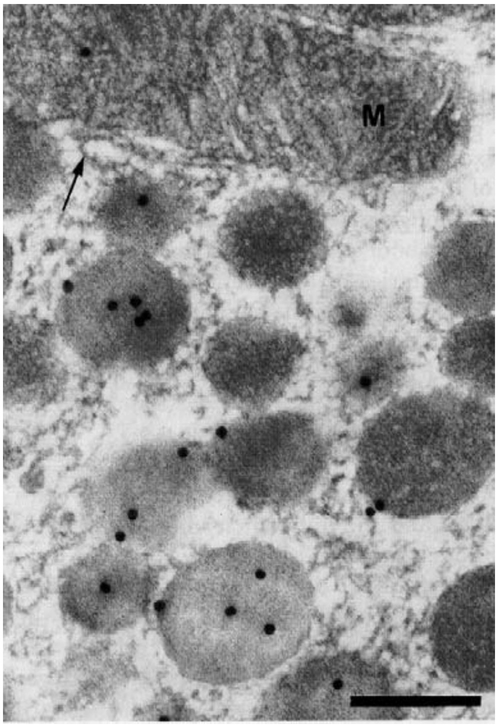

Figure 12 Electron micrograph of a section of the cytoplasm of a prolactin cell from the pituitary of *Tilapia mossambicus* labeled with immunogold. Granules in the cytoplasm containing the hormone prolactin have picked up the labeled antigen which appears as black spots. M, mitochondrion; arrow, endoplasmic reticulum. Bar = 0.25 μm. From Hwang and Wang (1993) Immunoelectron microscopical study of prolactin in pituitary of tilapia (*Oreochromis mossambicus*). *Acta Histochemica et Cytochemica* 26: 203–211, figure 9.

follicle-stimulating hormone (FSH) and luteinizing hormone (LH). TSH regulates thyroid function. MSH brings about color change in the skin of teleosts by affecting distribution of pigment granules in stellate melanophores; this effect is modulated by the sympathetic nervous system.

The distribution of hormone-secreting cells in elasmobranchs is less certain. ACTH and MSH may be produced in the neurointermediate lobe, TSH in the ventral lobe of the pars distalis (which was omitted from **Figure 7**), and PRL in the rostral pars distalis. The origins of GH and the gonadotropes FSH and LH are unclear. Conventional histological staining has produced only tentative speculation as to the nature of hormones produced by the pituitary of cyclostomes. In lampreys, immunocytochemistry has shown the presence of MSH in the pars intermedia and the rostral pars distalis. ACTH was confined largely to the rostral pars distalis. Information is sketchy for the hagfishes. The ultrastructure of pituitary cells suggests somatotropes and corticotropes in the adenohypophysis. In cyclostomes and elasmobranchs, the sympathetic nervous system is not involved in color change.

Hormones of the Neurohypophysis

Two similar polypeptide hormones of nine amino acids each are released at the axon endings in the pars nervosa of teleosts and elasmobranchs. Arginine vasotocin is said to have an effect on osmoregulation and salt/water balance. Oxytocin plays a role in reproduction, especially mating and egg laying. The picture is less clear in cyclostomes where arginine vasotocin may influence salt/water balance.

Histological Structure of the Adenohypophysis

The adenohypophysis consists of cords and clusters of secretory cells supported by a sparse stroma of delicate reticular fibers. It is invaded by fenestrated sinusoidal blood vessels with their accompanying connective tissue. The various secretory cells have been described for several species. Cells of the pituitary of the sailfin molly, *Poecilia latipinna*, will be described here.

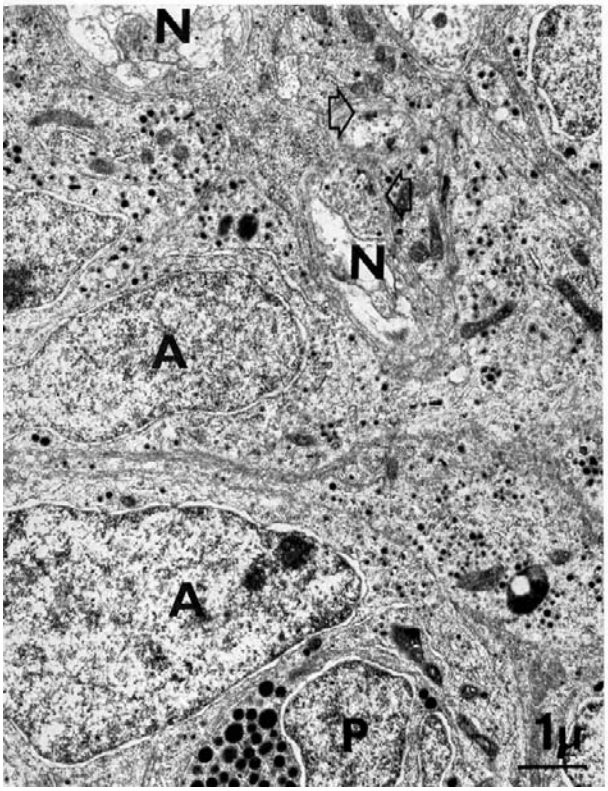

Figure 13 Electron micrograph of a section of the adenohypophysis of the sailfin molly *(Poecilia latipinna)*. ACTH cells (A) lie between prolactin cells (P) and the neurohypophysis (N). Arrows indicate terminations of nerve fibers. 12 000×. From Batten *et al.* (1975) Ultrastructure of the adenohypophysis in the teleost *Poecilia latipinna*. *Cell and Tissue Research* 161: 239–261, figure 3.

Cells of the Rostral Pars Distalis

ACTH cells (corticotropes) form a layer between the rostral pars distalis and the neurohypophysis, often only three or four cells deep. Two basal laminae separate the two regions. Nuclei of the corticotropes are often indented and elongated (**Figure 13**). The sparse cytoplasm contains a few round or rod-shaped granules and forms a narrow rim around the nucleus. A Golgi complex and mitochondria are present; granular endoplasmic reticulum is rare but free ribosomes were scattered throughout the cytoplasm.

PRL cells occupy most of the rostral pars distalis (**Figures 13** and **14**). They are usually rounded with a central round nucleus that is often deeply indented and contains one or two small nucleoli; electron-dense secretory granules pack the cytoplasm. The Golgi complex consists of scattered arrays of flattened cisternae and small vesicles; mitochondria are scarce. These features change when the ambient salinity is reduced – in fish adapted to freshwater, the PRL cells appear more active, with less granulation, more mitochondria, prominent Golgi complexes, and extensive granular endoplasmic reticulum.

Stellate cells are nonsecretory interstitial cells (**Figure 14**) with long, narrow processes that extend between the secretory cells to contact processes from other stellate cells, the basal lamina of the neurohypophysis, and the membrane around blood spaces. They may regulate the passage of materials throughout the adenohypophysis by way of intercellular channels. Their nuclei are flattened with an indistinct nucleolus. The pale cytoplasm occasionally contains Golgi-like vesicles, mitochondria, fragments of granular endoplasmic reticulum, and scattered ribosomes.

Cells of the Proximal Pars Distalis

Somatotropes (GH cells) lie in the inner regions of the proximal pars distalis intimately interdigitated with the neurohypophytsis (**Figure 15**). The nucleus is small, often irregular, usually lying at one end of the cell. The dense cytopasm contains abundant round secretory granules.

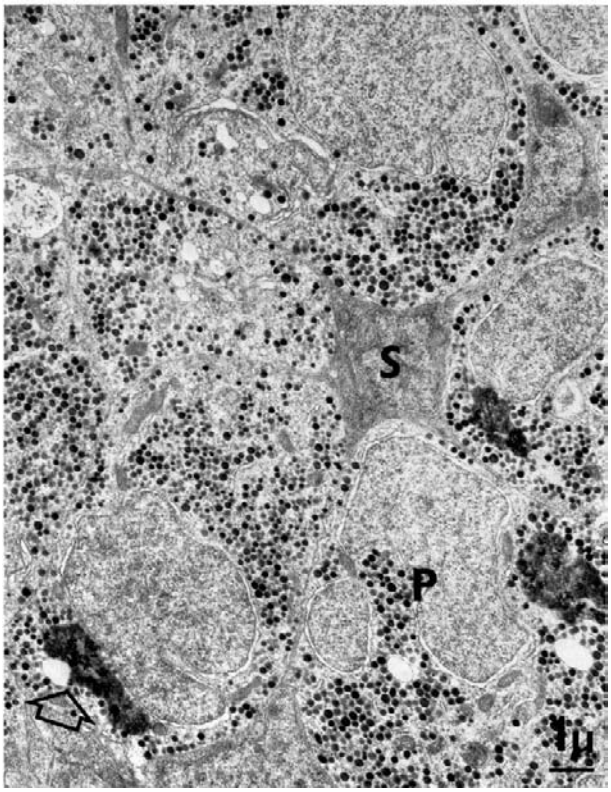

Figure 14 Electron micrograph of a section of the adenohypophysis of the sailfin molly (*Poecilia latipinna*). Prolactin cells packed with granules (P) surround stellate cells (S). 8000×. From Batten *et al.* (1975) Ultrastructure of the adenohypophysis in the teleost *Poecilia latipinna. Cell and Tissue Research* 161: 239–261, figure 4.

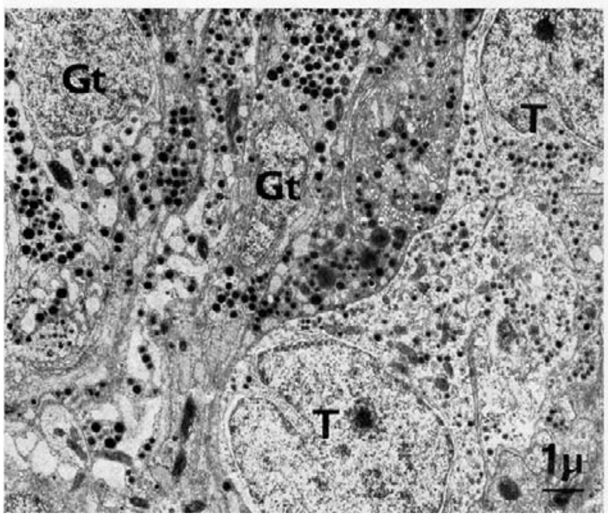

Figure 16 Electron micrograph of a section of the adenohypophysis of the sailfin molly *(Poecilia latipinna)*. Thyrotropes (T) border an area of gonadotropes (Gt). 8000×. From Batten *et al.* (1975) Ultrastructure of the adenohypophysis in the teleost *Poecilia latipinna. Cell and Tissue Research* 161: 239–261, figure 7.

Gonadotropes (GtH cells) show great variability depending on the condition of the gonads (**Figure 16**). In a female fish with oocytes in late vitellogenesis, the gonadotropes displayed a central round or oval indented nucleus and an indistinct nucleolus. The secretory granules are less electron dense than those of the somatotropes and prolactin cells. The cytoplasm varies, sometimes containing an extensive Golgi complex, abundant mitochondria, clear vesicles, dilated granular endoplasmic reticulum, free ribosomes, and multivesicular bodies.

Thyrotropes (TSH cells) are mixed with somatotropes. They vary considerably in appearance (**Figure 16**). Usually, they are large, irregular cells with a large, deeply indented nucleus lying at one end of the cell; occasionally, a small nucleolus is present. Mitochondria are abundant, but Golgi complexes are inconspicuous. The granular endoplasmic reticulum exists in scattered fragments throughout the cell. Secretory granules vary in size, shape, and electron density.

Stellate cells are also present in the proximal pars distalis, often lying between the gonadotropes. They send their processes between the secretory cells to approach the neurohypophysis.

Cells of the Pars Intermedia

Two types of secretory cells – both of uncertain function – have been identified in the pars intermedia: lead-hematoxylin cells (PbH+ cells) and periodic acid-Schiff-positive cells (PAS+ cells) (**Figure 17**).

Glossary

Adrenocorticotrophic hormone (ACTH) A protein hormone produced in the pituitary that causes release of cortisol from the interregnal.

Anadromy Life-history strategy entailing reproduction and early rearing in freshwater followed by a significant growth phase in seawater.

Apoptosis The process of programmed cell death.

Cortisol The major corticosteroid of teleosts, produced in the interrenal and acting on metabolism and ion regulation.

Cystic fibrosis transmembrane conductance regulator (CFTR) An apical chloride channel involved in chloride secretion.

Euryhaline Animals that physiologically adjust to a wide range of water salinity are considered euryhaline (eury ‘broad’; haline ‘salt’), in contrast to stenohaline animals.

Growth hormone (GH) A pituitary protein hormone controlling growth, metabolism, and ion regulation.

Hormone Signaling molecule released by a cell that either stimulates the cell of origin (autocrine), nearby cells (paracrine), or travels via the bloodstream to distant cells (endocrine).

Insulin-like growth factor-I (IGF-I) A protein hormone produced in the liver in response to growth hormone and acting on growth and ion regulation.

Na^+,K^+-ATPase (NKA, the sodium pump) A major ATP-consuming ion pump that, directly or indirectly, drives many ion-regulatory processes, including maintaining sodium and ion gradients across cell plasma membranes and being present at high levels in ionocytes.

Na^+,K^+,$2Cl^-$ cotransporter (NKCC) An ion-translocating enzyme that utilizes a sodium gradient to transport Na^+, K^+, and Cl^- into the cell.

Prolactin A protein hormone produced in the pituitary acting on ion balance and reproduction.

Receptor A signal transduction molecule that is activated by a hormone.

Stenohaline Describes an organism that cannot live in environments that undergo large changes in salinity (steno ‘narrow’).

Thyroid hormones Thyroxine and triiodothyronine, produced in the thyroid gland and acting on development and metabolism.

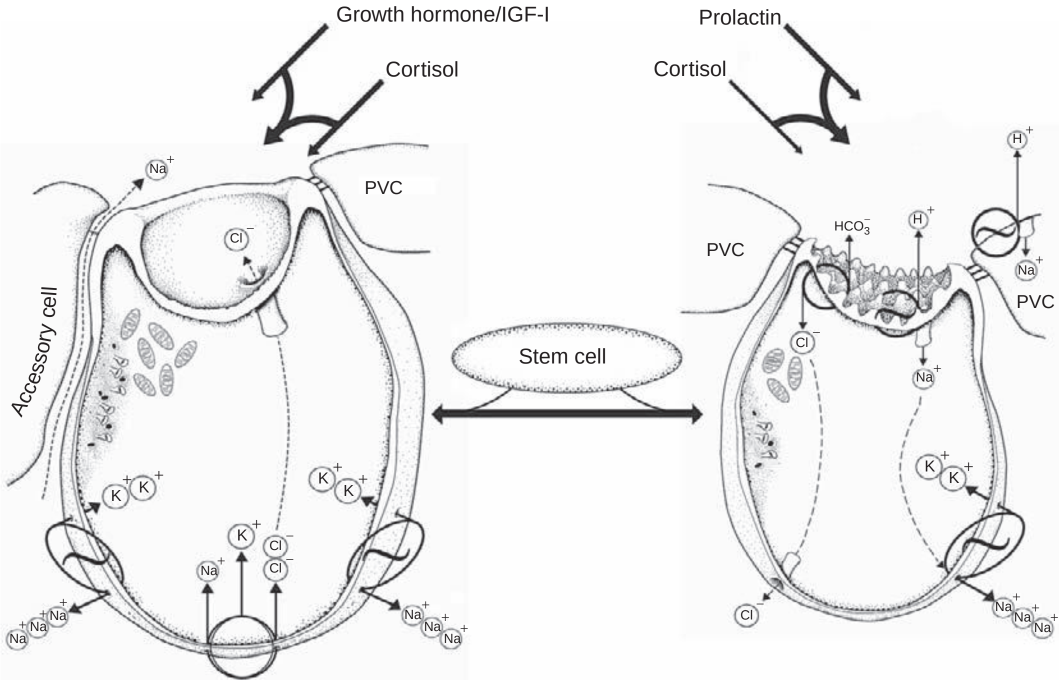
Transactivation Binding of a transcription factor, such as a receptor–ligand complex, to DNA resulting in increased gene transcription.

Introduction: Salt and Water Balance in Fish

Whether in freshwater or seawater, teleost fish maintain their plasma osmotic concentration at about one-third that of seawater (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). In freshwater, this requires counteracting the passive gain of water and loss of ions, and is accomplished through the production of large volumes of dilute urine and active uptake of ions across the gills. In seawater, teleosts must counteract the passive gain of ions and loss of water. This is accomplished by drinking seawater, absorbing water and salts across the gut, and excreting monovalent ions across the gills and divalent ions through the kidney. It has been estimated that 95% of teleost species are stenohaline, living wholly in either freshwater or seawater. The remaining 5% are euryhaline, having the capacity to tolerate a wide range of salinities. This trait is widespread among teleost lineages and has apparently evolved many times, and may be one reason that teleosts can be found in almost all aquatic habitats.

As outlined above, the gills are the primary site of sodium and chloride transport, actively taking up salts in freshwater and excreting them in seawater. Most of the recent work on the endocrine control of ion transport in fish has focused on the gill, so this review will necessarily be biased in this direction. It has been known for some time that the mitochondrion-rich cell (also known as the chloride cell) is the site of salt secretion (**see also Role of the Gills**: Morphology of Branchial Ionocytes and **Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). There is substantial evidence indicating that the major transporters involved in salt secretion in the gill include basolaterally located Na^+,K^+-ATPase (NKA, the sodium pump) and Na^+,K^+,$2Cl^-$ cotransporter (NKCC), and an apical Cl^- channel that is homologous with the cystic fibrosis transmembrane conductance regulator (CFTR) (**Figure 1**).

The site and mechanisms involved in ion uptake by the gill in freshwater are less certain. Both mitochondrion - rich cells and pavement cells may be involved in sodium and chloride uptake (**see also Osmotic, Ionic and**



Seawater (ion secretion)

Freshwater (ion uptake)

Figure 1 Morphology, transport mechanisms, and hormonal control of gill chloride cells in freshwater and seawater. Chloride cells are characterized by numerous mitochondria and an extensive tubular system that is continuous with the basolateral membrane. In seawater, mitochondrion-rich cells are generally larger and contain a deep apical crypt, whereas in freshwater, there is a broad apical surface containing numerous microvilli. Growth hormone and cortisol can individually promote the differentiation of the seawater chloride cell, and also interact positively to control epithelial transport capacity. Prolactin inhibits the formation of seawater chloride cells and promotes the development of freshwater chloride cells. Cortisol also promotes acclimation to freshwater by maintaining ion transporters and chloride cells, and by interacting to some degree with prolactin PVC, pavement cell. Reproduced from McCormick SD (2001) Endocrine control of osmoregulation in teleost fish. *American Zoologist* 41: 781–794.

Nitrogenous-Waste Balance: Mechanisms of Ion Transport in Freshwater Fishes). Chloride is exchanged for HCO_3^- at the apical surface and leaves at the basolateral membrane moving downhill on an electrical gradient (the chloride cell being more negative than the blood). Sodium may enter the gill epithelia by exchange with H^+, or through an apical Na^+ channel coupled to an apical H^+-ATPase, and pass into the bloodstream at the basolateral gill surface through NKA. Recent work suggests that in some species there is also a Na^+/Cl^- co-transporter on the apical surface that is involved in ion uptake. More direct evidence is needed to be certain of the roles and location of these transporters involved in ion uptake in teleosts.

There are three primary lines of evidence for the involvement of hormones in ion regulation. The first involves the treatment of animals (*in vivo*) or isolated tissues (*in vitro*) with hormones and examining ion regulatory performance and/or the response of ion transport proteins and cells. The second line of evidence comes from changes in circulating hormones when environmental salinity is changed, such as a transfer from freshwater to seawater. Third, the presence and regulation of specific hormone receptors in the organs and cell types responsible for ion regulation is taken as evidence for the involvement of that hormone in salt and water balance.

This article illustrates that there are many common features to the endocrine control of osmoregulation in teleost fish. It should be noted, however, that only a small number of teleosts have been examined and that we know little or nothing about the hormonal control of osmoregulation in the vast majority of fish. Given the great diversity among teleosts and the differing acclimation responses and strategies that have evolved, it should not be surprising to find that not all teleost fishes conform to a single scheme. Indeed, one of our outstanding research challenges is to determine how the hormonal control of osmoregulation differs among teleosts, and to what extent it has been shaped by natural selection.

Cortisol

Cortisol and Seawater Acclimation

Cortisol is the major corticosteroid produced by the interrenal tissue of teleost fish (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids). This hormone has several established physiological roles in osmoregulation, intermediary metabolism, growth, stress, and immune function. It has been shown for many species of euryhaline fish that treatment with cortisol in freshwater improves their subsequent survival and capacity to maintain low levels of plasma ions after exposure to seawater. This effect is due to increases in the size and abundance of gill mitochondrion-rich cells, which has been demonstrated *in vivo* and *in vitro*. Cortisol has also been shown to increase the transcription and abundance of the major transport proteins involved in salt secretion by the gill: NKA, NKCC, and CFTR. The effect of exogenous cortisol generally requires several days to reach its peak, suggesting that cell proliferation and differentiation are required for its complete action. In the intestine, exogenous cortisol stimulates NKA activity, together with ion and water absorption, thus improving acclimation to high environmental salinity. An increased drinking response after transfer to seawater has been observed in salmonids treated with cortisol.

Changes in circulating cortisol in response to increased environmental salinity are reported for many teleost species. The clearance rate (the inverse of the amount of time a compound remains in circulation) of cortisol also increases in seawater, suggesting increased utilization by osmoregulatory target tissues (**see also Integrated Control and Response of the Circulatory System**: Hormone Metabolism in the Circulation). The release of cortisol from the interrenal is primarily controlled by the pituitary hormone adrenocorticotrophic hormone (ACTH), though other endocrine factors may also be involved (**see also Hormonal Responses to Stress**: Hormone Response to Stress). Although there is evidence for activation of pituitary ACTH cells, salinity effects on circulating levels of ACTH have not been detected. ACTH production by the isolated pituitary does not appear to be directly responsive to changes in external osmolality. The increase in cortisol during osmotic stress occurs in both stenohaline and euryhaline fishes and may be part of a general stress response. Thus, the presence and regulation of cortisol receptors is also a critical component of osmoregulation in these fishes.

The classical signaling action of steroids begins by transport into the cell, followed by binding to a cytosolic receptor, which is then translocated into the nucleus. There, the steroid binds to specific genes to increase or decrease their expression. A large number of binding studies in fish have found evidence for a single class of corticosteroid receptors (CRs). These receptors are present in high concentrations in the gill, gut, and kidney, and their abundance is often altered by environmental salinity. During exposure to increased salinity, intracellular cortisol and CR levels in the gill shift from the cytosol to the nucleus, indicative of CR binding and translocation. High concentrations of CR have been found in the gill mitochondrion-rich cells.

In the past several years, molecular techniques have demonstrated the presence of genes in several teleost species related to the mammalian glucocorticoid receptors (GRs) and mineralocorticoid receptors (MRs). Two isoforms of fish GR genes have been found in several teleost species, and these have different activation affinities for cortisol. In addition, an MR-like gene has been characterized in rainbow trout (*Oncorhynchus mykiss*) and the cichlid (*Haplochromis burtoni*). When the rainbow trout MR gene is expressed in a mammalian cell line, it was found to have high transactivation efficiency for both aldosterone and 11-deoxycorticosterone (DOC), similar to the binding characteristics of the mammalian MR. It has been suggested that DOC, present in the plasma of some teleosts at levels that could activate the fish MR, might be a mineralocorticoid in fish. Injection studies indicate, however, that DOC cannot carry out the seawater-adapting functions of cortisol. Thus, the physiological function of DOC and MR in fish remains to be established.

Cortisol and Freshwater Acclimation

As noted above, cortisol has largely been identified as a seawater-adapting hormone in a large number of teleost species. There is an increasing body of evidence demonstrating that cortisol is also involved in ion uptake, thus giving it a dual osmoregulatory function. Cortisol treatment in freshwater fish increases the surface area of gill mitochondrion-rich cells and the influx of sodium and chloride, affecting both renal and branchial functions. Survival and plasma ion levels of freshwater fish that have had their pituitary removed are increased by treatment with adrenocoritcotrophic hormone (ACTH), which can be presumed to be acting through its stimulation of cortisol release from the interrenal. Cortisol is also required to maintain water movement across the gut of freshwater eels. Cortisol treatment significantly increases the ion regulatory capacity of marine fish during exposure to low salinity and the ability of acid-resistant fish to maintain plasma sodium levels after exposure to acidic water.

Changes in circulating levels of cortisol also provide supporting evidence for a role of this hormone in ion uptake. Transfer of euryhaline species from seawater to freshwater results in short-term increases in plasma cortisol. Transfer of several species of marine fish from high to low salinity results in increased circulating cortisol that remains elevated for days to weeks. In Mozambique tilapia (*Oreochromis mossambicus*), transfer from freshwater to distilled water or injection of prolactin (PRL) results in elevated plasma cortisol. These studies on increasing cortisol levels in response to decreases in salinity, along with the cortisol treatment studies described above, provide evidence that, in many teleosts, cortisol has a physiological role in promoting ion uptake. This function of cortisol has not been fully appreciated due to an emphasis on the role of cortisol in salt secretion.

Although there is substantial evidence indicating that cortisol can increase gill and gut NKA, it is unclear whether this is primarily related to cortisol's seawater-adaptive effects, or whether upregulation of the sodium pump is also involved in ion uptake. If maintenance of the sodium pump is indeed integral to ion uptake, then the effect of cortisol on gill NKA could be one mechanism by which cortisol exerts a dual osmoregulatory function. In addition, cortisol also likely promotes the development of the freshwater morphology of chloride cells. Recent evidence indicates that in salmonids there are two salinity-dependent isoforms of gill NKA: one that is more abundant in freshwater and the other more abundant in seawater. Cortisol upregulates both of these isoforms, which is further evidence for a dual osmoregulatory role for this hormone.

Prolactin

By removing the pituitary (hypophysectomy) and then replacing the lost PRL with injections, Grace Pickford conclusively demonstrated 50 years ago that the pituitary hormone PRL was critical for the maintenance of ion balance of teleost fish in freshwater. Since then, evidence for PRL as an important freshwater-adapting hormone in fish comes from studies on exogenous PRL treatment, changes in PRL gene expression and circulating levels in response to salinity change, and the localization and regulation of PRL receptors.

Although PRL has been shown to have sodium- and chloride-retaining activity in a variety of freshwater and euryhaline teleosts, there is surprisingly little information on the cellular and biochemical effectors of the osmoregulatory actions of PRL. Throughout vertebrates, a large proportion of the various actions of PRL seem to be associated directly or indirectly with cell proliferation and/or apoptosis. PRL has been shown to affect chloride cells, both by inhibiting the development of seawater chloride cells and promoting the morphology of ion uptake cells. PRL treatment also reduces ion and water permeability of the esophagus and intestine, a response that normally occurs during acclimation to freshwater. PRL can induce intestinal cell proliferation in some euryhaline fishes. It has recently been shown that the abundance of NaCl co-transporter present on the apical surface of ion uptake cells in the tilapia gill decreases following hypophysectomy and is restored to original abundance with PRL treatment.

Gene expression, synthesis, secretion, and plasma levels of PRL all increase following exposure to freshwater. Metabolic clearance rate of PRL increases following fresh water acclimation of salmonids. In some teleosts such as tilapia, plasma osmolality and cortisol exert direct regulatory actions on PRL secretion. As in mammals, however, a specific hypothalamic PRL-releasing factor, PRL-releasing peptide (PrRP), has recently been identified in teleosts. PrRP promotes PRL transcription and secretion, with the histochemical localization of PrRP neuronal terminals near PRL cells in the pituitary. Moreover, PrRP seems to be an essential stimulator of PRL since antiserum to PrRP decreases circulating PRL levels. In the amphibious euryhaline mudskipper (*Periophthalmus modestus*), the brain-pituitary axis of PrRP-PRL operates during both terrestrial and freshwater acclimation.

PRL receptor transcription and abundance are high in osmoregulatory organs such as the gill, intestine, and kidney. In the gill, the transcription and abundance of PRL receptor are lower in seawater than in freshwater in tilapia and salmonids. High levels of PRL receptor transcription have been found in mitochondrion-rich cells of the gill and enterocytes of the intestine.

There is evidence that both PRL and cortisol are necessary for normal ion regulation in freshwater. The two may even interact to control ion uptake. In hypophysectomized catfish (*Heteropneustes fossilis*), PRL and cortisol together cause a greater elevation of plasma ions than either hormone alone. Also, cortisol and PRL together have a greater effect than either hormone alone in promoting the transepithelial resistance and potential of an *in vitro* gill-cell preparation. In hypophysectomized and/or interrenalectomized fish, both PRL and/or ACTH or cortisol are necessary to completely restore ion and water balance in freshwater. Although an interaction between PRL and cortisol in controlling freshwater acclimation has been proposed, there is as yet little direct evidence for this hypothesis and no mechanism has been proposed.

Growth Hormone and IGF-I

In the 1950s, D.C.W. Smith observed that multiple injections of growth hormone could increase the capacity of brown trout to tolerate exposure to seawater. At first, this was attributed to the growth effect of the hormone because size confers greater salinity tolerance in salmonids. Several decades later, it was found that a single injection of growth hormone in unfed fish was sufficient to increase salinity tolerance, indicating a relatively rapid effect that was independent of body size. Growth hormone has since been shown to increase the number and size of gill mitochondrion-rich cells as well as the abundance of NKA and NKCC (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Growth Hormone Overexpression in Transgenic Fish).

A major route of the osmoregulatory action of GH is through its capacity to increase circulating levels and local tissue production of insulin-like growth factor-I (IGF-I). Exogenous treatment of IGF-I has been found to increase the salinity tolerance of rainbow trout, Atlantic salmon (*Salmo salar*), and killifish (*Fundulus heteroclitus*). GH cannot directly (in culture) increase gill NKA activity, whereas IGF-I can. The ability of prior GH treatment to increase *in vitro* responsiveness of gill tissue to IGF-I further suggests an indirect action of GH on gill tissue, and a direct action of IGF-I. Levels of IGF-I mRNA in gill and kidney increase following GH injection and exposure to seawater, indicating that local production of IGF-I may act in a paracrine fashion to influence transport capacity of gill and renal epithelia.

In addition to the effects of exogenous hormones, changes in gene expression, secretion, circulating levels, and metabolic clearance rate of growth hormone and IGF-I also provide evidence for the osmoregulatory actions of the GH/IGF-I axis in several euryhaline species. Plasma GH levels have also been found to increase in stenohaline freshwater fish following exposure to brackish water (e.g., 12 ppt). Following exposure of rainbow trout to seawater, there are increases in plasma levels of IGF-I and three of its binding proteins. IGF-I mRNA levels in liver, gill, and kidney increase following growth hormone injection and exposure to seawater, indicating that local production of IGF-I may also act to influence transport capacity of gill and renal epithelia. IGF-I has been found specifically in gill chloride cells whose number and/or size are stimulated by growth hormone.

Growth hormone receptors in high concentrations have been found in the liver, gill, gut, and kidney of euryhaline teleost fish. Occupancy of hepatic growth hormone receptors by growth hormone increased following exposure to seawater. Growth hormone transcription has also been detected in osmoregulatory organs and may be acting in an autocrine or paracrine manner in these tissues. Growth hormone receptor mRNA levels in the gill increase after seawater acclimation of salmonids. Specific high-affinity, low-capacity IGF-I receptors have been found in gill tissue of salmon and tilapia, and have been immunocytochemically localized to gill chloride cells in striped bass (*Morone saxatilis*) and tilapia.

Few teleost species have been examined for the physiological impact of the GH/IGF-I axis on osmoregulation. Exogenous treatments have been found to affect salmonids, tilapia, and killifish. Changes in circulating hormones and production of IGF-I in osmo-regulatory organs in salmonids provide convincing evidence for both endocrine and paracrine actions of the GH/IGF-I axis, but there is relatively little information in this area from other teleosts. There is no apparent osmoregulatory role for GH in sea bream, a marine species with a limited capacity for hyperosmoregulation. Species variation linked to different ion regulatory capacities and/or strategies for ion regulation may determine to what extent the GH/IGF-I axis is involved in osmoregulation. A similar situation may occur for PRL: there may be limited osmoregulatory effects of PRL in stenohaline marine teleosts where any ion uptake may be maladaptive. Expanded research on both euryhaline and stenohaline species will be necessary to determine how widespread the osmoregulatory actions of PRL and the GH/IGF-I axis are among teleosts, and how phyletic histories and natural selection have acted to bring about any observed patterns.

Interaction of the GH/IGF-I Axis with Cortisol

The GH/IGF-I and cortisol axes work together to regulate salt secretion in teleosts. Injection of GH and cortisol together increases gill NKA activity and salinity tolerance in salmonids and killifish to a greater extent than either hormone alone. This effect can be seen in both hypophysectomized and intact fish. Cortisol treatment of freshwater Atlantic salmon causes an increase in both the freshwater and seawater isoforms of NKA, but treatment with GH and cortisol causes the seawater isoform to increase to an even greater extent, and the freshwater isoform to decrease. Much of the interaction of GH and cortisol is through GH's capacity to upregulate the number of gill cortisol receptors, which makes the tissue more responsive to cortisol.

Growth hormone increases mitotic activity in several cell types in the gill of rainbow trout. Cortisol has no effect on mitotic activity but increases the number of chloride cells, suggesting that cortisol acts primarily to promote differentiation of chloride cells. Therefore, another pathway for GH/IGF-I and cortisol interaction is stimulation of stem cell proliferation by GH and/or IGF-I, creating more stem cells that can then be acted on by cortisol. The GH/IGF-I axis and cortisol may also interact at higher regulatory pathways, such as the hypothalamus and pituitary. *In vivo* and *in vitro* exposure to GH increases the sensitivity of interrenal tissue to ACTH, causing increased release of cortisol. Corticotropin-releasing hormone is a potent stimulator of *in vitro* growth hormone release in the European eel (*Anguilla anguilla*).

Thyroid Hormones

Although there is conflicting evidence regarding the role of thyroid hormones in osmoregulation, most studies have found that thyroid hormones, by themselves, cannot increase ion uptake or secretory capacity. Exceptions to this are prolonged thyroxine (T4) treatment that accelerated smolt-related increases in gill mitochondrion-rich cells and NKA activity in Atlantic salmon, and dietary triiodothyronine (T3) treatment that increased the number of gill mitochondrion-rich cells without affecting gill NKA activity. Thyroid hormones play at least a supportive role in seawater acclimation, and may interact with both the GH/IGF-I and cortisol axes. Inhibition of the thyroid axis with thioruea in killifish caused increased plasma ions in seawater but had no effect in freshwater. T4 treatment alone has no effect, but potentiates the action of cortisol on gill NKA activity in tilapia, and the action of GH on gill NKA activity in salmon. Inhibiting the conversion of T4 to T3 interferes with normal and GH-induced seawater acclimation in trout. T3 treatment increases the number of gill cortisol receptors in trout and salmon. Thyroid hormones thus appear to exert their influence on salt secretory mechanisms primarily through an interaction with cortisol and the GH/IGF-I axis.

The Special Case of Anadromy

As part of their normal life history, anadromous fish (such as salmon) must move between freshwater and seawater at least twice during their life history (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle). As juveniles in freshwater, salmon have only a limited capacity to enter seawater. At the time of their downstream migration (when they are known as smolts), juvenile salmon develop a very high capacity for salt secretion before they actually arrive in the ocean. The timing of this developmental process differs among salmonids, but is accompanied by changes in the gill (increased mitochondrion-rich cells, NKA, and NKCC), gut, and kidney.

During smolt development, GH, IGF-I, and cortisol increase in response to developmental and/or environmental cues such as photoperiod and temperature (**Figure 2**). PRL can inhibit smolt development, and increases early during smolt development, but then decreases at the peak of smolting. Thyroid hormones also increase during smolting and are thought to play an indirect role in osmoregulatory changes, but a direct role in morphological, metabolic, and behavioral changes. Thus, the same hormones that are altered by exposure to salinity in other species increase prior to seawater exposure in salmon, inducing preparatory changes in salt secretory mechanisms that allow rapid movement into seawater with minimal osmotic perturbations.

The developmental changes that occur during smolting in salmon appear to be similar to other species, such as lamprey and shad that make just one or a few migrations from freshwater to seawater. Species that make more frequent migrations between freshwater and seawater may rely more on rapid regulation ion uptake or salt secretion rather than developmentally cued regulation.

Summary

Cortisol has long been known to have an important role in seawater acclimation of teleost fishes. Current evidence indicates that the GH/IGF-I axis also has a role in seawater acclimation, and that GH, IGF-I, and cortisol interact positively to promote salt secretion and the underlying physiological mechanisms. PRL has a

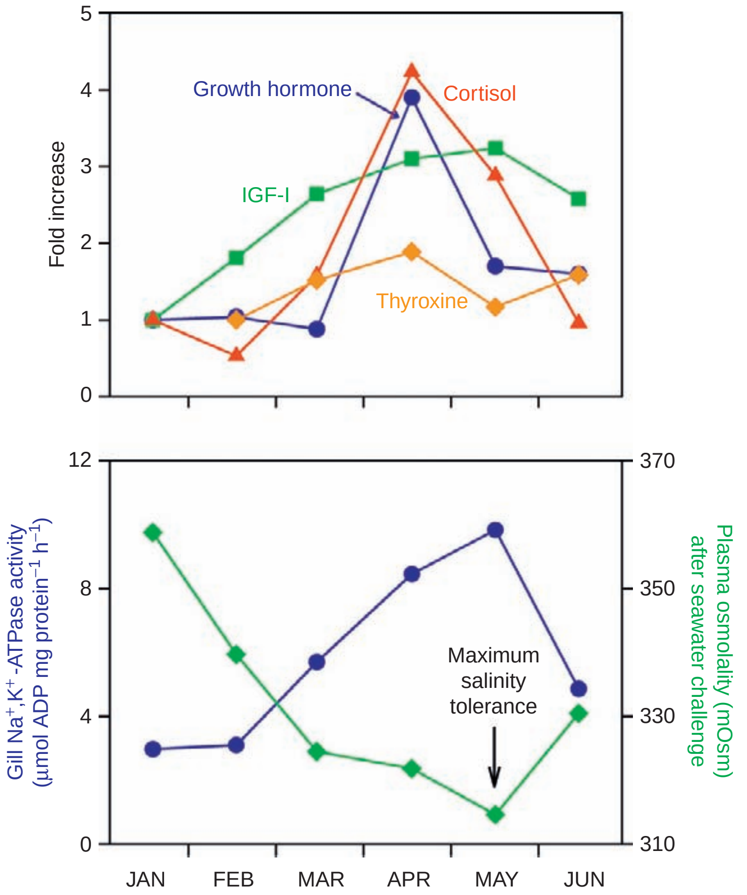


Figure 2 Changes in plasma hormone levels, gill NKA activity, and salinity tolerance during the parr–smolt transformation of Atlantic salmon. Interaction among cortisol, growth hormone, IGF-I, and thyroid hormones results in physiological changes that are preparatory for seawater entry. Adapted from McCormick SD, Lerner DT, Monette MY, Nieves–Puigdoller K, and Björnsson BTh (2009) Taking it with you when you go: How perturbations to the freshwater environment, including temperature, dams and contaminants, affects seawater performance of anadromous fish. In: Haro AJ, Smith KL, Rulifson RA, *et al*. (eds.) *Challenges For Diadromous Fishes in a Dynamic Global Environment.* American Fisheries Society Symposium, vol. 69, pp. 195–214. Bethesda, MD, USA.

well-established role in ion uptake and inhibition of salt secretion. In addition to its role in seawater acclimation, several studies indicate that cortisol is also involved in ion uptake and can interact positively with PRL, indicating that cortisol has a dual osmoregulatory function in teleosts. The action of cortisol in promoting ion uptake or secretion may therefore depend partly on its interaction with growth hormone and PRL: when growth hormone is high and PRL is low, cortisol may act primarily to promote salt secretion. Conversely, when growth hormone is low and PRL is elevated, cortisol will act to promote ion uptake.

Glossary

Corticosteroid A collective term for glucocorticoid (such as cortisol and corticosterone) and mineralocorticoid (aldosterone and DOC) hormones.

Corticosteroid receptors Ligand-activated nuclear hormone receptors with the ability to bind corticosteroids, such as GR and MR.

Glucocorticoid response element (GRE) A response element for glucocorticoid hormones, a short sequence of DNA within the promoter of a gene, that specifically binds GRs and MRs to regulate transcription. The consensus sequence is a pair of inverted repeats separated by three nucleotides.

Half-maximal effective concentration (EC_{50}) The concentration of a ligand that induces 50% of the maximum response. It is a measure commonly used to express the potency of a ligand.

Interrenal tissue The fish analog of the mammalian adrenal cortex located in the head kidney region, which produces and releases cortisol upon stimulation.

Ligand A molecule that binds to another molecule, such as an enzyme substrate, cofactor, or signaling molecule (Latin ligare = to bind).

Ligand-activated nuclear hormone receptor A family of cytoplasmic-located proteins, which, upon ligand binding, translocates to the nucleus, where it binds specific response elements to regulate gene transcription.

Polymerase chain reaction (PCR) A method to measure mRNA transcript levels by amplification of specific target sequences.

Teleost fish A large group of modern bony fishes, including the most common fishes, distinct from the group of elasmobranches (sharks and rays).

Trans-activation Stimulation of transcription by a transcription factor binding to DNA. These molecules are said to act in trans, that is, one gene product (a protein) interacts with another gene (promoter).

Introduction

Corticosteroids are a group of steroid hormones derived from cholesterol, which are used as endocrine signaling molecules in all classes of vertebrates. Corticosteroids are traditionally divided in two classes according to their main function. The glucocorticoids (cortisol, cortisone, and corticosterone) are named after their role in the regulation of glucose metabolism (carbohydrate metabolism and gluconeogenesis) and their synthesis takes place in the adrenal cortex. Mineralocorticoids (aldosterone and 11-deoxycorticosterone (DOC)) are named after their function in the regulation of hydromineral balance (water and ions).

The main corticosteroid hormone in teleost fish, cortisol is involved in regulation of many physiological functions besides metabolism, such as growth, immune function, reproduction, development, cardiovascular function, behavior, and hydromineral homeostasis, and is an essential part of the stress response. It is especially interesting to note the osmoregulatory function of cortisol in fish, a function otherwise taken care of by aldosterone in higher vertebrates (amphibians, reptiles, birds, and mammals). Aldosterone cannot be synthesized in fish in the absence of suitable enzymes. However, a mineralocorticoid-like hormone, DOC, has recently been identified in fish and may be an ancestral corticosteroid hormone. Overall, the corticosteroid signaling system in fish shows many similarities with that of higher vertebrates; significant differences also exist. The essentials of the corticosteroid signaling system in fish and the specific differences it exhibits from that of mammals are discussed in this article.

Corticosteroid Synthesis

Corticosteroid synthesis takes place in the steroidogenic cells in the interrenal tissue of the head kidney, which is equivalent to the adrenal cortex in mammals, and released upon endocrine stimuli from the brain (see later). While cortisol is the steroid mainly produced, other steroids such as cortisone, corticosterone, 11-deoxycortisol, and the mineralocorticoid-like DOC are synthesized to a lesser extent. Cortisol is predominantly synthesized by converting cholesterol to pregnenolone, by cytochrome P450 (CYP)11A1, followed by a C-17 hydroxylation by CYP17 to yield 17-hydroxy-pregnenolone, which, in turn, converted to 17-hydroxy-progesterone by 3*β*-hydroxysteroid dehydrogenase (HSD) and further hydroxylated to 11-deoxycortisol by CYP21 before being converted into cortisol by C-11 hydroxylation by CYP11B (**Figure 1**). A minor portion of cortisol synthesis might come from DOC or corticosterone, since the hydroxylation of C-11 and C-21 does not prevent C-17 hydroxylation. Due to the lack of the aldosterone synthetase enzyme (CYP11B2), fish cannot produce the main mammalian mineralocorticoid, aldosterone. However, DOC, which is synthesized from pregnenolone by C-21 hydroxylation of progesterone, could potentially bind and activate the MR in fish (see later). In mammals, increasing evidence suggests that paracrine signaling is possible by extra-adrenal synthesis of corticosteroids, for example, in the brain.

Central Regulation of Cortisol Release

The endocrine control of cortisol release is managed by the hypothalamic–pituitary–interrenal (HPI) axis. The neuropeptide corticotrophin-releasing hormone (CRH) is released from the hypothalamic nucleus preopticus in response to stressors such as handling, hypoxia, exercise, social stress, ambient water temperature, osmolality, infection, and pollutants (**Figure 2**). CRH controls the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary to the blood stream. ACTH, which is the main regulator of cortisol release, then in turn stimulates cortisol release from the interrenal cells in the head kidney. The endocrine control of cortisol release appears very complex since several other neuroendocrine peptides and pituitary hormones affect cortisol release, such as isotocin, vasotocin, dopamine, neuropetide Y, melonophore-concentrating hormone, thyrotropin-releasing hormone, catecholamines, angiotensin II, and melanophore-stimulating hormone. Furthermore, control of cortisol release is autoregulated through negative

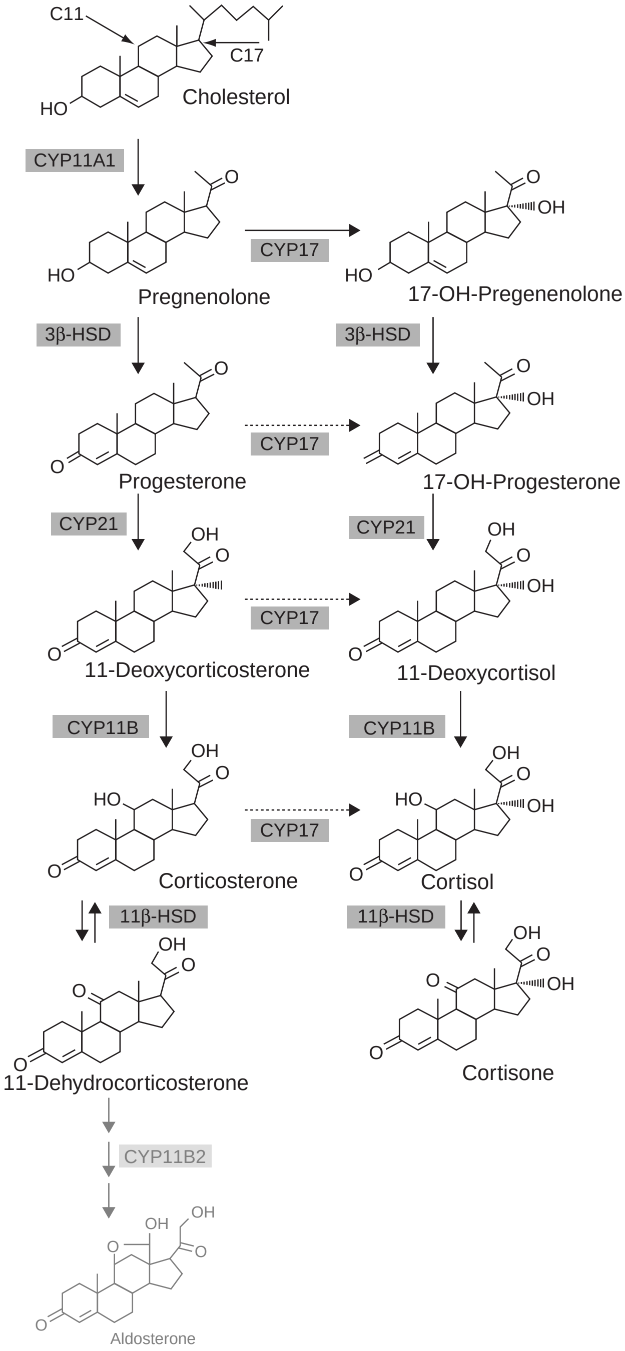

Figure 1 Overview of the synthesis pathway of corticosteroid hormones from cholesterol. CYP denotes cytochrome P450 proteins and HSD denotes the hydroxysteroid dehydrogenases comprising the steroidogenic enzymes. Fish lack CYP11B2 aldosterone synthase and cannot produce aldosterone. Redrawn from Bury NR and Sturm A (2007) Evolution of the corticosteroid receptor signalling pathway in fish. *General and Comparative Endocrinology* 153: 47–56.

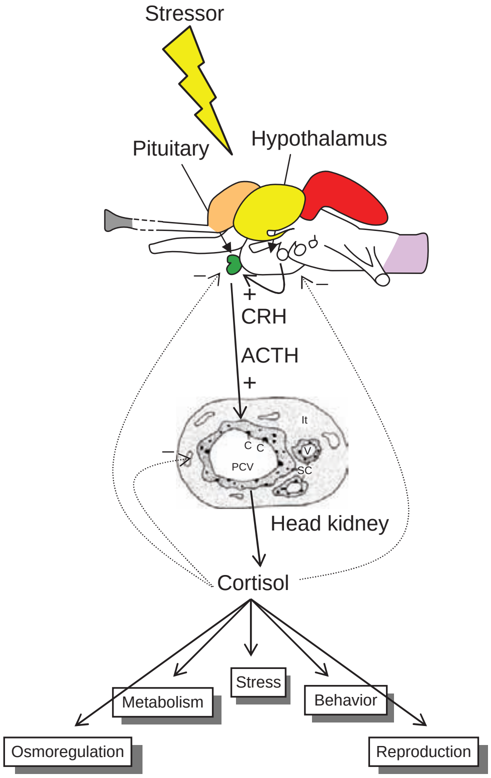

Figure 2 Schematic representation of the hypothalamic–pituitary–interrenal and cortisol-target-tissue axis. Corticosteroid-releasing hormone (CRH) is released from hypothalamus upon stimuli. CRH triggers the release of adrenocorticotropic hormone (ACTH) from the pituitary to the blood stream (denoted by a plus sign). ACTH, then, in turn triggers steroidogenic cells (sc) in the interrenal tissue of the head kidney to release cortisol to the blood stream. Some of the physiological processes regulated by cortisol are boxed. Cortisol exerts negative regulation on release of CRH and ACTH from the hypothalamus and pituitary, respectively, and cortisol release from head kidney (denoted by a minus sign). From HowStuffWorks 2001 © and Wendelaar Bonga SE (1997) The stress response in fish. *Physiological Reviews* 77: 591–625.

feedback of the hormone at all levels of the HPI axis, the preoptic nucleus, the anterior pituitary, and the interrenal (**see also Hormonal Responses to Stress**: Hormone Response to Stress).

Corticosteroid Plasma Levels

Plasma levels of cortisone, corticosterone, 11-deoxycortisol, and DOC are relatively low – around 0.1–1.0 nM. Plasma cortisol in a nonstressed condition is around 5 ng mL^{-1} (10 nM), but can increase up to 10–100-fold (up to 1000 nM) in response to stress. Since only cortisol and DOC function as high-affinity ligands for the corticosteroid receptors, and thus must be expected to have some physiological relevance, these are the only corticosteroids discussed in the remainder of this article.

In mammals, around 90% of the cortisol is bound by corticosteroid-binding globulins (CBGs) in the plasma, which transports glucocorticoids in blood and regulate the bioavailability and access to target cells. The question of CBGs in fish has received incredibly little attention so far. Early investigations suggesting the presence of such proteins in fish have never been confirmed. In fact, CBGs seem to be absent in fish, based on recent database searches for a CBG ortholog in the sequenced fish genomes available.

Molecular Biology of Corticosteroid Receptors

In fish, three different corticosteroid receptors have recently been identified and described: two glucocorticoid receptors (named GR1 and GR2) and one mineralocorticoid receptor (MR). These three receptors show differences in hormone binding, transcriptional activity, and regulation among them, suggesting the presence of three functional receptors in fish compared to only two, one GR and one MR, in mammals. Analogous to mammals, the glucocorticoid receptor operates only as a cortisol receptor, whereas the MR is efficiently activated by cortisol, aldosterone, and DOC alike.

In general, the corticosteroid receptors consist of the GR (NR3C1) and the MR (NR3C2), both belonging to subfamily 3C of the nuclear hormone receptor superfamily, which also consists of the androgen, progesterone, and estrogen receptor. Composition of the fish GRs and MR structure is identical to the well-described mammalian nuclear hormone receptors, with an amino-terminal transactivating domain (the A/B-domain), a central DNA-binding domain (DBD), a hinge region, and a carboxy-terminal ligand-binding domain (LBD) (**Figure 3**). The highest degree of sequence conservation between the corticosteroid receptors (CRs) is found in the DBD, which consists of two zinc-finger-binding motifs, which recognize and bind specific DNA sequences, called response elements, in the target-gene promoters. As a result, all three CRs bind the same DNA sequence and are potentially able to regulate transcription from the same target genes. The differences in the LBDs provide different ligand-binding properties, where MR binds both cortisol and DOC, whereas GRs bind only cortisol. These differences may also contribute to the different cofactor-binding capacities and possibly to dimerization efficiency/ability, thus yielding an important diversity in the signaling potential. The A/B domain is the most divergent among the nuclear hormone receptors and contains a ligand-independent activation function.

Although carried out in mammalian cell lines using simplified model promoters, transient transfection analysis of hormone binding and transactivation properties of

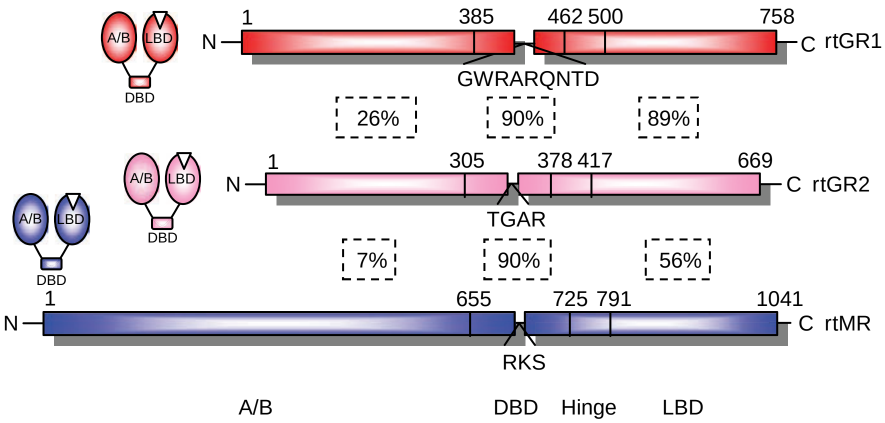

Figure 3 Corticosteroid receptors identified in rainbow trout (rt GR1, rtGR2, and rtMR). Numbering of amino acids is placed above the receptors. The amino- and carboxy-terminal ends are marked with N and C, respectively. Numbers in punctuated boxes between two receptors denote amino acid identity to rtGR1. The different steroid receptor domains are denoted A/B regulatory domain, DNA-binding domain (DBD, C-domain), hinge (D-domain), and ligand-binding domain (LBD, E-domain). Amino acid inserts between the two DBD zinc fingers in CR splice variants are shown below the receptor.

the fish CRs have proven interesting. As in mammals, cortisol and dexamethasone (a synthetic glucocorticoid widely used in studies of glucocorticoid effects) are the most effective steroids stimulating fish GR1 and GR2 transactivation, when measured as the half-maximal transcriptional activity induced by the hormone (EC_{50}). While GR1 and GR2 have the same binding affinity for glucocorticoids (dexamethasone), GR2 transactivation is induced at far lower concentrations of dexamethasone and cortisol compared to GR1. MR has the same sensitivity to cortisol when compared to GR2 but is around 50 times more sensitive to cortisol than GR1 (**Figure 4**). Interestingly, aldosterone and DOC are about 10 times more potent activators of MR than cortisol, which suggests that DOC could be a physiological ligand of MR in fish.

By and large, and even with some profound homologies with the mammalian corticosteroid signaling system (including structure, hormone, and DNA-binding abilities), several unique features have been identified in the teleost corticosteroid signaling system. Nevertheless, detailed knowledge of the functional and physiological significance of these features is still lacking.

11β-Hydroxysteroid Dehydrogenase Type 2

With cortisol plasma levels about 10–100-fold higher than DOC, glucocorticoid signaling through MR is apparently favored over mineralocorticoid signaling. Thus, although the EC_{50} value is 10 times lower for DOC than cortisol, the MR is expected to be occupied by cortisol even at its resting levels. This resembles the situation in mammals where co-localization of MR with the 11βHSD2 enzyme that converts cortisol to cortisone, which does not activate MR, seems to be a prerequisite to ensure specific aldosterone signaling. By comparison, co-localization of

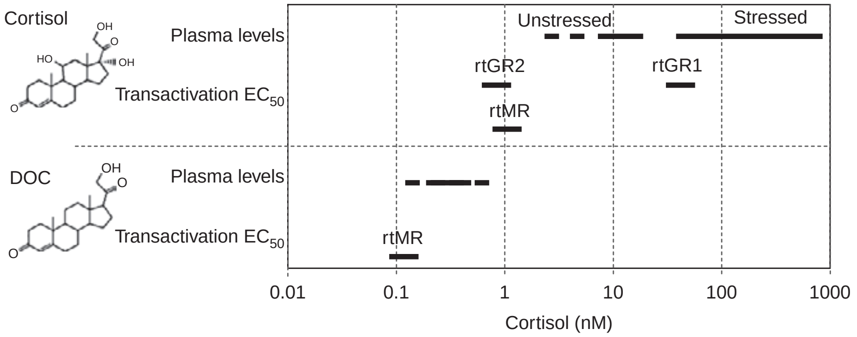

Figure 4 Comparison of the cortisol half-maximal effective concentration (EC_{50}) value of the corticosteroid receptors and plasma cortisol levels in unstressed and stressed rainbow trout. Cortisol resting levels are normally in the range of 10 nM – enough to activate MR and GR2, but not GR1. Stress induces an increase in cortisol plasma levels up to 100–1000 nM.

11βHSD2 with MR is probably equally essential to ensure the proposed DOC signaling in teleosts. Recently, the presence of a functional 11βHSD2 enzyme, located in many different organs and cell types, was described in fish. Regulation of 11βHSD2 mRNA abundance in salmon gill after osmotic stress (when cortisol levels increase) suggests a physiological significance for this enzyme. However, details are scarce at this point.

Molecular Mechanisms of Corticosteroid Signaling

In the absence of hormone, the corticosteroid receptors are located in the cytosol, chaperoned by heat shock proteins (hsp) and immunophilins (**Figure 5**). Upon hormone binding, the receptor translocates to the nucleus, dimerizes, and binds to specific DNA sequences in target-gene promoters called glucocorticoid response element (GRE, three-basepair spaced, imperfect, inverted hexamer palindromes).

Due to the high sequence similarity in the DBD, all three CRs may bind the GREs. However, small differences in the DBD among the receptors may affect GRE recognition and binding affinity. Furthermore, splice variants of GR1 and MR encompassing nine and three amino acids inserted between the zinc fingers, respectively, may further confer regulatory specificity of the fish CRs.

When bound to DNA, the corticosteroid receptors modulate corticosteroid target-gene transcription by inducing or inhibiting transcriptional activity. Furthermore, these receptors are also extensively involved in regulation of target genes for other signaling pathways, through DNA-dependent as well as independent mechanisms by interaction with other transcription factors. A whole regulatory network where GR interacts with a diversity of transcription and cofactors (such as NF-κB, AP-1, Stat5, FoxA, HNF6, PPARγ, Ets, YY1, Oct-1, and C/EBPβ) and participates in regulation of a vast variety of genes has been described in mammals. Even though such information is still lacking in fish, a similar situation is expected.

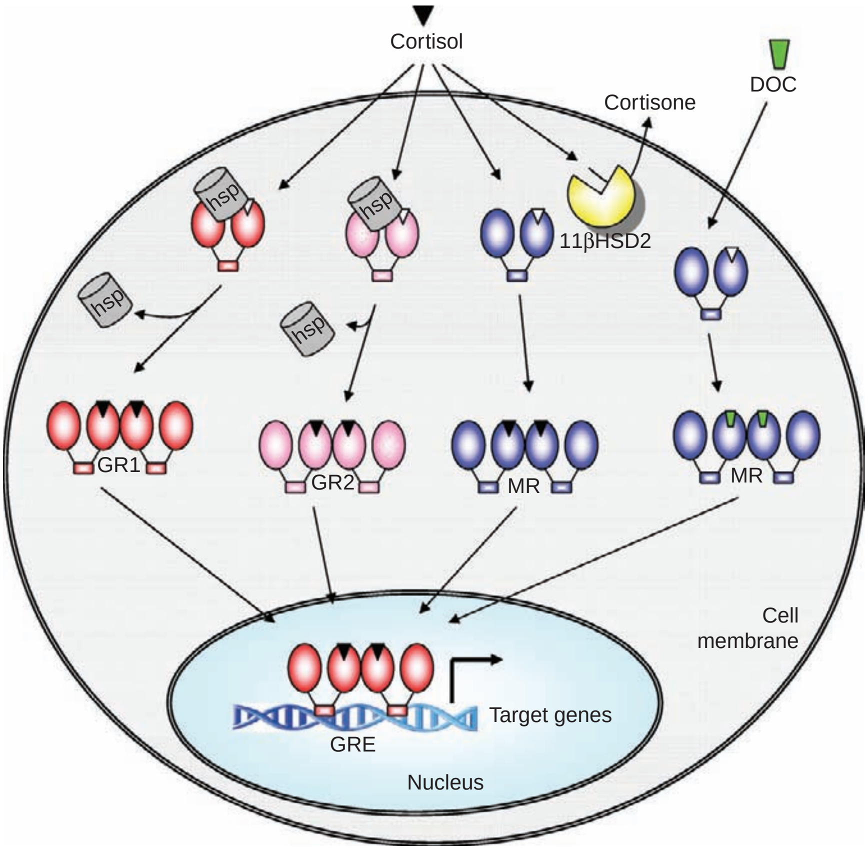

Figure 5 Simplified molecular mechanism of corticosteroid hormone receptor activation. Cortisol and DOC are transported in the blood where they enter the target-cell cytoplasm. Cortisol binds to the cytoplasmic-located GR1, GR2, or MR, whereas DOC binds only the MR. In cells containing 11βHSD2, cortisol is converted to the receptor-inactive cortisone to facilitate DOC-binding to MR. In a nonligand state, the corticosteroid receptors are bound by heat shock proteins (hsp's), but dimerize and translocate to the nucleus upon hormone binding. Specific glucocorticoid response elements (GREs) in target-gene promoters are recognized and bound by the receptor dimers to alter mRNA transcription.

Corticosteroid Target Tissue: Expression of Teleost Corticosteroid Receptors

All three corticosteroid receptors are widely expressed in fish tissue representing all major tissue groups such as osmoregulatory tissue (gills, kidney, and intestine), neurological tissue (brain and pituitary), metabolic tissue (liver and muscle), cardiovascular tissue, reproductive organs, and immune tissue (head kidney and spleen). Consequently, all tissue types and organs are potential targets for corticosteroid regulation. The level of GR1 transcript seems to be fairly equal among the tissues investigated, whereas GR2 and MR levels seem to be highest in the spleen and brain, respectively. Whether this has significance for the physiological roles of these receptors is still unknown.

With reference to the stress response, the major cortisol target tissue is depicted in **Figure 6**. In the stress response, cortisol serves to mobilize energy for an acute increase in energy consumption of specific tissues, such as increased activity in muscles, brain, liver, heart (cardiac activity), and gills (oxygen uptake). Increase in glycolysis, gluconeogenesis, lipolysis, and proteolysis in liver and proteolysis in muscle provide substrates for increased hepatic gluconeogenesis leading to hyperglycemia. Among particular cortisol target genes coding for proteins related to metabolism in these tissues are aminotransferases for tyrosine, alanine, and aspartate, glutamate dehydrogenase and synthetase, glucose 6-phosphatase, glucose 6-phosphatase dehydrogenase, phosphoenolpyruvate carboxykinase, glycerol kinase, glycogen phophorylase, and 3-hydroxyl-coenzyme A dehydrogenase.

The increase in energy demand in the organism is distributed to organs with essential functions in the stress response, including brain, muscle (increased activity), liver, heart, and gills (increased oxygen uptake). This reallocation of energy is carried out at the expense of energy consumption of gills (osmoregulation), muscle (growth), head kidney, and gonadal tissue, thus impairing hydromineral balance and acid–base regulation, growth, immune function, and reproduction, respectively. Thus, cortisol differentially activates or inhibits specific functions in the same organ to cope with a stressor. If the stress becomes chronic, the stress response eventually becomes unfavorable and results in disadvantages on growth, immune function, and reproduction (**see also Hormonal Responses to Stress**: Hormone Response to Stress).

Regulation of the Corticosteroid Signaling System by Stress Exposure

Autoregulation of GR levels by cortisol is well known in mammals – this is especially important in ensuring the functionality of a negative feedback loop to efficiently

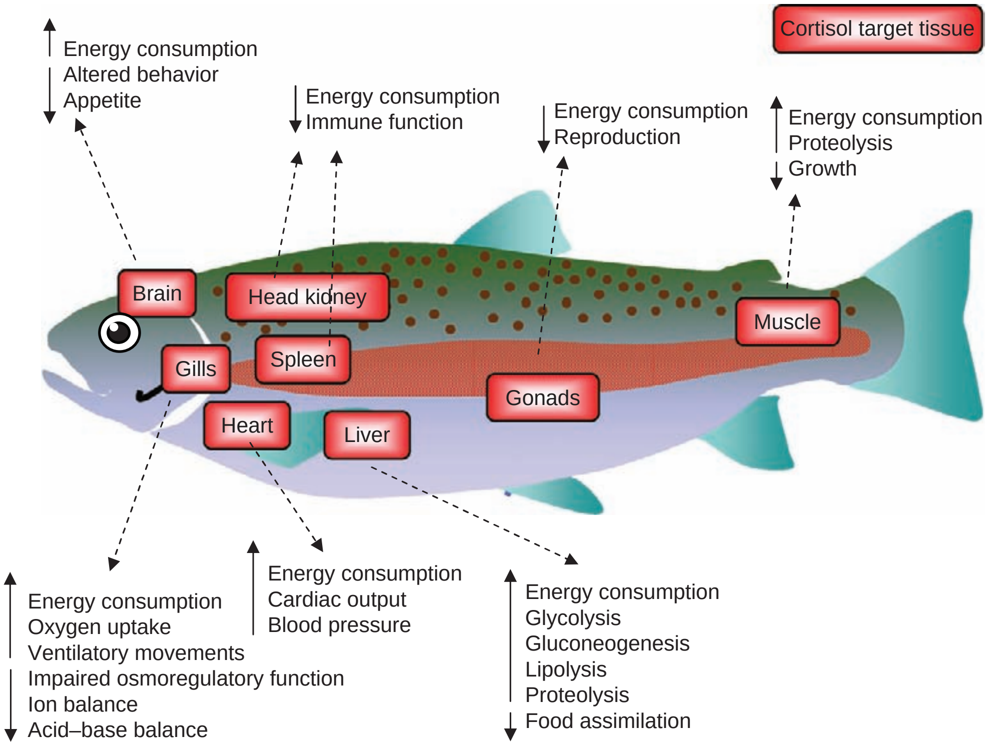

Figure 6 Summary of the main cortisol target tissue in the stress response and the major physiological processes regulated. An upward or downward arrow indicates an increase or decrease, respectively, of the physiological process. Trout drawing by G. Yoshizaki.

regulate release of cortisol along the HPI axis (**Figure 1**). In parallel, binding studies using radiolabeled ligands have demonstrated an inverse correlation between plasma cortisol levels and GR numbers in several different tissues (such as gill, liver, peripheral blood leukocytes, and brain), thus confirming autoregulation of GRs in fish as well. On the other hand, an elevation of plasma cortisol after osmotic stress or during smoltification (pre-preparatory development of saltwater tolerance in salmonids) has been correlated with an increase in gill GR mRNA transcript levels. Differences in the methods used to measure the GR level, whether measuring the total number of cortisol-binding proteins (GR1, GR2, and MR) using binding studies or measuring a specific corticosteroid receptor type (GR1, GR2, or MR) at the mRNA level using PCR methods, might account for some of these discrepancies.

However, the effect of cortisol on GR levels is not straightforward. It is certainly dependent on the type and duration of the stressor (physical, acute, or chronic), target tissue, developmental stage, and previous corticosteroid history of the fish. Thus, due to the recent identification of two GR subtypes and a MR, any stress-related differential regulation among these receptors is at present largely unknown.

Evolution of the Teleost Corticosteroid Signaling System: What Is the Role of the Mineralocorticoid-Like Axis?

The two teleost glucocorticoid receptors (GR1 and GR2) we know today were generated by a genome duplication (2R) specific for the teleost lineage early in the evolution of teleost fish. A notable exception is the zebrafish *(Danio rerio)*, where only one GR subtype has been identified in the fully sequenced genome. Differences in the regulation of receptor levels and ligand-induced transactivation, together with the preservation of two GR genes in most fish species despite the high evolutionary pressure in fish, suggest that the two GRs have different functions (neofunctionalism). However, this is still to be confirmed. As a result of the teleost-specific genome duplication, two MR isoforms should theoretically exist, but one copy seems to have been lost during evolution, since only one MR isoform has been found in teleosts so far.

The contribution of glucocorticoids in hydromineral regulation has changed during evolution from a predominant osmoregulatory corticosteroid in fish and anuran amphibians to shared osmoregulatory roles in terrestrial amphibians and reptiles, and ultimately fully to aldosterone and MR in birds and mammals. The ability of MR to bind aldosterone is an inherited trait from the ancient CR, from which MR and GR both evolved. The emergence of steroid hormone receptors can be narrowed down to the beginning at the vertebrate lineage around Agnathans (lamprey and hagfishes), where only one CR is present. This ancient receptor, which possessed the ability to bind cortisol, DOC, and aldosterone with high affinity, is considered the ancestral receptor from which the modern GR and MR evolved. A genome expansion (1R) after the divergence of jawed vertebrates from cyclostomes, but before the split between bony and cartilaginous vertebrates, gave rise to two CR genes (**Figure 7**). One CR gene – the MR – retained the ancient hormone-binding abilities with affinity for cortisol and DOC (and aldosterone), and the other CR – the GR – through only two mutations in the hormone-binding pocket of the receptor changed the hormone-binding ability from DOC, aldosterone, and cortisol to cortisol only. Thus, through evolution, MR retained the ancient hormone-binding abilities whereas GR evolved a restricted hormone-binding ability, being able to bind only cortisol.

Consequently, the osmoregulatory role of cortisol in fish essentially questions the physiological role and regulation by the mineralocorticoid-like signaling axis, MR-DOC. MR could be a third cortisol receptor in teleosts, conferring the corticosteroid signaling system with more diversity by mediating the cortisol signal. However, the recent discovery of the MR-specific agonist DOC suggests that MR has functions other than the cortisol signaling pathway. DOC was present in lamprey, apparently, before the emergence of GR and MR from CR (**Figure 7**), suggesting that DOC might be an ancient corticosteroid agonist. The presence of 11βHSD2 enzyme in teleost fish further suggests MR-specific signaling. It was suggested that 11βHSD2 emerged during evolution sometime between the invertebrate urochordates and the vertebrate actinopterygii (ray-finned fish), but a more exact appearance is unknown.

Taking a look at the evolution of the 11βHSD family of enzymes may be helpful in attaining a better understanding of the corticosteroid signaling system in fish. At this point, three 11βHSD enzymes have been identified: 11βHSD1, -2, and -3. 11βHSD1 catalyzes the conversion of CR inactive cortisone to cortisol; 11βHSD2 catalyzes the opposite reaction as mentioned above; and the enzymatic function of 11βHSD3 is still unknown. Evolutionarily speaking, 11βHSD3 seems to be the ancestral 11βHSD since it arose in invertebrates (long before evolution of CRs) long before 11βHSD1 and -2, which were first described in shark. While all three 11βHSDs are found in terrestrial vertebrates, teleost fish seem to have lost 11βHSD1 during evolution and possess only 11βHSD2 and -3. Some species (zebrafish and fathead minnow (*Pimephales promelas*)) even have two 11βHSD3 isoforms, 3A and B. Yet, while neither 11βHSD1, -2, nor -3 are found in the lamprey genome, the evolution of the 11βHSDs is still not fully understood. Furthermore, since

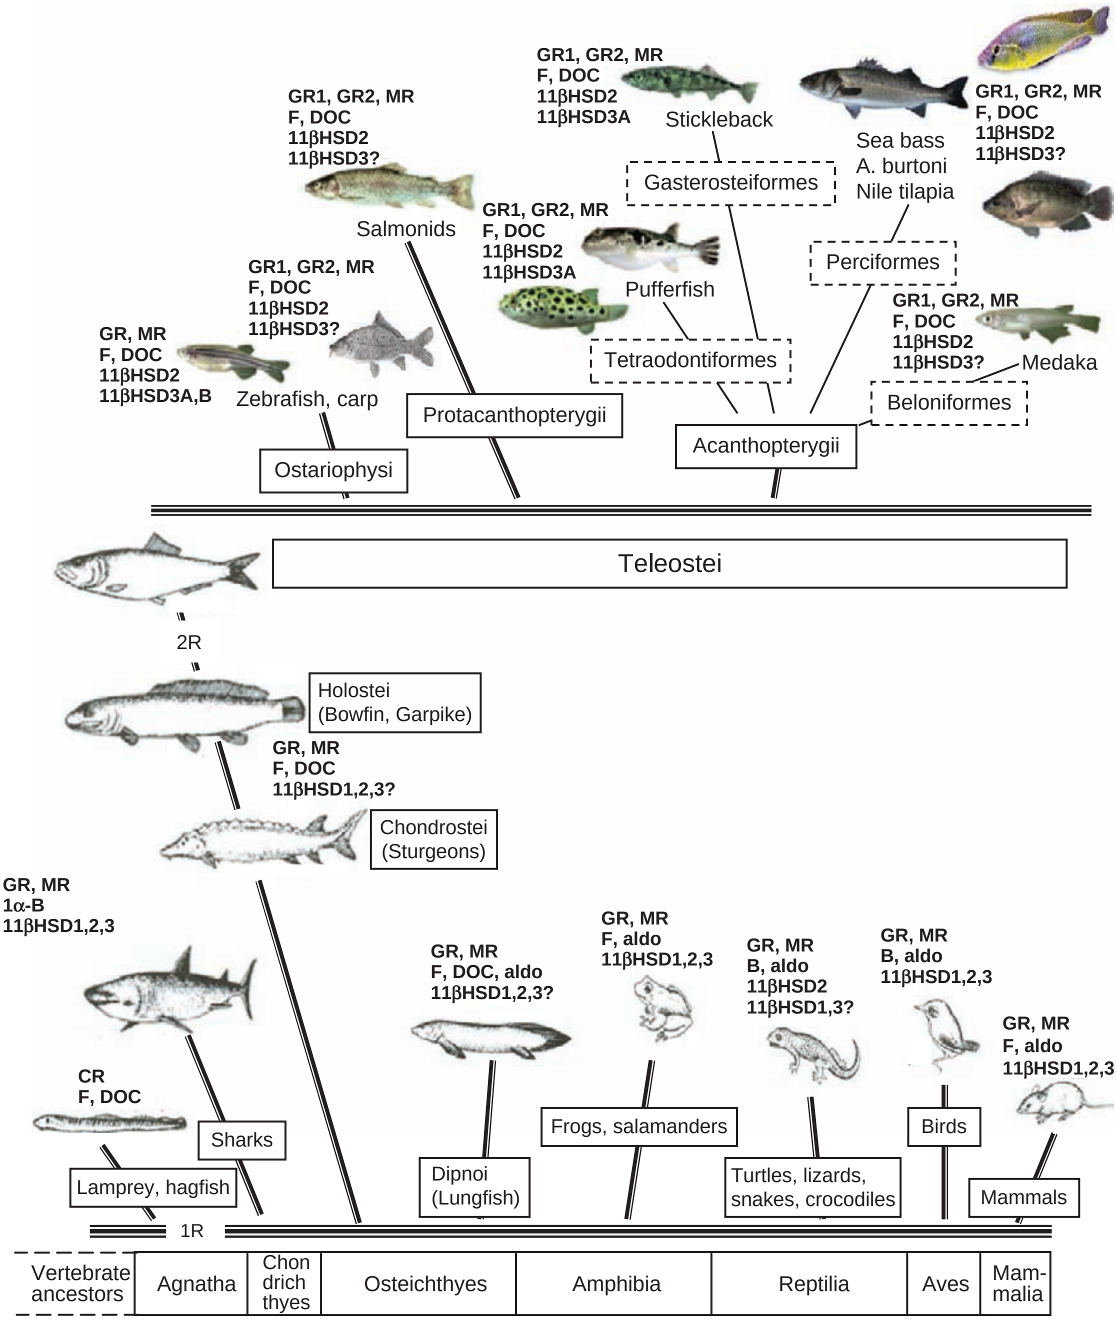

Figure 7 Schematic overview of evolution of corticosteroid signaling system in vertebrates. In the ancestral agnathan vertebrate lineage, only one corticosteroid receptor (CR) is present together with the hormones cortisol (F) and 11-deoxycorticosterone (DOC). A whole genome duplication (1R) before the split of cartilaginous and bony fish created two corticosteroid receptors, the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR). A teleost-specific second genome duplication (2R) gave rise to two GR subtypes, which are present in three large teleost suborders. The aldosterone-synthesizing ability first arose in lungfish, comprising an evolutionary transition between water and air breathing, explaining the lack of aldosterone (aldo) in teleosts. The corticosteroid signaling system in teleosts thus consists of MR, GR1, GR2, cortisol, and DOC, whereas the tetrapod similarly consists of MR, GR, cortisol, and aldosterone. For comparison, the evolution of 11β hydroxysteroid dehydrogenase (11βHSD) enzymes is included. A question mark denotes the lack of data on the presence of 11βHSDs in that species or animal group. The 11βHSD ancestor, 11βHSD3, arose in invertebrates (not depicted here), whereas 11βHSD1 and -2 seem to have arisen sometime in evolution between agnatha (lamprey and hagfish) and chondrichthyes (sharks). 1α-B denotes 1α-hydroxycorticosterone (only found in sharks and rays). Common names and Latin names for the fishes in the figure are: Zebrafish, *Danio rerio*; Common carp, *Cyprinus carpio*; Salmonids, *Salmoniformes*; Pufferfish, *Tetraodontiformes*; Three-spined Stickleback, *Gasterosteus aculeatus*; European Sea bass, *Dicentrarchus labrax*; Burtons Mouthbrooder, *Astatotilapia burtoni*; Nile tilapia, *Oreochromis niloticus*; Medaka, *Oryzias latipes*. the exact enzymatic function, tissue distribution, and regulation of 11βHSD3 are still unknown, it is too soon to reach any conclusion on the significance of the presence or absence of the 11βHSDs for the corticosteroid signaling system in fish.

Glossary

Anorexigenic complex A collection of brain regions that inhibit food intake.

Brockmann body Large aggregate of endocrine pancreatic tissue found especially within teleost fish.

Chondrocyte A cell type in cartilage that produces extracellular cartilage matrix.

Circadian rhythm An internal rhythm, free running under constant conditions with a period slightly differing from the environmental 24 h cycle.

Compensatory growth A period of accelerated growth following a period of stress, such as food deprivation.

Euryhaline fish A species of fish that can survive in water of wide-ranging salinity.

Hyperplasia Growth by increase in the number of cells of an organ or tissue.

Hypertrophy Growth by increase in the cell size of an organ or tissue.

Hypoosmotic regulation The ability of an organism to survive in an environment of greater osmotic concentration than its own body fluids by effectively regulating ion and water movement across its surfaces.

Hypothalamus A region at the floor of the brain that controls several physiological processes, including food intake and secretion of hormones from the pituitary gland.

Myoblast A type of progenitor cell that can differentiate into skeletal muscle cells.

Neurosecretory cell A neuron that is specialized in secreting hormones into blood.

Orexigenic complex A collection of brain regions that promote food intake.

Sexual maturation A process an organism undergoes that enables it to reproduce.

Smoltification A collection of physiological, morphological, and behavioral processes that a juvenile salmonid fish undergoes in preparation for the transition from freshwater to seawater.

Food Intake and Growth Are Coordinated

Fish, like all animals, must obtain matter and energy from the environment in order to support their life processes. Energy and matter are taken up in the form of food; once ingested, the food is digested into absorbable units and assimilated into tissues (**Figure 1**). Energy is partitioned into maintenance metabolism, growth, reproduction, and storage. Some energy is lost to the environment during transformation reactions, and metabolic by-products are eliminated as waste. The flow of nutrients, from their uptake to their partitioning, is tightly regulated and elaborate mechanisms involving many hormonal systems serve to coordinate and integrate energy allocation. Prioritization of energy allocation is not fixed; adjustments are made as an animal moves through its life history. For example, as an animal undergoes sexual maturation, more resources are devoted to reproduction while fewer are devoted toward growth. As fish occur in a diverse range of aquatic habitats, they have evolved elegant and often elaborate life-history patterns so as to adjust to the conditions present in their environments. Consequently, the energy-allocation strategies and regulatory mechanisms of fish vary somewhat with their life-history pattern, and they are strongly influenced by environmental factors such as temperature, photoperiod, and salinity.

The effective coordination of nutrient allocation results from linkages between and among regulatory systems. As fish growth cannot occur in the absence of nutrients (i.e., food-deprived individuals do not grow), the regulatory systems that serve to control food intake and growth are tightly linked. This article describes basic aspects of feeding and growth, as well as the hormonal systems that serve to regulate them.

General Features of Appetite Regulation

The control of food intake involves interactions between the brain and signals from the peripheral environment, including sensory information as well as signals conveyed via the blood (e.g., hormones and nutrient molecules). The main region of the brain that regulates food intake is the inferior lobe of the hypothalamus. Two distinct collections of neurons in the hypothalamus govern appetite and feeding: one that stimulates food intake (orexigenic complex) and one that inhibits food intake (anorexigenic complex). Other regions of the fish brain are also involved in appetite control. For example, electrical stimulation of the ventral telencephalon or optic tectum stimulates food intake, whereas lesion of the olfactory tract inhibits food intake. The hypothalamic centers integrate information from these other neural circuits in the brain as well as sensory information conveyed by peripheral nerves. Hormones produced by peripheral tissues and organs such as the gut, pancreas, interrenal gland (homologous to the adrenal cortex of mammals), and adipose, as well as the energy state of the animal as reflected by metabolites in the blood, all affect the activity of neurons in the orexigenic and anorexigenic complexes to influence food intake. A model illustrating the brain (central) and peripheral factors that influence feeding is shown in **Figure 2** (**see also Integrated Function and Control of the Gut**: Nervous System of the Gut).

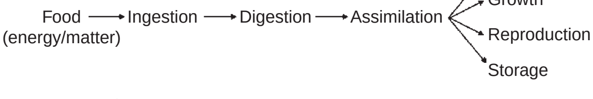

Figure 1 Schematic of the processing of energy and matter in fish. Matter and energy derived from food are assimilated into the organism and partitioned into four basic processes: (1) maintenance metabolism, (2) growth, (3) reproduction, and (4) storage.

Appetite Stimulation

Several compounds produced by different neurons in the hypothalamus and other regions of the brain have been found to stimulate food intake. Neuropeptide Y (NPY), galanin, orexins (includes orexin A and orexin B), and ghrelin are produced by different neurons and stimulate food intake. For example, injection of NPY, galanin, orexins, or ghrelin into the ventricles of the brain (referred to as intracerebroventricular (ICV) injection) stimulates food consumption. The orexigenic action of these factors is supported by the observation that their expression increases during periods of food deprivation. Interactions between and among some of the central orexigenic factors also take place. For example, galanin acts synergistically with NPY and orexins. Similarly, NPY augments the actions of galanin and orexins, and orexins promote the action of NPY.

Ghrelin is also produced in the stomach/gut of fish; therefore, ghrelin acts systemically via the blood. Peripheral injection of ghrelin increases food intake in a manner similar to ICV injection. Immediately after feeding, ghrelin expression in the hypothalamus and gut declines in concert with reduced plasma levels of ghrelin. Ghrelin also stimulates the release of growth hormone (GH) from the pituitary gland, an action that links appetite regulation with growth control. Notably, GH treatment of fish (via intraperitoneal injection (IP) or implantation) stimulates feeding behavior (**see also Integrated Function and Control of the Gut**: Endocrine Systems of the Gut).

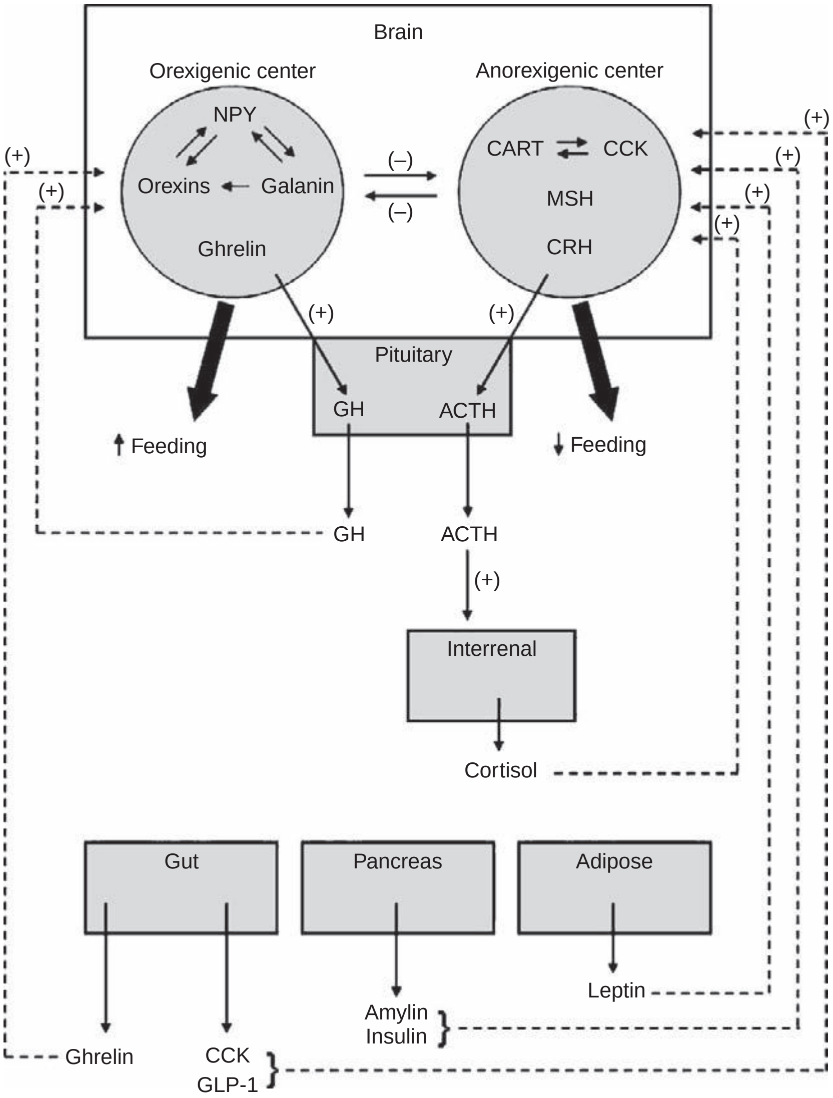

Figure 2 Model of appetite regulation in fish. The orexigenic and anorexigenic centers of the brain integrate sensory information from the external environment as well as information from the periphery of the animal to control feeding. Solid lines indicate direct actions; dashed lines indicate feedback actions.

Appetite Suppression

The brain also produces a number of compounds that suppress appetite and reduce food intake. Cocaine- and amphetamine-regulated transcript (CART), corticotropin-releasing hormone (CRH), cholecystokinin (CCK), and melanocyte-stimulating hormone (MSH) are produced by different neurons in various regions of the brain and are part of the anorexigenic complex. ICV injection of CART, CRH, CCK, or MSH inhibits food intake. Hypothalamic levels of CART messenger (mRNA) increase immediately after eating and decline in association with fasting. In addition, CCK antagonists stimulate food intake. Similar to the situation for the orexigenic complex, there are interactions between components of the anorexigenic complex. For example, CCK and CART augment each other's actions. In addition, there is reciprocal inhibition between the orexigenic and anorexigenic complexes. Notably, CART inhibits both NPY- and orexin-stimulated food intake, whereas NPY blocks CART- and CRH-inhibited food intake.

Several hormones produced by peripheral organs/tissues suppress food intake by stimulating the anorexigenic complex in the brain. Leptin and leptin-like material have been isolated from adipose tissue from several species of fish. Although leptin has been shown to inhibit food intake in mammals, studies in fish have been hampered by the lack of available fish leptin; therefore, most studies in fish have been conducted with mammalian hormone and the results are mixed. For example, mammalian leptin has no effect on food intake in salmon or catfish, but ICV or IP injection of mammalian leptin significantly decreases food intake of goldfish. In addition, ICV injection of mammalian leptin augments the anorexigenic actions of CART and CCK and inhibits NPY- and orexin-induced food intake in goldfish. Recent work in trout showed that recombinant trout leptin suppresses food intake and reduces NPY mRNA expression in the brain. The gastrointestinal tract produces CCK (which is in addition to that produced by the brain) and glucagon-like peptide-1 (GLP-1) (derived from the same precursor as that giving rise to glucagon). Plasma levels of CCK and GLP-1 increase following a meal, and peripheral injection of either peptide suppresses food intake. Insulin and amylin are produced by the endocrine portion of the pancreas of fish (referred to as the Brockmann body) and elsewhere. ICV injection of insulin or amylin can inhibit food intake. Cortisol is produced by the interrenal tissue of fish (homologous to the cortex of the mammalian adrenal gland) under the influence of adrenocorticotropic hormone (ACTH) from the pituitary and, ultimately, CRH from the hypothalamus. Cortisol has many functions including mediation of organismal stress responses (e.g., mobilization of stored energy reserves and suppression of immune system), and in some species of fish, cortisol inhibits food intake, which may explain, at least in part, stress-induced appetite suppression.

Environmental Influences on Food Intake

Several intrinsic (i.e., nutritional status; and stage of life history, including sexual maturity) and extrinsic (i.e., temperature, photoperiod, salinity, etc.) environmental factors can inhibit or stimulate food intake of fish. The presence of nutrients in the blood, especially glucose or amino acids, reduces food intake; the higher the concentration of glucose in the blood, the longer the time to the next feeding. Nutrients may affect feeding directly by altering metabolic processes of neurons in the orexigenic and anorexigenic complexes and indirectly by acting on peripheral tissues/organs. For example, the effects of amino acids could be explained, in part, by stimulating insulin release from the pancreas, and the insulin, in turn, stimulating the anorexigenic complex to suppress food intake. The profile of many of the appetite-regulating hormones varies over the course of development, with clear species differences observed in the profiles. In some cases, factors appear early in development and perhaps play a role in embryogenesis or nutrient-absorption acquisition in larvae, while in other cases, factors appear later in development and perhaps play a role in metamorphosis or shift in feeding strategy. Sex-specific differences in the distribution and expression of appetite-regulating factors such as galanin and ghrelin have been observed. The seasonal changes in NPY are correlated with gonadal cycles. The role of sex steroids on feeding behavior, however, remains to be clarified.

The influence of temperature on feeding is complex; generally food consumption increases with increasing temperature, but at extreme temperatures (either low or high), feeding is suppressed. The mechanisms that underlie temperature-associated changes in food intake are not fully known, but hypothalamic CART (a component of the anorexigenic complex) expression is higher in fish held in cold water compared with fish held in warmer water (**see also Food Acquisition and Digestion:** Cost of Digestion and Assimilation).

Food intake is also influenced by photoperiod in some species of fish but not others. In trout and salmon, for example, food intake (and growth, as is discussed next) is stimulated by a longer daily-light regime. Many hormones may be responsible for such effects, including GH and melatonin, the latter of which is produced in a circadian rhythm by the pineal organ on the dorsal surface of the brain and exhibits peak levels during periods of darkness. Recent studies indicate that IP injection of melatonin inhibits food intake.

Patterns of Growth in Fish

Organismal growth integrates a host of biological processes that lead to a fertilized egg developing into an adult and to the maintenance and modulation of adult structures appropriate to their function. Animal growth is influenced by genetic, environmental, and nutritional factors. Extrinsic factors are particularly important in the growth of poikilothermic vertebrates, such as teleost fish, which rely on temperature, photoperiod, and food availability to trigger developmental processes such as hatching, metamorphosis, smoltification, sexual maturation, and spawning. Integration of external and internal cues leads to the coordination of animal growth via the interplay of numerous hormones.

Fish are unique among vertebrates in that most species have the capacity to grow continuously throughout their life. Such indeterminate growth is in contrast to determinate growth, in which an increase in body size ceases, usually after sexual maturation. Typically, however, the rate of body growth for fish slows over time, especially just prior to sexual maturity when energy is channeled to gonad growth and gamete production.

The GH–Insulin-Like Growth Factor System

The primary control of growth of vertebrates including fish is through the GH–insulin-like growth factor (IGF) system. GH, the initial hormone in this system, has been isolated from the pituitary gland from representatives in every extant class of vertebrate. GH results in increased amino acid uptake, increased RNA synthesis, increased protein synthesis, increased muscle growth, and increased cartilage synthesis. Many of the growth-promoting actions of GH in fish and other animals are mediated by IGF-1, so named because of it structural similarity to insulin (INS). Circulating GH stimulates the synthesis and secretion of IGF-1 from liver and other sites (e.g., gill and muscle) and IGF-1, in turn, binds to IGF-1 receptors (IGFR-1s) on target tissues, which are distinct from INS receptors, resulting in growth promotion and other biological actions (e.g., energy metabolism and osmoregulation). GH has also been shown to stimulate differentiation of chondrocyte stem cells into cells which respond to and/or produce IGF-1. The availability and actions of GH and IGF-1 are influenced by GH-binding proteins and IGF-1-binding proteins (IGFBPs), respectively. IGFBPs also have direct, non-IGF-1-dependent effects on growth. The GH–IGF system of teleost fish is more complex as a result of a genome duplication associated with their evolution, and multiple forms of GH, GH receptors (GHRs), and IGFR-1s have been described. An overview of the GH–IGF system is depicted in **Figure 3**.

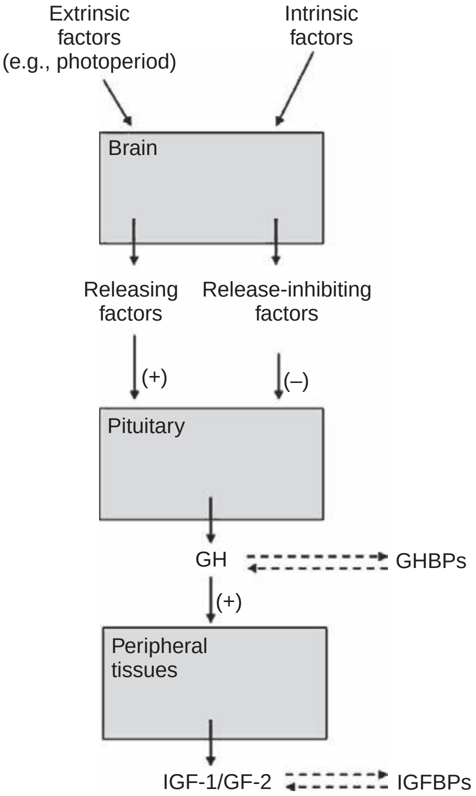

Figure 3 Schematic of the growth hormone (GH)–insulin-like growth factor (IGF) system in fish. External and internal environmental information is integrated by the brain and results in the secretion of either GH-releasing- or GH-release-inhibiting factors from the hypothalamus. With a preponderance of GH-releasing factors, the pituitary secretes GH which, in turn, stimulates the secretion of IGF-1 and IGF-2 from the liver and other tissues. The distribution and action of GH and IGF-1/IGF-2 are influenced by GH-binding proteins (GHBPs) and IGF-binding proteins (IGFBPs), respectively.

Other Growth-Regulating Hormones

Numerous other hormones are known to influence the growth of fish. Many of these growth-promoting actions result from modulation of some aspect of the GH–IGF system. INS is required for normal growth of fish and INS deficiency results in growth retardation. INS appears to act synergistically with GH to promote IGF-1 production, especially in liver. Thyroid hormones (e.g., thyroxin, T4) are also necessary for normal growth and development of fish. Experimentally induced hypothyroidism (using propylthiouricil) reduces body growth and food conversion, effects that likely result from an attending deficiency in plasma GH. The steroid hormones, cortisol and 17β-estradiol (E2) (the major estrogen in fish), also promote growth by stimulating GH (which is discussed in more detail, next). It should be noted, however, that the actions of E2 are especially complex, sometimes promoting growth while at others inhibiting growth – disparate actions that may be related to the stage of sexual maturation.

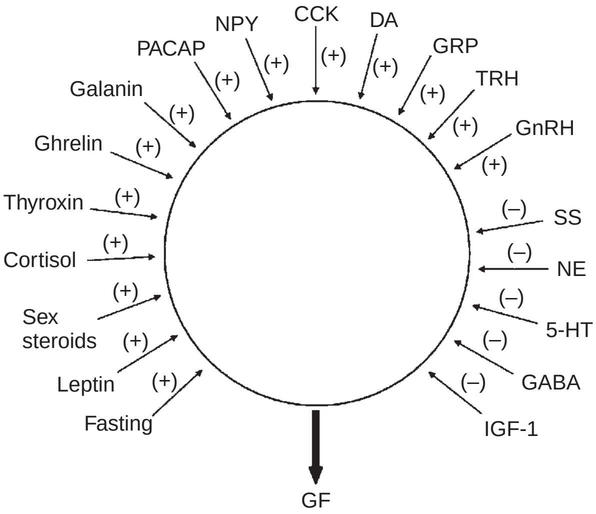

Figure 4 Schematic of the control of growth hormone (GH) release from the pituitary gland of fish. Numerous factors from the hypothalamus of the brain or from the periphery influence, either positively or negatively, the secretion of GH.

Control of Growth Hormone Production and Release

Much of the research on the regulation of animal growth has focused on the production and release of GH (**Figure 4**). In most species studied, including mammals and fish, pituitary GH release is under dual antagonistic control from the hypothalamus of the brain. Neurosecretory cells originating in the hypothalamus release amines and peptides that either stimulate or inhibit the production/release of GH. The major inhibitors of GH release are somatostatins (SSs), a structurally and functionally diverse family of peptide hormones. In fish, the structural heterogeneity arises from the tissue-specific processing of a larger precursor molecule (preprosomatostatin (PPSS)) as well as from the existence of multiple PPSS-encoding genes. SSs are not equipotent in their ability to inhibit GH. For example, SS-14, a SS form that appears highly conserved in vertebrates, from fish to mammals, is very effective in inhibiting GH from isolated goldfish pituitary fragments, but teleost SS-25, a form containing Tyr^7, Gly^{10} amino-acid substitutions in its *C*-terminus and found only in teleost fish, has almost no effect. Norepinephrine (NE), 5-hydroxytryptamine (5-HT; or sometimes called serotonin) and γ-aminobutyric acid (GABA) also inhibit secretion of GH from fish pituitary. Numerous neurosecretory factors stimulate GH release, including GH-releasing hormone (GHRH), pituitary adenylate cyclase-activating peptide (PACAP), dopamine, gonadotropin-releasing hormone (GnRH), thyrotropin-releasing hormone (TRH), gastrin-releasing peptide (GRP), galanin, CCK, ghrelin, and NPY. The efficacy of these various factors to promote GH release varies among species.

Factors produced by peripheral organs and delivered to the pituitary through the systemic circulation also affect GH release. In addition to cortisol, T4, and E2, leptin, which is expressed in adipose tissue and liver of fish, can stimulate GH in fish just as in mammals. By contrast, IGF-1 (predominately expressed in liver) inhibits GH release, completing a negative feedback loop for growth control. It should be noted that some factors produced by neurosecretory cells in the hypothalamus are also produced by epithelial cells in peripheral organs; as a result, such factors affect GH release by two routes. One example is SS, which in addition to the hypothalamus is also produced by epithelial cells in the gut and by δ-cells of the endocrine pancreas (**see also Gut Anatomy and Morphology**: Pancreas). A second example is ghrelin, which is also produced by epithelial cells in the lining of the stomach and the upper intestine of fish. A third example is NE, which is also produced by dispersed chromaffin tissue (equivalent to the medulla of the adrenal gland of mammals). High circulating levels of NE (as well as epinephrine) are observed under stressful conditions, which may contribute to stress-associated suppression of both feeding and growth. Given the complexity of the GH–IGF system and the observation that there are tissue-specific differences in growth, it is increasingly clear that the regulation of growth also occurs at many levels outside the pituitary (**see also Integrated Function and Control of the Gut:** Nervous System of the Gut).

Peripheral Control of Growth

Increasing research indicates that growth of fish is also regulated by adjusting peripheral sensitivity to GH and IGF-1, as well as by modulating GH and IGF-1 actions in target cells. In keeping with its moniker as 'the great inhibitor', SS has effects on several levels of the GH–IGF system outside the pituitary, where it inhibits GH release. For example, SS reduces peripheral sensitivity to GH in liver cells by inducing the internalization of surface-associated GHR and by decreasing the biosynthesis of new GHRs. SS also inhibits IGF-1 biosynthesis in, and secretion from, liver cells. Furthermore, the sensitivity to IGF-1 is reduced by SS in target cells, such as those found in the gill, via inhibition of mRNA and functional expression of IGFR1s. SS may also influence growth through its actions on other hormonal systems. In particular, SS inhibits INS secretion from the endocrine pancreas of fish, and plasma levels of SS are inversely correlated with plasma levels of T4. Other hormones also appear to affect peripheral components of the GH–IGF system. INS and androgens such as testosterone may heighten sensitivity to GH by increasing expression of GHR mRNAs, particularly in liver. Hepatic IGF-1 mRNA expression is stimulated by androgen and inhibited by E2. A negative feedback is provided by IGF-1 by inhibiting expression of IGFR-1 mRNAs in muscle, including cardiac muscle (**see also Cellular, Molecular, Genomics, and Biomedical Approaches:** Growth Hormone Overexpression in Transgenic Fish).

Environmental Influences on Growth

As for feeding, several intrinsic (i.e., nutritional status; and stage of life history, including sexual maturity) and extrinsic (i.e., temperature, photoperiod, salinity, etc.) environmental factors affect the growth of fish. The quantity and quality of food are the most important regulators of growth. Fasting and reduced ration result in decreased growth. Carnivorous fish fed a high carbohydrate diet also display reduced growth. Several nutrient–hormone interactions may explain these observations. In particular, fasting reduces INS secretion and increases SS secretion, alterations that together would lead to reduced growth as discussed above. Moreover, INS-secreting cells of carnivorous fish are more sensitive to amino acids than to glucose; therefore, such fish fed a high carbohydrate diet have a reduced INS response compared to when fed a lower carbohydrate and higher protein-content diet.

Refeeding fish after a period of food deprivation leads to a period of compensatory growth during which the rate of growth is accelerated. During compensatory growth, fish display increased food intake and increased food conversion compared with periods of normal growth. The hormonal mechanisms that underlie compensatory growth are not fully known, but they may be related to IGF-1 kinetics and interaction with the orexigenic complex.

Generally, increased temperature increases growth, within the temperature-tolerance range of the fish, a response that appears to be related to enhanced IGF-1 production at high temperatures.

Photoperiod has varying effects on the growth of fish, depending on the species. Some species (e.g., Atlantic salmon, Atlantic halibut, and Atlantic cod) display higher growth rates when reared under extended photoperiod conditions, whereas the growth of other species (e.g., black porgy and sunshine bass) does not appear to be affected by extended daylength. Extended photoperiod, which elevates plasma GH, is used to advance the timing of smoltification and sexual maturation in the salmon aquaculture industry.

The influence of salinity is complex and depends on other variables (temperature and oxygen level). Generally, marine fish have higher growth rates in reduced salinity (optimal growth in the range of 12–19 parts per thousand (ppth), where seawater is typically 35 ppth), whereas freshwater fish have higher growth rates in water of elevated salinity (2 ppth). The argument advanced for these observations surrounds reduced costs of osmoregulation, enabling animals to channel more energy into growth. Both GH and IGF-1 stimulate hypoosmotic regulatory ability, and transfer of euryhaline fish from freshwater to seawater is accompanied by transient increases in plasma levels of GH and IGF-1 as well as an increase in GHR and IGFR1 expression. The extent to which such changes in the components of the GH–IGF system may underlie salinity-associated growth is not known.

Glossary

False hermaphroditism Sometimes called juvenile hermaphroditism, this refers to gonochoristic species of the undifferentiated type at the stage of development when the gonads contain both ovarian and testicular tissues.

Genotypic sex Also known as genetic sex. Sex given by the genotype of an individual, usually established shortly after fertilization during the formation of the zygote. Except in species with simple (monofactorial) sex determining systems or with well defined molecular markers, the genotypic sex usually cannot be distinguished. In species with strong environmental sex determination, genotypic sex proper does not exist or is irrelevant, because the sex of the individual depends on the environmental conditions experienced during specific windows of development.

Intersex Individual with both testis and ovary or with gonads with male and female germ cells that occupy different areas of the gonads, or are intermixed. Thus, strictly speaking, all hermaphrodites are intersex at one time point, but not all intersexes are hermaphrodites. This definition usually is applied to gonochoristic species to describe those individuals that are not normal for the species. Many intersexes are the result of exposure to chemicals present in the aquatic environment.

Phenotypic sex Also known as gonadal sex. Sex defined according to the gonads of an individual. Sperm producers are males and egg producers are females. Gonadal sex usually (but not always) is established by the process of sex differentiation in accordance with the mechanism of sex determination. Sex differentiation is very labile in fish and easily influenced by external factors. Thus, under some circumstances, phenotypic sex does not necessarily coincide with genotypic sex.

Sex change A process present in sequential hermaphrodites whereby animals reorganize their gonads to produce gametes different from those produced during the last sexual maturation. According to the polarity of change, species are classified as protandrous (male → female), protogynous (female → male), or bidirectional (male ↔ female).

Sex determination A genetic or environmental process whereby the gender (male or female) is established in an individual. In most species, sex determination depends on the genotype (genotypic sex determination, GSD), but in some it depends on the value of some environmental variables during a specific developmental stage (environmental sex determination, ESD), with temperature being the most common one (temperature-dependent sex determination, TSD). Even in species with ESD, there always is a genetic component controlling sex determination.

Sex differentiation A process whereby a sexually undifferentiated gonad transforms into a testis or an ovary, according to genetic information, the influence of the environment, or both. Sex differentiation results in the gonadal or phenotypic sex.

Sex ratio The relative number of males and females in a population. Primary, secondary, tertiary, and operational sex ratio refer to the sex ratios of a population right after fertilization, at hatching, during adulthood, and of the part of the population that actually reproduces, respectively.

Sexuality type Fish exhibit three major types of sexuality: gonochorism or separate sexes, by far the most frequent type, in which each individual functions as either a male or a female; hermaphroditism, in which all or most individuals produce both types of gametes during their lifetime, either simultaneously or sequentially; and unisexuality, in which all individuals are females that reproduce by parthenogenesis, either gynogenesis or hybridogenesis.

Testis–ova Also known as ovotestis, in medicine, it refers to a true hermaphroditic gonad with both male and female tissues. In fish, this term usually indicates males of gonochoristic species whose testes, because of certain circumstances (exposure to hormones, pollutants, or high temperatures), contain female germ cells, usually previtellogenic oocytes. Testis–ova are a particular case of intersex.

Introduction

With almost 30 000 species, fish are by far the largest and most diverse group of vertebrates. Furthermore, fish inhabit a wide range of habitats, from shallow waters to the deep sea and have also a wide range of life-cycle strategies. Thus, it is not surprising that they also vary in their reproductive styles.

Fish exhibit all the sexuality types known among vertebrates: gonochorism, hermaphroditism, and unisexuality (**Table 1**). Gonochoristic species (separate sexes) are by far the most abundant – each animal functions either as a male (sperm producer) or as a female (egg producer).

In hermaphroditic species (~500 species), all or most individuals act both as males and females during their lifetime. Hermaphrodites can function as males and females in a sequential (consecutive) or in a simultaneous manner. Sequential hermaphroditic species are grouped according to which sex matures first. In protogynous species, the most abundant type of hermaphrodites, fish mature first as females and then change to males and continue maturing as such. In protandrous species, it is the other way around. Recently, some members of the family Gobiidae have been found to be able to sex change more than once and are referred to as both-way or bidirectional sequential hermaphrodites. In contrast, simultaneous hermaphrodites, such as some members of the family Serranidae, can mature as males and females at the same time, thus producing sperm and eggs. To avoid self-fertilization, usually cross-fertilization takes place. However, in the mangrove rivulus *Kryptolebias* (formerly *Rivulus*) *marmoratus*, self-fertilization can occur. Finally, unisexual species (~100 species) reproduce by parthenogenesis, including hybridogenesis and gynogenesis.

Whether an animal becomes male or female depends on the combined processes of sex determination and sex differentiation (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Molecular and Chromosomal Aspects of Sex Determination). Sex differentiation is the development of an undifferentiated gonad and its transformation into either a testis or an ovary. This produces an individual's phenotypic sex, which contributes to the sex ratio of the population. The processes involved in gonad differentiation are quite plastic in many fish species and thus sex ratios vary with environmental conditions.

Knowledge of the mechanisms leading to a particular sex ratio is of both basic and applied importance. From a basic point of view, it is important to understand the evolution of sex-determining mechanisms. Studying sex determination and differentiation is also important to understand sex allocation, that is, the distribution of resources to each sex, and for understanding the evolution of mating strategies. Recently, it has become evident that the lability of sex determination and differentiation in fish may contribute to the process of speciation. As the sex ratio strongly influences the reproductive capacity of populations, knowledge of sex differentiation is relevant from an applied point of view as well – for example, to manage the sex ratio in aquaculture and population-control programs. It is also important to understand the effects of chemical pollution and climate change, especially for species with environmental sex determination.

Morphological Aspects

The gross morphological aspects of fish gonadal development have been known for some time, but only for a

Table 1 Sexuality types in fish with some representative examples

Sexuality type	*Subtype*		*Representative species*
Gonochorism[a]	Differentiated		Atlantic salmon (*Salmo salar*)
			European sea bass (*Dicentrarchus labrax*)
			Medaka (*Oryzias latipes*)
			Nile tilapia (*Oreochromis niloticus*)
			Platyfish (*Xiphophorus maculatus*)
			Rainbow trout (*Oncorhynchus mykiss*)
	Undifferentiated[b]		European eel (*Anguilla anguilla*)
			Guppy (*Poecilia reticulata*)
			Zebrafish (*Danio rerio*)
Hermaphroditism	Sequential	Proterandry	Gilthead seabream (*Sparus aurata*)
		Proterogyny	Common pandora (*Pagellus erythrinus*)
		Bidirectional	Okinawa rubble goby (*Trimma okinawae*)
	Simultaneous		Blackspot seabream (*Pagellus bogaraveo*)
Unisexuality	Gynogenesis		Amazon molly (*Poecilia formosa*)
			Prussian carp (*Carassius auratus gibelio*)
	Hybridogenesis		Guatopote (*Poeciliopsis monacha-lucida*)

[a] Sometimes referred to as separate sexes.

[b] Sometimes referred to as false hermaphroditism or (incorrectly) as juvenile hermaphroditsim.

fraction of the total number of fishes. In general, fish gonads are paired organs located in the dorsal side of the body cavity in close vicinity to the mesonephros and between the celomic epithelium and the gut. In some species, however, such as some agnathans and some viviparous teleosts, the gonads form a single, centrally fused lobe. In species with swimbladder, gonads are usually attached to it (**see also The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis, Regulation of Spermatogenesis, and **Role of the Kidneys**: Histology of the Kidney).

Patterns of Gonadal Development

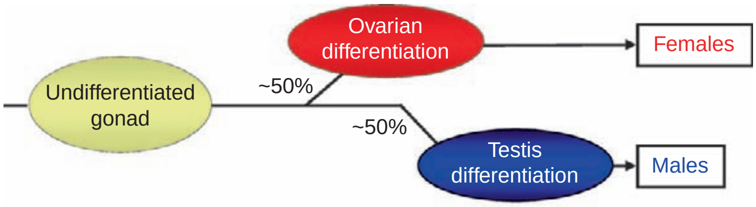
Most fish species (more than 90%) are gonochoristic and two patterns of gonadal development are recognized (**Figure 1**). Gonochoristic differentiated species display one pattern. These species are those in which the formed, but sexually undifferentiated gonad directly differentiates into either ovary or testis. Usually, ovarian differentiation precedes testicular differentiation so that there is a period of time when sexually undifferentiated fish coexist with fish starting ovarian differentiation. Examples include the common carp (*Cyprinus carpio*), trout (*Oncorhynchus mykiss*), Atlantic salmon (*Salmo salar*), medaka (*Oryzias latipes*), and the European sea bass (*Dicentrarchus labrax*).

Gonochoristic undifferentiated species display the other pattern. These species all begin differentiation toward an ovarian-like structure, complete with developing oocytes. Later, about half of the individuals proceed with ovarian differentiation to become females, while the other half stop ovarian differentiation, regress the ovarian-like structures formed so far, and then testicular differentiation takes place. This regression possibly involves programmed cell death (apoptosis), although this process has not been studied in a sufficiently large number of species to allow firm generalizations. Examples include lampreys (*Lampetra* sp.), hagfish (*Myxine* sp.), guppy (*Poecilia reticulata*), European eel (*Anguilla anguilla*), and zebrafish (*Danio rerio*).

Usually, gonadal development in fish depends more on size than on age and thus growth rates can influence its course in species in which there is a genotype–environment interaction in sex determination in such a way that growth rates above average usually cause a higher incidence of females. This phenomenon is known as 'growth-dependent sex differentiation'. Fish arriving at a certain critical developmental stage develop as one sex or the other depending upon their size. Although theoretically larger animals can develop as either sex, in fish that exhibit this growth-dependent sex differentiation, larger individuals at the critical time usually develop as females, whereas the smaller ones develop as males.

From a morphological point of view, the process of sex differentiation in fish can be divided into two major periods regardless of reproductive strategy: the undifferentiated period and the gonadal differentiation period. In turn, the first one is subdivided into the pregonadal stage, in which the primordial germ cells (PGCs) appear early during embryogenesis, migrate along the dorsal mesentery, and concentrate along the peritoneal wall where the future gonads are going to develop; and the gonad formation stage, in which first epithelial cells proliferate and form the gonadal ridges, which are then colonized by the

(a) Gonochoristic differentiated species



(b) Gonochoristic undifferentiated species

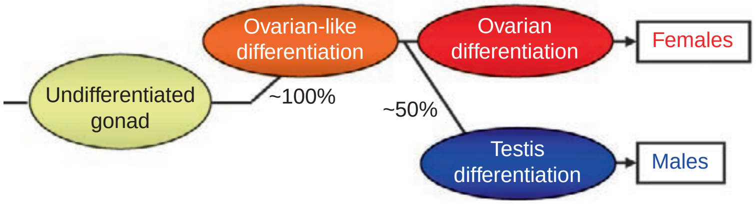


Figure 1 Patterns of sex differentiation in gonochoristic species. (a) Differentiated species. About 50% of the animals differentiate as females while the rest remain undifferentiated and later differentiate as males. The degree of overlap in male vs. female sex differentiation may be species specific and may depend on environmental conditions affecting growth rates. (b) Undifferentiated species. Initially, all fish start developing as females. Later, about 50% stop female differentiation and differentiate as males.

PGCs and somatic cells derived from the mesenchyme. At this point, the animal has sexually undifferentiated gonads (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Germ Cell Migration and Trans Sex).

Sexual differentiation proper takes place during the gonad differentiation period when ovarian and testicular differentiations occur. Usually, ovarian differentiation precedes testicular differentiation. The first histological signs of ovarian differentiation are the elongation of gonad ridges by active mitosis, refolding, and formation of the future ovarian cavity. Cytologically, the first signs of female differentiation are marked by the entry of some oogonia into meiosis to become primary oocytes.

The process of sex differentiation can take a cephalocaudal (head to tail) or caudocephalic (tail to head) gradient depending upon the species. For example, in salmonids such as the coho salmon, *Oncorhynchus kisutch*, the gonads develop in a cephalocaudal fashion, whereas in the European sea bass, it is the other way around. The process of sex differentiation can be completed in a matter of a few weeks, as in medaka or zebrafish, or take many months, as in turbot, *Scophthalmus maximus*, or Atlantic cod, *Gadus morhua*. The process of sex differentiation in the European sea bass is illustrated in **Figure 2**.

Endocrine Control of Sex Differentiation

Fish gonads, like other vertebrate gonads, have two major functions: the production of gametes (gametogenesis) and the production of sex steroids (steroidogenesis) (**see also The Reproductive Organs**

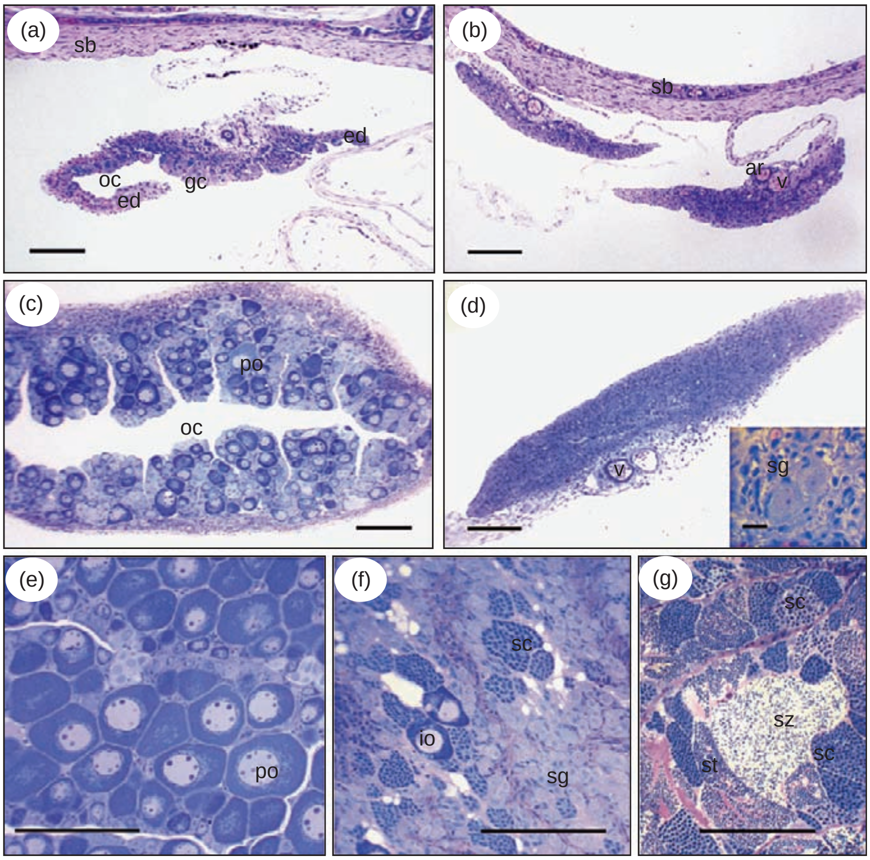

Figure 2 Histological sex differentiation in the European sea bass (*Dicentrarchus labrax*), a gonochoristic differentiated teleost. (a) Differentiating ovary attached to the swimbladder (sb) at 150 days post-hatching (dph). The two edges (ed) of the gonad join to form the ovarian cavity (oc). Clutches of germ cells (gc) are present. (b) Undifferentiated presumptive male gonads at 150 dph attached to the swimbladder (sb), with the vein (v) and artery (ar) visible. (c) Ovary at 200 dph, with primary oocytes (po) and a well-developed ovarian cavity (oc). (d) Testis at 200 dph with spermatogonia (sg, insert) dispersed among somatic cells (v, vein). (e) Completely differentiated ovary at 250 dph. The ovarian lamellae are filled with primary oocytes (po). (f) Testes at 250 dph, showing cysts filled with spermatogonia (sg) as well as spermatocytes (sc). Some isolated intratesticular oocytes (io) are also present. (g) Maturing testis at 300 dph undergoing spermatogenesis, containing all types of germ cells: spermatocytes I and II (sc), spermatids (st), and spermatozoa (sz). and Processes; Anatomy and Histology of Fish Testis, Regulation of Spermatogenesis).

Some species, including the medaka, rainbow trout, and Nile tilapia, have a chromosomal system of sex that allows the production of fish of a particular genotype after crossing normal individuals with sex-reversed individuals. As sex is known well before gonadal differentiation takes place, it is possible to ascribe changes in the expression of genes encoding key steroidogenic enzymes, receptors, and transcription factors to the developmental events of a given genotype.

Sex Steroids

The sex or gonadal steroids are the sex hormones; the major product secreted by the gonads. However, other organs such as interrenal glands, liver, brain, or adipose tissue also can synthesize sex steroids. Besides sex differentiation, the sex steroids also are implicated in the regulation of the onset of puberty in both sexes, oogenesis in females and spermatogenesis in males during the adult reproductive cycle, and with sexual behavior.

Sex steroids are synthesized from cholesterol first by the action of P450 cholesterol side-chain cleavage, a steroidogenic enzyme localized in the inner membrane of mitochondria. Subsequently, several other steroidogenic enzymes are involved (**Figure 3**). These enzymes are located in special somatic cells in the gonads, globally referred to as steroidogenic cells. In males, they primarily are the Leydig cells, located in the interstitial space surrounding the seminiferous tubules, whereas in females they are the follicular cells, granulose and theca cells that surround the oocytes.

The two main classes of sex steroids are androgens, with a molecular structure consisting of 19 carbon atoms, and estrogens, with 18 carbon atoms. Progestagens (21 carbon atoms) are the third class of sex steroids, distinct from androgens and estrogens. In fish, progestagens are important for gamete maturation but have no known relevance in sex differentiation. Although all types of sex steroids are present in both sexes, albeit at different levels, in general, androgens are considered as male sex hormones, because they have masculinizing effects, while estrogens and progestagens are considered as female sex hormones. Thus, treatment of sexually undifferentiated fish with androgens or estrogens usually results in the production of males and females, respectively, regardless of genotypic sex.

The sex steroids, secreted in small amounts and exerting an autocrine or paracrine effect in the sexually undifferentiated gonad, are also responsible for gonadal sex differentiation. Thus, the major product of secretion of the gonads contributes to their differentiation during the early stages. Estrogens, specifically estradiol-17β (E_2), are essential for female development. Regarding androgens, fish gonads secrete testosterone (T) but 11-oxygenated androgens, such as 11-ketotestosterone (11-KT), 11β-hydroxyandrostenedione (11β-OHΔ^4), and 11β-hydroxytestosterone (11β-OHT), are in fact the androgens linked with male sex differentiation.

Steroidogenic Enzymes

In contrast to other reproductive hormones (e.g., gonadotropins) sex steroids once synthesized are not stored. Thus, the expression and activity of the steroidogenic enzymes actively contribute to the regulation of the relative abundance of the different types of sex steroids. This is reflected in differences between sexes in steroidogenic cell activity and sex-steroid content in the gonads prior to and during sex differentiation.

Cytochrome P450 aromatase (cyp19) is the enzyme that irreversibly catalyzes the conversion of androgens into estrogens. As all estrogens derive from androgens and since cyp19 is at the end of the steroidogenic pathway, cyp19 determines the balance between 11-oxygenated androgens and estrogens. This balance at a critical period during development, rather than their absolute amounts, determines the course of sex differentiation.

In contrast to tetrapods, where there is only a single copy of cyp19, teleost fish have two isoforms of cyp19. One isoform is found primarily in the gonad and referred to as gonadal aromatase, cyp19a, cyp19a1, or P450aromA, and the other localized primarily in the brain and referred to as brain or neural aromatase, cyp19b, cyp19a2, or P450aromB.

Several lines of evidence indicate that cyp19a is of central importance for ovarian differentiation in fish. Changes in cyp19a messenger (mRNA) levels during early development are linked with female sex differentiation. Suppression of cyp19a gene expression, inhibition of aromatase activity, or blocking the effects of estrogen at the receptor level during the key period of sex differentiation invariably leads to genotypic females developing as phenotypic males. This emphasizes the importance of cyp19a and of the presence of estrogens for proper ovarian differentiation in fish. In species in which temperature can affect sex differentiation, cyp19a is present at feminizing temperatures but suppressed at masculinizing temperatures. Cyp19a is also essential to control gonadal reorganization during sex reversal of hermaphrodites, with cyp19a mRNA levels increasing during protandrous sex change and decreasing during protogynous sex change. In hermaphrodites, sex change depends on the antagonistic functions of E_2 and 11-KT signaling. In fact, the evidence demonstrating that cyp19a is a key and central element in fish sex differentiation is so compelling that it is now possible to use cyp19a as an early marker of ovarian differentiation.

The regulation of cyp19a transcription is relevant for controlling cyp19a enzyme abundance. The promoter regions of piscine cyp19 genes of both gonochoristic and hermaphrodite species with different sex-changing

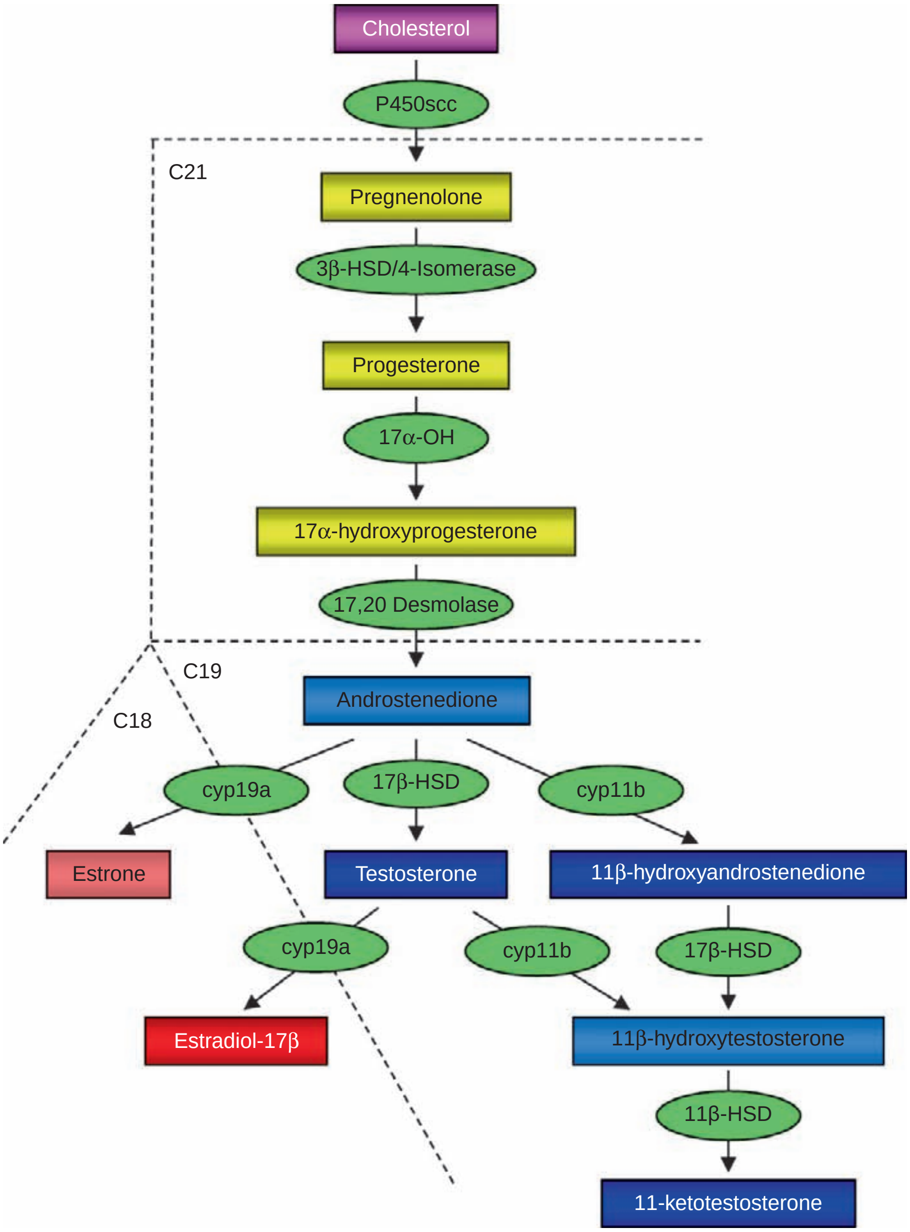

Figure 3 Simplified steroidogenic pathway from cholesterol to the main sex steroids involved in gonadal sex differentiation. The main steroidogenic enzymes are drawn in green. Progestagens, sex steroids with 21 carbon atoms (C21), are shown in yellow, the androgens (19 carbon atoms, C19) in blue, and the estrogens (18 carbon atoms, C18) in red. Darker blue and darker red indicate higher relative androgenic and estrogenic potencies, respectively. Notice that the relative abundance of androgens vs. estrogens essentially depends on the activity of the enzyme aromatase (cyp19a). Abbreviations: P450scc, cytochrome P450 side-chain cleavage; 3β-HSD/4-Isomerase, 3β-hydroxysteroid-dehydrogenase/4-isomerase; 17α-OH, 17α-hydroxylase; 17β-HSD, 17β-hydroxysteroid-dehydrogenase; cyp19a, aromatase; cyp11b, 11β-hydroxylase; 11β-HSD, 11β-hydroxy-steroid-dehydrogenase.

strategies contain a similar repertoire of potential *cis*-acting elements, notably binding sites for transcription factors that exhibit sex-specific changes during early sex differentiation (see below).

The neural form of aromatase, cyp19b, is one of the earliest transcribed genes in developing fish. Thus, the teleost brain is the first aromatization site because the brain develops earlier than the gonads. Further, the teleost brain is characterized by having a remarkably high abundance of cyp19b, which is thought to be related to the capacity of this organ for continued growth through life. Thus, a recurrent question in the study of fish sex differentiation has been whether changes in cyp19b levels somehow dictate gonadal sex differentiation in gonochoristic fish. In fact, in hermaphroditic species changes in some neurotransmitters, gonadotropin-releasing hormone (GnRH), or gonadotropins are correlated with the process of sex change. So far, there is no convincing evidence to support this; however, the brain may signal the gonad to differentiate via pituitary follicle-stimulating hormone (FSH) after stimulation by GnRH.

Besides cyp19a, the other steroidogenic enzyme with a clear sex-specific expression is cytochrome P450 11β-hydroxylase (cyp11b). This enzyme catalyzes the conversion of androstenedione and T into 11-oxygenated androgens such as 11β-OHΔ^4, 11β-OHT, and the precursors for 11-KT synthesis. In fish, cyp11b mRNA also occurs in the head kidney. As opposed to cyp19a, cyp11b is regarded as a marker for testis differentiation.

Sex Steroid Receptors

The sex steroids exert their action by interacting with nuclear hormone receptors which, when bound and activated, act as transcription factors and elicit slow genomic responses. The two major types concerned with fish sexual differentiation are the androgen receptor (AR) and the estrogen receptor (ER). In fish, there are at least two subtypes of ARs, named arα and arβ. Likewise, fish possess three ERs, named erα, erβ1, and erβ2, most likely the products of gene duplications. These ERs are characterized by different tissue distribution and expression patterns, regulation, and nucleotide sequence, and thus different ligand-binding properties.

The presence of ARs and ERs in developing gonads is concordant with the evidence of the effect of sex steroids in sexual differentiation. ARs have been identified in several species of fish but a cause–effect relationship with male development has not been established. Rather, ARs correlate with male sex differentiation only when this differentiation is underway. Thus, in the European sea bass, for example, AR mRNA levels are essentially the same in developing gonads and only higher in males that have initiated active spermatogenesis.

On the other hand, the levels of ERs are positively influenced by estrogens in a positive feedback loop (**Figure 4**). This is important in the context of sex differentiation because it means that basal amounts of estrogen

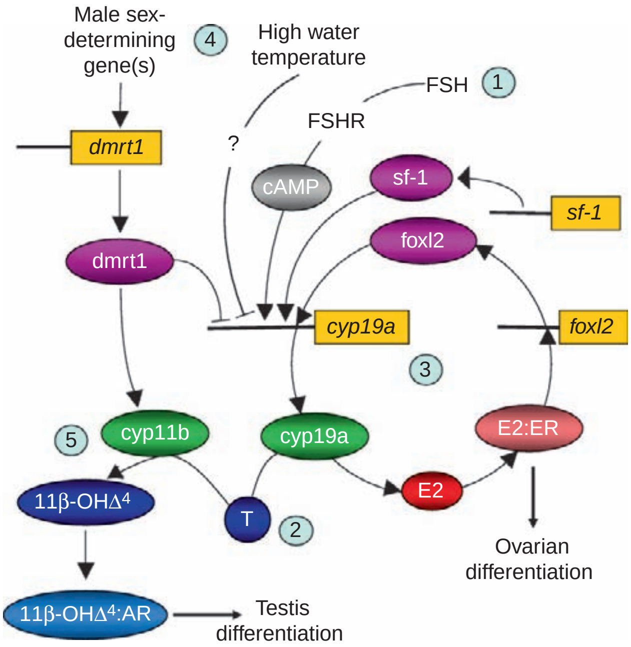

Figure 4 Endocrine control of sex differentiation. Diagram illustrating some of the core players involved, without relating to any particular species. A simplified pathway from either a major or a set of sex-determining genes or an environmental factor to downstream genes is presented but only a subset of the involved genes and regulatory pathways is included. In future females, the ovarian aromatase gene (*cyp19a*) is basally expressed or stimulated by the brain through follicle-stimulating hormone (FSH) signaling on its receptor (FSHR) and the cAMP pathway (1). This results in aromatase enzyme (cyp19a) being synthesized, which converts testosterone (T) into estradiol (E_2) (2). This sets a positive feedback loop (3) that involves the estrogen receptor (ER) and the transcription factor foxl2. Another transcription factor, sf-1, is likely to contribute. In future males – or females exposed to high water temperature (4) – the transcription factor dmrt1 or a still unidentified mechanism (?) inhibits *cyp19a* transcription, resulting in less cyp19a enzyme. This, along with a possible direct stimulation of 11β-hydroxylase (cyp11b), results in more T being converted to 11β-hydroxyandrostenedione (11β-OHΔ^4), which acts through the androgen receptor (AR) or is eventually converted to 11-ketotestosterone, the two major active androgens in fish. The lack of estrogen, essential for female sex differentiation, allows male sex differentiation (5). Thus, the regulation of the steroidogenic enzyme cyp19a and the transcription factor dmrt1 occupy a central position in sex differentiation in fish, which seems to be conserved across species. In females, estrogen is essential for ovarian differentiation, whereas in males, androgens may be a product of testis differentiation.

may be sufficient to start further production of cyp19a, aromatase activity, and estrogen production. However, no major differences in ER levels occur at the beginning of sex differentiation. However, the observation that erα and erβ appear even before the steroidogenic enzymes suggests an important role for estrogen receptors in sexual differentiation. The observation that transgenic medaka undergo normal gonadal differentiation while overexpressing ER, and show the same degree of sex reversal as wild-type nontransgenic fish after treatments with estrogen or androgen, is concordant with this view.

Activated nuclear sex steroid receptors regulate gene expression directly by binding to specific response elements in the promoter of target genes or indirectly by interacting with transcription factors regulating relevant genes. Steroids also can elicit fast, nongenomic responses by interacting with membrane-bound specific receptors. However, because these membrane receptors elicit biological responses minutes or hours after being activated, as opposed to the days or weeks of the classic nuclear hormone receptors, they probably are not involved in sex differentiation of the gonads, a comparatively much slower process.

Transcription Factors

In the process of sex differentiation, from the early stage of germ cell migration and gonadal ridge formation to the final stages of gonad formation, many transcription factors are involved. As many of these are common to all vertebrates, relevant differences are observed not only in their sequence, but also in their sex specificity and temporal expression between species. Of particular importance are those regulating the expression of steroidogenic enzymes. The most studied ones are those that bind cyp19a given its central role in the regulation of fish sex differentiation.

The forkhead box transcription factor l2 (foxl2) is a member of the Winged helix/forkhead group. Foxl2 is one of the earliest known sex dimorphic markers of ovarian differentiation and duplicated copies may occur in fishes due to genome duplications. Foxl2 is expressed mainly in the granulosa cells of the developing ovary and its expression may precede that of cyp19a. Both *in vivo* and *in vitro* studies show that foxl2 acts as a potent transcriptional activator of cyp19a and thus it is important for female sex differentiation. Foxl2 expression can be induced by estrogen treatment and downregulated by exposure to androgen, aromatase inhibitors, or high water temperature. Disruption of endogenous foxl2 in genetically female tilapia results in varying degrees of testicular development, with occasional female-to-male reversal. Together, these observations emphasize the decisive role of foxl2 in ovarian differentiation in fish.

Double-sex and Mab-3 related transcription factor 1 (Dmrt1) is present in both invertebrates and vertebrates and always is associated with the development of the male reproductive system. In fact, dmrt1 is thought to be the male sex-determining gene in birds. A duplication of dmrt1, named dmrt1bY or DMY, is the sex-determining gene in medaka. Dmrt1 is involved in normal testis differentiation in both gonochoristic and hermaphrodite fish. Further, after induced masculinization by treatment with a synthetic androgen, such as 17α-methyltestosterone (MT), or after treatment with an aromatase inhibitor, dmrt1 increases. Dmrt1 may act as a transcription repressor of cyp19a, resulting in suppressed E_2 synthesis, impaired ovarian differentiation, and thus male sex differentiation.

There are many other transcription factors involved in gonadal sex differentiation. Some of the ones that have received more attention include several members of the SRY-related high-mobility group (HMG) containing box (Sox) genes, the dosage-sensitive sex-reversing adrenal hypoplasia congenital critical region on the X (Dax1 or Nr0b1), the Wilm's tumor-suppressor-1 gene (Wt1), and the steroidogenic factor-1 (Sf1), also named adrenal-4-binding protein (Ad4bp) and fushi tarazu factor-1 (Ftz-f1). This nuclear receptor product of the Nr5a1 gene is involved in the expression of steroidogenic enzymes. Notably, a potent interaction between sf1 and cyp19a1 has been demonstrated in several teleosts.

Growth Factors and Other Elements

Several growth factors are also involved in the regulation of sex differentiation. Among them, the anti-Müllerian hormone (amh; also known as Müllerian inhibiting hormone) has been the most studied. Amh is a member of the transforming growth factor β (Tgf-β) superfamily of growth and differentiation factors. Usually, amh expression is detected in undifferentiated gonads and further expressed in juvenile testis but not juvenile ovaries. Other elements for which there is less evidence regarding their involvement in fish gonadal differentiation include some proteins associated with entry into meiosis.

Environmental Influences

As mentioned earlier, one of the characteristics of fish sex differentiation is its lability when compared with other vertebrates. Thus, environmental (biotic or abiotic) influences can easily alter or determine the course of sex differentiation. Here, however, it is important to distinguish between gonochoristic species versus hermaphroditic species. In the latter, it is well established that the process of sex change, which at the gonadal level can be regarded as a sort of a second sexual differentiation toward the opposite sex, is controlled by social stimuli that are integrated by the brain. The brain, then, with its secretion of neurotransmitters is able to change secretion of gonadotropins and contribute to gonadal sex change.

There is no strong evidence showing the influence of social stimuli in the gonadal development of gonochoristic species, although some early studies pointed in this direction (**see also Social and Reproductive Behaviors**: Socially Controlled Sex Change in Fishes). In these species, the environmental influences on sex determination are abiotic. Here, again, we must distinguish the normal condition from effects of fish under exceptional conditions. In species with environmental sex determination (ESD), the abiotic conditions experienced during specific windows in early development determine the sex of the individual. Among the abiotic factors, temperature is by far the most studied (temperature-dependent sex determination, TSD). Water pH has been shown to affect sex ratios in some South American cichlids of the genus *Apistogramma*. Clearly, more research is needed to learn what environmental factors can serve as a cue for sex differentiation and the species differences. Likewise, it is of central relevance to learn how environmental signals are transduced in morphological changes, that is, the molecular basis underlying cellular responses to a changing environment.

Sex differentiation also can be influenced by the presence of endocrine-disrupting chemicals in their aquatic environment. These chemicals cause altered sex ratios mainly by their ability to act as substances with androgenic or, more often, estrogenic capacity, by binding to estrogen receptors. This does not represent any sort of natural condition; it is only due to the contamination of many water bodies throughout the world.

Concluding Remarks

Despite the large number of fish species and the diversity of their sexuality types, certain general principles emerge in light of recent research. Thus, there is a certain relationship between the patterns of morphological gonadal development and the underlying molecular mechanisms controlling sex determination and differentiation, in such a way that the former reflect the actions of the latter. The presence of a male sex-determining gene or set of genes acting early during gonadal development is reflected in the pattern seen in gonochoristic differentiated species, whereas male sex-determining mechanism that acts relatively later accounts for the pattern observed in gonochoristic undifferentiated species. In any case, the balance between androgens and estrogens in the early stages of gonadal formation accounts for the course of sex differentiation toward ovarian development, in those cases where the self-perpetuating female pathway is not interrupted, or toward the male pathway, when the female pathway is braked by the presence of a natural inhibitor of estrogen synthesis acting on aromatase activity (**Figure 4**). Moreover, new technologies such as the analysis of the transcriptome by using microarrays will undoubtedly contribute toward a better understanding of the genes implicated and how they interact with one another, allowing the emergence of a set of genes with conserved roles or interactions across species. Of particular importance is the elucidation of the molecular mechanisms underlying the response to varying environmental conditions in the context of environmental sex determination in gonochoristic species. Also relevant is the question regarding how social influences controlling sex change in hermaphroditic species are transduced. Finally, cell-fate studies concentrating on the development of gonadal cells starting from precursor cells will be important as will be those studies aimed at elucidating cell–cell interaction during gonadal formation and sex differentiation, particularly concerning the interaction of somatic cells with germ cells.

Glossary

Follicle-stimulating hormone (FSH) A glycoprotein hormone secreted by the pituitary; stimulates early phases of gametogenesis: spermatogenesis in males and early development of oocytes in females.

Gonadotropin-releasing hormone Neuropeptide hormone produced in the hypothalamus, released at the anterior pituitary gland to regulate gonadotropin secretion and is a key regulator of reproduction.

Luteinizing hormone (LH) A dimeric glycoprotein hormone released from the anterior pituitary gland that acts through gonadal membrane receptors to stimulate steroidogenesis and gametogenesis. LH is a gonadotropin.

Oogonia Female germ cells at the beginning of their development toward becoming an oocyte and egg prior to meiotic division.

Spermatogonia Male germ cells at the beginning of their development toward becoming spermatozoa and prior to meiotic division.

Introduction – Overview of the Brain–Hypophyseal–Gonadal Axis

Environmental signals, in conjunction with social cues, are conveyed by sensory signals to various brain centers culminating in the hypothalamus. In the absence of hypophyseal portal system, hypothalamic nerve fibers branch throughout the adenohypophysis to regulate the synthesis and release of the gonadotropic hormones, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Dopamine secreted by the hypothalamus may inhibit LH release. FSH and LH, in turn, bind to their respective receptors in the gonads (FSH-R and LH-R, respectively).

The gonads respond by secretion of sex steroid hormones; estradiol 17β (E2) in females that promotes oogonial proliferation and vitellogenesis, and progestogens such as 17α,20β dihydroxy-4-pregnen-3-one (DHP) that promotes initiation of germ cell meiosis and follicular maturation and ovulation (**Figure 1**(**a**)). In males, these are androgens, mainly 11 ketotestosterone (11-KT), that regulate spermatogenesis and spermiogenesis, as well as DHP that initiates the meiotic division of spermatogonia and controls the spermatozoa maturation and spermiation. DHP in its free or conjugated forms serve as pheromones as well. Generally, fertilization occurs in the water, either in specialized nests guarded by one or both parents or in the open water. Several teleost fish such as the guppy (*Poecilia reticulata*) are viviparous.

Oogenesis

Oogonial Proliferation and Meiosis

Oogonia proliferate mitotically under the stimulation of E2 (**Figure 2**). Meiotic division commences in a subpopulation of the oogonia that can be visualized by the presence of synaptonemal complexes (a hallmark feature of homologous chromosomal synapses). Another marker of meiosis is Spo11, a protein involved in the creation of double-stranded breaks in the DNA at early stages of meiotic recombination. Addition of DHP to the medium of cultured ovarian fragments results in increased abundance of synaptonemal complexes and increased expression of Spo11, indicating that DHP acts to induce meiosis in the oogonia of teleost ovary (**Figure 2**).

Oocyte Growth

As the oocyte starts growing during fish puberty, it is still arrested at the prophase of the first meiotic division

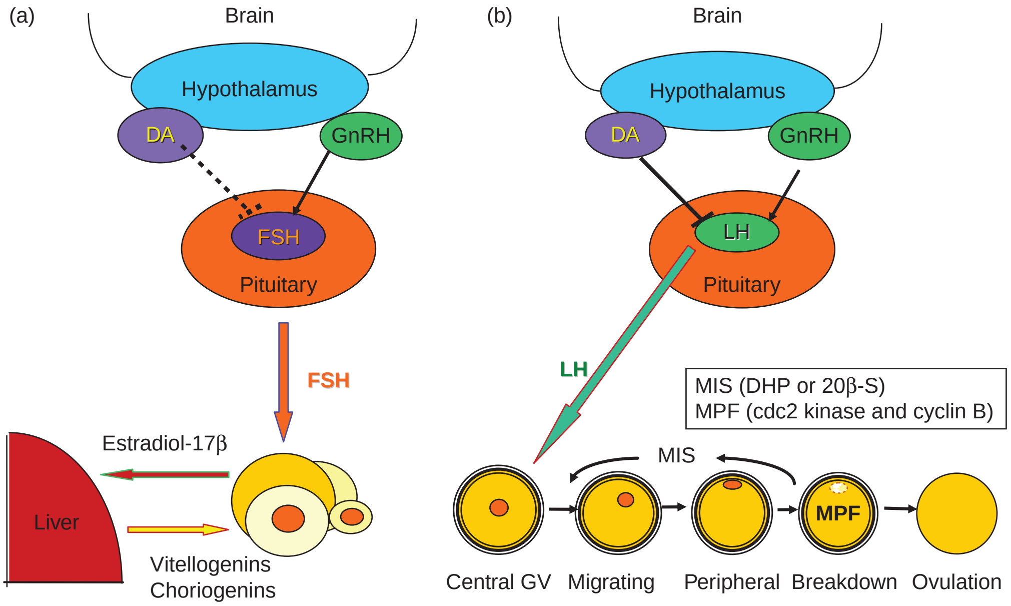

Figure 1 (a) An overview of the endocrine chain, brain–pituitary–gonadal axis (BPG axis) in model female fish during the vitellogenic phase. (b) An overview of the BPG axis during final oocyte maturation and ovulation.

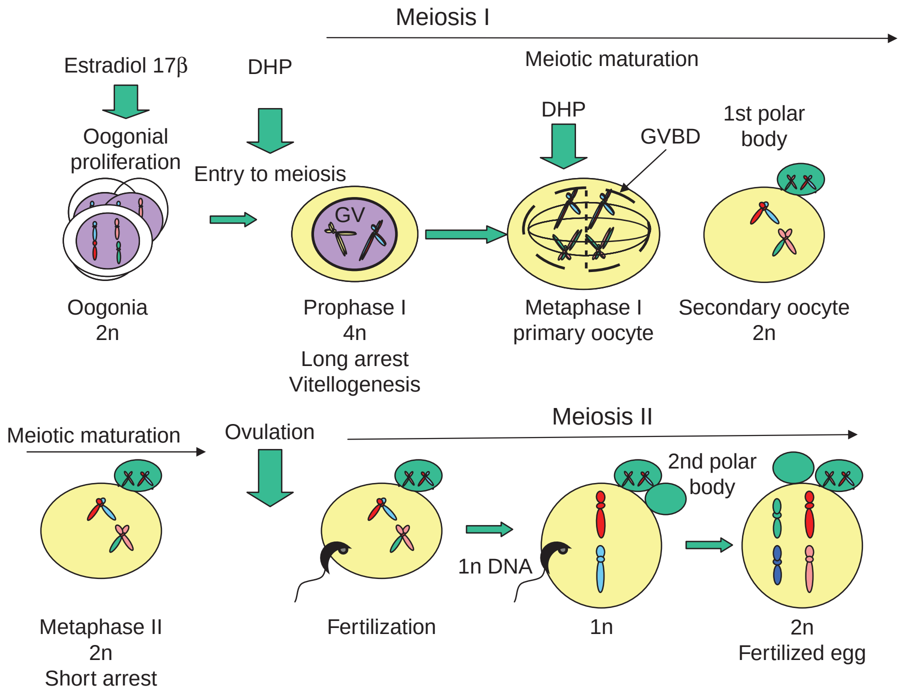

Figure 2 Stages of fish oogenesis and their endocrine regulation.

(**Figure 2**). At this phase, it sequesters yolk precursors (vitellogenins) and chorionic proteins (choriogenins) mainly produced by the liver under estrogenic stimulation. The yolk accumulates in the oocyte which increases in diameter. FSH regulates both the secretion of estradiol and the incorporation of vitellogenins into the oocytes (**Figure 1**(**a**)).

Mutual Regulation of the Follicle Cells and the Oocyte

The granulosa cells surrounding the oocyte and the oocyte itself maintain a mutual communication system by which molecules of the epithelial growth factor

(EGF) family secreted by the oocyte affect the adjacent granulosa cells. Activin, a major mediator of fish pituitary gonadotropins, is released by the somatic cells of the follicle and affects the oocyte through activin receptors present in this germ cell.

Oocyte Maturation

The post-vitellogenic oocyte may remain quiescent for several months but following environmental, social, or pheromonal cues, it begins the process of final maturation, that is, the resumption of meiosis (**Figure 2**). This will commence with a surge in gonadotropin-releasing hormone (GnRH), with or without a decrease in dopaminergic inhibition, followed by a rise in circulating LH. Upon binding of LH to its receptors on the granulosa cells, the ovarian follicle starts the process of maturation, beginning with the production of the maturation-inducing steroid (maturation-inducing steroid (MIS) such as DHP or 17α-20β,21 Trihydroxy-4-pregnen-3-one (20β-S)). Binding of the MIS to its receptors on the oocyte plasma membrane is followed by activation of the maturation-promoting factor (MPF), a complex consisting of existing cdc2-kinase and newly synthesized cyclin B. (**Figure 1**(**b**)). The process of oocyte maturation is reflected morphologically by the migration of the germinal vesicle (GV) toward the animal pole (GV migration) and the disintegration of its membrane, a stage known as GV breakdown (GVBD) (**Figures 1**(**b**) and **2**). The chromosomes then condense, a spindle is formed, and the first polar body is extruded which marks the end of the first meiotic division (**Figure 2**). At this stage the oocytes absorb water and inflate; this is especially pronounced in marine fish with pelagic eggs, the pressure within the follicle increases, the follicular wall is ruptured, and the oocyte is released (ovulated) into the ovarian lumen or to the coelomic cavity. The meiosis is arrested again at metaphase II. Completion of the second meiotic division and extrusion of the second polar body are further delayed and will proceed only if the egg is fertilized (**Figure 2**).

Spermatogenesis

Endocrine Regulation of Spermatogenesis

Spermatogenesis consists of several successive processes, each regulated by a distinct set of hormones. Mitotic divisions of spermatogonia that lead to germ cell renewal are regulated by E2 secreted by the interstitial Leydig cells under gonadotropic stimulation, mainly FSH. Upon binding of E2 to their receptors in the Sertoli cells, the latter secrete the spermatogonial stem-cell renewal factor (possibly gonadal soma-derived growth factor (GSDF)) that stimulates spermatogonial mitotic proliferation (**Figure 3**).

Experimental increase or decrease in the FSH and FSH-Rs expression in the testis of African catfish (*Clarias gariepinus*) resulted in respective changes in Sertoli cell proliferation and testicular growth, suggesting that in fish, as in mammals, FSH in cooperation with androgens is probably the regulator of Sertoli cell number.

Gonadotropic stimulation in the Japanese eel (*Anguilla japonica*) shifts a subpopulation of spermatogonial germ cells from a renewal line to a proliferation line ensuing by meiosis. Gonadotropins (mainly FSH) elicit a surge in the secretion of 11-KT from Leydig cells to stimulate in Sertoli cells the production of several mediators such as activin B, insulin-like growth factor I (IGF-I), and anti-Müllerian hormone (AMH). The action of 11-KT on this spermatogonial line is positively mediated by activin B and IGF-I, and negatively by AMH (**Figure 3**). However, the initiation of meiotic division leading to the formation of spermatids is induced by DHP, which is produced by the germ cells themselves, exerting their effect on the germ cells in a paracrine or autocrine manner (**Figure 3**). The need for DHP to initiate meiosis was demonstrated by 11-KT stimulating DNA replication and meiosis in organ culture of eel testes and anti-DHP serum blocking this effect. Moreover, addition of DHP resulted in the expression of two meiosis-specific markers DMC1 and Spo11, and the appearance of synaptonemal complexes in testicular sections.

Immature spermatozoa undergo sperm maturation, which is also regulated by DHP acting directly on spermatozoa to activate carbonic anhydrase. This enzymatic activation is followed by an increase in the seminal plasma pH, which augments intrasperm cAMP levels to enable their motility (**Figure 3**).

Gonadal Steroids

Formation of Gonadal Steroids in Fish

Fish gonadal steroids are mainly synthesized through pathways similar to those in other vertebrates with a few exceptions (**Figure 4**). Testosterone in fish testis is hydroxylated at carbon 11 by P450-11β and, after oxidation by 11β- hydroxysteroid dehydrogenase (11β-HSD), is converted into 11-KT that is the potent androgen of teleost fish. In certain fish, testosterone hydroxylation occurs in an extra-testicular tissue, the liver. The conversion of 17-hydroxyprogesterone by 20β-HSD produces DHP that acts as the MIS in many fishes. However, in a number of marine perciform fish, the MIS is 17α,20β,21-trihydroxy-4-pregnen-3-one (21β−S). This steroid too derives from

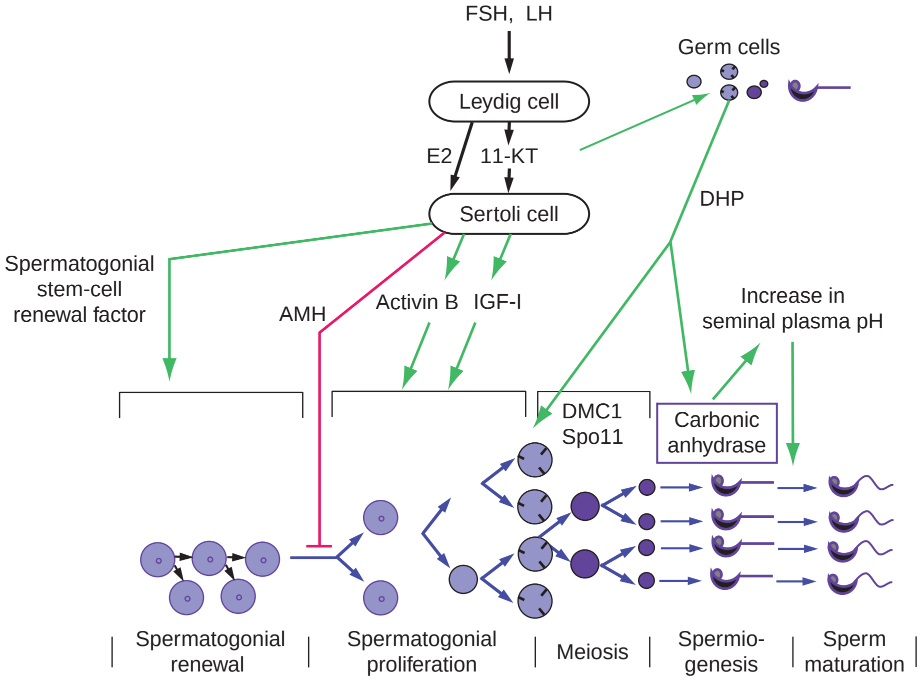

Figure 3 Endocrine mechanisms regulating spermatogenesis in the Japanese eel (*Anguilla japonica*). 11-KT, 11-ketotestosterone; AMH, a peptide homologous to anti-Müllerian hormone; DHP, 17α,20β-dihydroxy-4-pregnen-3-one; DMC1 and Spo11, markers specific to early phases of meiosis; IGF-I, insulin-like growth factor I. Cells at the upper right corner depict the germ cells as the source of DHP acting upon themselves in a paracrine or autocrine manner. Modified from Miura T and Miura C (2001) Japanese eel: Model for analysis of spermatogenesis. *Zoological Science* 18: 1055–1063 and from Miura T and Miura C (2003) Molecular control mechanisms of fish spermatogenesis. *Fish Physiology and Biochemistry* 28: 181–186.

17-hydroxyprogesterone that is hydroxylated at carbon 21 by 21 hydroxylase (P450c21) to form 11-deoxycortisol. The latter is oxidized by 20β-HSD to form 20β–S (**Figure 4**).

The Shift from Estradiol to Progestogens

At the onset of the periovulatory phase, the LH surge is followed by a dramatic shift in the steroidogenic pattern. There is an increase in the formation of DHP concurrently with a decline in E2 level. The shift in the steroidogenic pattern from the formation of C18 and C19 steroids (estrogens and androgens, respectively) toward the formation of C21 steroids (progestogens or corticosteroids) involves a decrease in 17–20 lyase activity and a rise in that of 20β-HSD.

Two genes encoding 17-hydroxylase (P450c17) occur in fish. One is P450c17-I which is similar to that in tetrapod gonads and displays lyase activity resulting in C19 steroids that serve as precursors for androgens and estrogens. P450c17-I is expressed in the ovarian granulosa cells during the vitellogenic phase. The other gene, P450c17-II, encodes a 17-hydroxylase that is devoid of lyase activity and is fully expressed in the oocytes of the Nile tilapia (*Oreochromis niloticus*) only during final oocyte maturation, increasing the production of progestogens instead of androgens and estrogens (**Figure 4**).

Irrespective of the mechanism leading to the steroidogenic shift, estradiol and its seven-transmembrane receptor (GPR30) in the oocyte maintain meiotic arrest. Therefore, the decrease in estradiol is essential for the resumption of meiosis during oocyte maturation (**Figures 1** and **2**).

In addition to the aforementioned free steroid compounds, teleost gonads produce a number of reduced and conjugated steroids, especially in the periovulatory phase. The glucuronidated testosterone and sulfated or glucuronidated progestogens, when released into the water, may act as sex pheromones.

The formation of sex steroids in the vitellogenic ovary of the salmon and probably in other fish as well is a two-step process in which the steroidogenic conversions from cholesterol to testosterone are carried out in the theca cells. The androgen diffuses into the surrounding and is taken up by the granulosa cells possessing P450arom that aromatizes testosterone to form E2 (**Figure 4**).

In a parallel manner, in the ovary approaching final oocyte maturation, all the steroid conversions from cholesterol to 17-hydroxyprogesterone is carried out in the theca of the post-vitellogenic ovary while the conversion

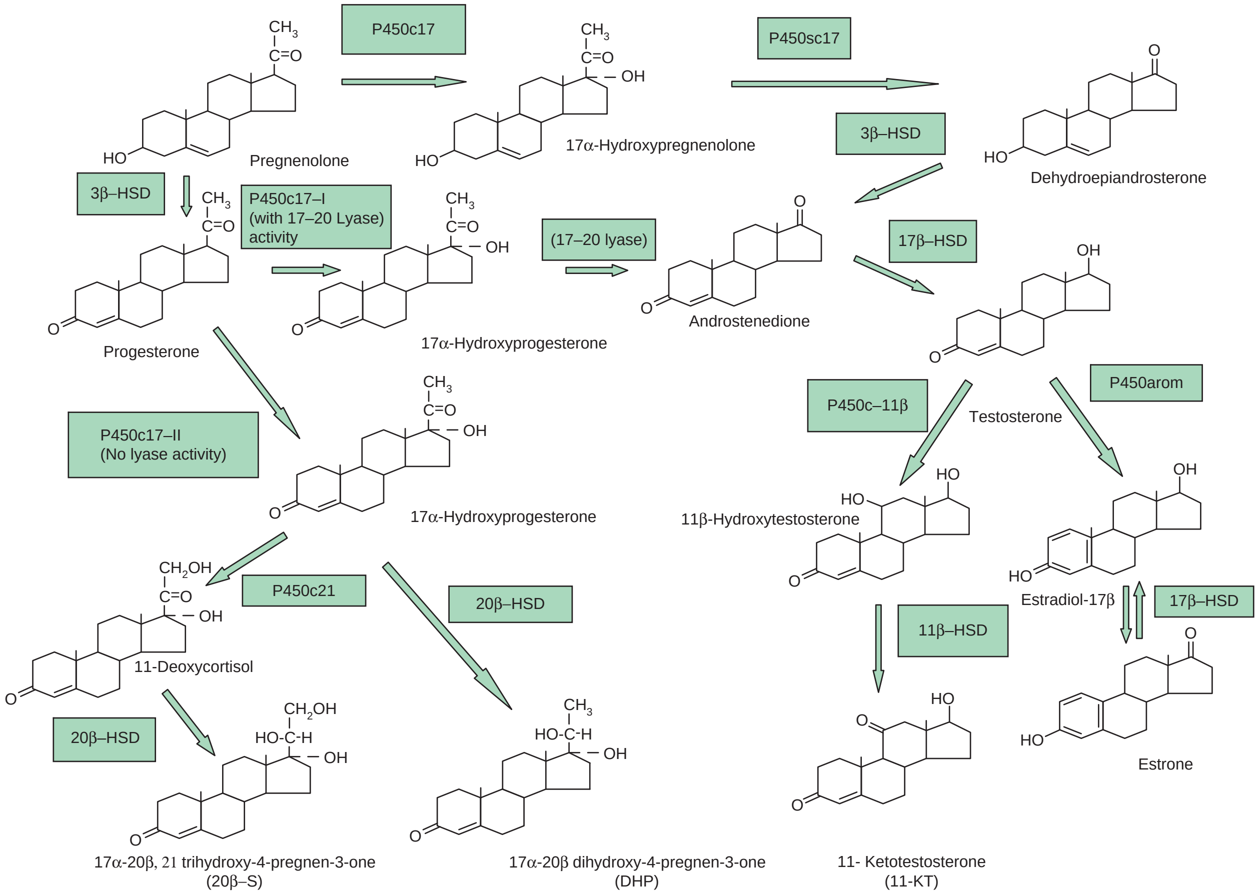

Figure 4 The main pathways in the formation of free gonadal steroids in fish, downstream from the pregnenolone step. Upstream steps are similar to those in mammals and are not shown here. The gonadal steroids specific to teleost fish are 11-KT, the most effective androgen, and DHP, a C21 steroid acting as maturation-inducing steroid (MIS); In several marine teleosts, the MIS activity is carried out by another progestogen, 17α,20β,21-trihydroxy-4-pregnen-3-one (20β–S), produced through oxidation of 11-deoxycortisol by 20β-hydroxysteroid dehydrogenase.

to DHP is performed by the granulosa cells possessing 20β-HSD (**Figure 4**).

Gonadotropins and Their Regulation

The fish pituitary produces and secretes two gonadotropins: FSH and LH. Both are heterodimeric glycoproteins formed by a shared α-subunit (GPα) noncovalently linked to a specific β-subunit. Each subunit, α, FSHβ, and LHβ, is encoded by a distinct gene.

Molecular cloning techniques allowed so far the isolation of the genes encoding the gonadotropin subunits for 56 fish species belonging to 14 teleost orders. The phylogenetic relationships of fish gonadotropins, together with their structural and biological characteristics, provided the evidence for their classification as the piscine counterparts of the mammalian FSH and LH.

The α-subunit is the most conserved among fish species and contains two potential sites for N-glycosylation and 10 conserved cysteines. LHβ and FSHβ subunits each contain 12 conserved cysteines linked by six disulfide bridges. This structure is conserved in fish LHβ subunits, but not in FSHβ, which is the least conserved gene.

All LHβ gene promoters isolated from fish contain putative response elements for Sf-1 and Pitx1, but unlike their mammalian counterparts, the teleost proximal promoters do not contain an early growth response factor 1 (Egr-1). The latter appears to have been replaced by the estrogen receptor (ER). Comparison of FSHβ5′ flanking region in the fish studies so far revealed that they all share several putative response elements, such as GSE, CRE, half sites of ERE, and activating protein 1 response element (AP1), the recognition site for the Fos and Jun transcription factors.

Recombinant Gonadotropins

Fish gonadotropin research has traditionally relied on the laborious isolation and incomplete purification of the native hormones extracted from thousands of fish pituitary glands. The isolation and cloning of cDNAs encoding piscine gonadotropin subunits enabled the production of recombinant hormones (rFSH and rLH) through their expression in heterologous systems. However, to endow the products with the correct biological activity, they have to be glycosylated, folded, and assembled as a heterodimers. All recombinant LH and/or FSH produced so far in teleosts can bind and activate the respective receptors, and stimulate sex-steroid output from isolated gonadal tissue. The lack of cross-contamination of these recombinant hormones enables the study of LH and FSH differential functions. In addition, it is anticipated that recombinant gonadotropins will find use in spawning induction in aquaculture.

Regulation of Gonadotropin Synthesis and Secretion

The hypothalamus regulates synthesis and release of gonadotropins through multiple neurohormones. The major ones are GnRH in its various forms, kisspeptins and dopamine, and potentially other hormones such as γ-aminobutyric acid (GABA), pituitary adenylate cyclase-activating peptide (PACAP), norepinephrine, neuropeptide Y (NPY), serotonin, secretoneurin, ghrelin, leptin, and glutamate (**Figure 5**). Of special interest are hormones associated with growth and metabolism (IGF-1, glutamate, leptin, and ghrelin), which signifies a relationship between reproduction, energy reserves, and body mass of the fish (**Figure 5**).

Gonadotropin-releasing hormone

GnRH stimulates the production and release of gonadotropins from the pituitary of teleosts as in other vertebrates. It increases the amounts of mRNA encoding gonadotropin subunits in the pituitary. The response of GPα and LHβ mRNAs to GnRH implantation in maturing females or males is higher than that of FSHβ, indicating differences in the hypothalamic regulation of the two gonadotropins.

GnRH effects vary with a fish's reproductive stage. In maturing salmonids sGnRH elevates pituitary mRNAs encoding for GPα and FSHβ, but not that of LHβ. The response of the gonadotropin subunit mRNAs to GnRH in common carp (*Cyprinus carpio*) too is differential and depends on the gender and reproductive stage. Thus, information regarding the reproductive stage is potentially conveyed via the steroid hormone profile that can modulate the response and make it specific to each phase (**Figures 1** and **5**). The three forms of GnRH present in the brain of gilthead seabream (*Sparus aurata*) and Nile tilapia (sbGnRH = GnRH1; cGnRHII = GnRH2; sGnRH = GnRH3) all have LH-stimulating activity in mature females. However, the form most abundant in the pituitary of mature fish, GnRH1, is the least potent in inducing LH release.

Dopaminergic inhibition of gonadotropins

Dopamine inhibits both basal and GnRH-stimulated LH secretion (**Figure 5**). *In vitro* experiments, as validated by molecular studies, show that dopamine D$_2$-like, but not D$_1$-like, receptors inhibit gonadotropin secretion directly in the pituitary. In fact, cyprinid spawning induction in aquaculture uses dopamine D$_2$ antagonists, such as domperidone, pimozide, or metoclopramide, to facilitate the stimulation by GnRH of LH release and ovulation. Nevertheless, the dopaminergic inhibition does not operate in all fish and is lacking altogether in

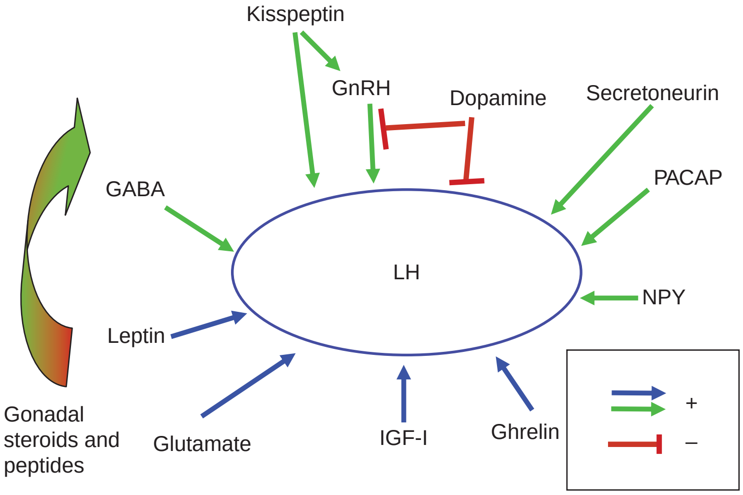

Figure 5 Regulation of LH secretion. Schematic presentation of brain and gonadal regulation of LH secretion. Hormones related to metabolism and growth are indicated by blue arrows.

Atlantic croaker (*Micropogonias undulatus*) and gilthead sea bream.

Kisspeptin regulation of gonadotropins

Kisspeptin, a member of the RF amide peptide family, has important roles in mammals in timing of puberty, maintaining gonadal functions, photoperiod control of seasonal breeding, metabolic gating of fertility, and insulin secretion. Kisspeptin has been proposed to be a novel gatekeeper for the gonadotropic axis of fish mainly due to its potent stimulation of gonadotropin secretion (**Figure 5**).

Kiss1 was cloned in several fish species and its involvement in gonadotropin release and signaling of sexual maturation/puberty has been confirmed so far in medaka (*Oryzias latipes*), zebrafish (*Danio rerio*) and the European sea bass (*Dicentrarchus labrax*). In addition, a second Kiss gene, namely Kiss2, exists in teleost fish. Apparently, the two Kiss genes arose by gene duplication early in vertebrate evolution, and Kiss2 gene might have been lost in the mammalian lineage (**Figure 6**). Kiss1 and Kiss2 in zebrafish are regionally expressed within the hypothalamus, and may exert differential or distinct effects on LH and FSH expression and secretion.

Fish possess two Kiss receptors: kiss1ra and kiss1rb. Sequence identity and genome synteny analyses indicate that zebrafish kiss1ra is a human KISS1R ortholog, whereas kiss1rb is a specific fish form. Both kisspeptins and their receptors are abundantly expressed in the brain, notably in the hypothalamus, suggesting that these ligand–receptor pairs have neuroendocrine and neuromodulatory roles. Fish kisspeptins differ in their signal transduction pathways, tissue distribution, and their gene expression pattern toward puberty.

Regulation by gonadal steroids

Steroids released from gonads can feed back and regulate the production and release of FSH and LH. This type of feedback effect (positive or negative) varies with the gonadal phase of reproductive development. Positive or negative feedback mechanisms operate either indirectly through certain hypothalamic nuclei, or directly on the pituitary cells. Negative feedback of gonadal steroids on gonadotropin secretion was demonstrated using gonadectomy and steroid-replacement protocols in certain teleost species. In rainbow trout (*Oncorhynchus mykiss*), the negative feedback of estrogens on the pituitary is direct or indirect through GnRH inhibition, and potentially by E2 upregulation of dopamine receptor mRNA. Nevertheless, a positive feedback of gonadal steroid also operates in fish, but only early in gonadal development. Estrogens and aromatizable androgens can stimulate LHβ-subunit gene expression and increase pituitary LH protein levels in juveniles of several fish species.

Regulation by gonadal peptides

Activins are peptides composed of two β-subunits that form either hetero- or homodimers: activin A (βa + βa), activin BA (βa + βb), and activin B (βb + βb). Activins A and B increase FSHβ and reduce LHβ mRNA levels in cultured pituitary cells. Furthermore, follistatin, an activin-binding protein, can reverse the effects of exogenous activin on FSHβ and LHβ expression, and also stimulate basal expression of FSHβ gene. In goldfish (*Carassius auratus*), Smad3 is likely the principal signal transducing molecule involved in activin stimulation of FSHβ expression. While activin was first identified as an FSH stimulator and its effect on FSH biosynthesis has been well studied in a variety of fish, the details of its action mechanism are poorly understood.

Gonadotropin Receptors

In line with the gonadotropic duality, two distinct receptors occur in fish gonads: the FSH-R and the LH-R. Both show different expression profiles during follicular development. Expression of FSH-R is associated predominantly with vitellogenesis, while the LH-R is prevalent during oocyte maturation and ovulation.

Studies on gonadotropin receptors selectivity in representatives of three teleost orders (salmoniformes, siluriformes, and cypriniformes) indicated that FSH-Rs not only show a preference for FSH but also respond to LH, whereas LH-Rs specifically respond to LH only. Amago salmon (*Oncorhynchus rhodurus*) is the only known exception to this scheme.

The FSH-Rs and LH-Rs are G-protein-coupled receptors (GPCRs) whose large extracellular domain contributes to the recognition and specific binding of the hormone. The transmembrane domain is the most conserved part of these receptors, both in structure and amino acid sequence. It has seven α-helices composed of 22–28 hydrophobic amino acids, with each crossing the lipid bilayer and being connected by three intracellular and three extracellular loops. The transmembrane domain is responsible for receptor activation and signal transduction of the hormone.

Generally, the cellular localization of the gonadotropin receptors agrees with their steroidogenic biopotencies in mature fish. *In situ* hybridization studies in African catfish revealed FSH-R expression in Sertoli cells, but in contrast to other vertebrates, FSH-R is expressed in the interstitial Leydig cells too, together with LH-R. In European sea bass, FSH-R transcripts are detected in the follicular cells surrounding the pre- and early vitellogenic oocytes but not on fully grown oocytes, indicating the involvement of FSH-R in the recruitment of new oocyte generation and initiation of vitellogenesis.

FSH-R was localized in the theca layer and intensely on granulosa cells of vitellogenic ovaries of coho salmon (*Oncorhynchus kisutch*), whereas in the preovulatory follicle, it occurred in the theca and interstitial connective tissue, but not in the granulosa. At all stages of oogenesis, only granulosa cells of the preovulatory follicle exhibited LH-R, which is in line with LH function in oocyte maturation.

The expression of LH-R in males is consistently correlated with spermiation and spawning in all fish species studied so far.

Unorthodox Sites for Kiss, GnRH, and Gonadotropins

Recently, evidence is accumulating that the gonads produce and release hormones, and contain receptors that originally were thought to be restricted to the hypothalamus and pituitary. Oocytes of the gilthead sea bream produce and release GtHs, processes that can be enhanced by GnRH and reduced by an GnRH antagonist. In the African catfish, GnRH-1 and GnRH-2 mRNAs are expressed in the testis, and GnRH-2 mRNA in the ovary. In addition, kiss1 and kiss1r occur in the ovary and testes of various fish. These local regulatory axes could finely tune the activity of hypothalamic–pituitary–gonadal axis. Nevertheless, further research is still required before an updated comprehensive model for this endocrine regulation of fish reproduction can be formulated.

Glossary

Anorexigenic	Inhibiting appetite.
Gene expression levels	Abundance of messenger RNA (mRNA: an RNA produced by transcription that carries the code for a particular protein from the nuclear DNA to a ribosome in the cytoplasm and acts as a template for the formation of that protein) within a specific cell or tissue.
Hypothalamus	Region at the floor of the forebrain (diencephalon) that controls several vegetative physiological processes, including food intake and secretion of hormones from the pituitary gland.
Intracerebroventricular	Situated within or administered into ventricles (cavities in the brain that are continuous with the spinal cord, and that contain fluid) of the brain.
Intraperitoneal	Situated within or administered by entering the peritoneum (abdominal cavity).
Neurohormone	Hormone produced by the brain that influences neural activity or functioning.
Orexigenic	That stimulates feeding.
Pituitary gland	Small endocrine gland located at the base of the brain and attached to the hypothalamus of the brain, which is also called hypophysis.
Poikilotherm	An animal whose body temperature fluctuates with that of the environment. The opposite of homeotherm, an organism, such as a mammal or bird, capable of maintaining its body temperature within a narrow range, usually above that of its surroundings despite large variations in environmental temperature.
Satiety	The quality or state of being fed to or beyond capacity.
Vagus nerve	Cranial nerve that travels from the brainstem through organs in the neck, thorax, and abdomen. In the abdomen, branches of the vagal nerve enter the stomach, pancreas, and the intestine.

How Is Appetite Regulated in Vertebrates?

In all vertebrates, survival depends on a balance between energy intake and energy expenditure. Energy intake is dependent on food intake, whereas energy expenditure is related to metabolic rate and physical activity. The brain, in particular the hypothalamus, plays a key role in monitoring energy status. Destruction of some hypothalamic areas is associated with increased food consumption and obesity, whereas destruction of other hypothalamic areas results in anorexia and weight loss. Such ablation experiments clearly demonstrate that the hypothalamus plays a role in the regulation of feeding and energy balance. These specific areas of the hypothalamus are often referred to as feeding centers.

The hypothalamus ultimately controls energy intake and expenditure by receiving and integrating sensory signals from the brain, the peripheral circulation, and the gastrointestinal (GI) tract via the vagus nerve (**Figure 1**). Although differences exist, fish brains follow the same basic plan as in other vertebrates (**see also Brain and Nervous System**: Functional Morphology of the Brains of Agnathans, Functional Morphology of the Brains of Sarcopterygian Fishes: Lungfishes and Latimeria, Functional Morphology of the Brains of Ray-Finned Fishes, Functional Morphology of the Brains of Cartilaginous Fishes, and Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern). Fish brains can be roughly subdivided into (1) hindbrain, which contains the brainstem and receives inputs from the vagus nerve; (2) midbrain, which contains the

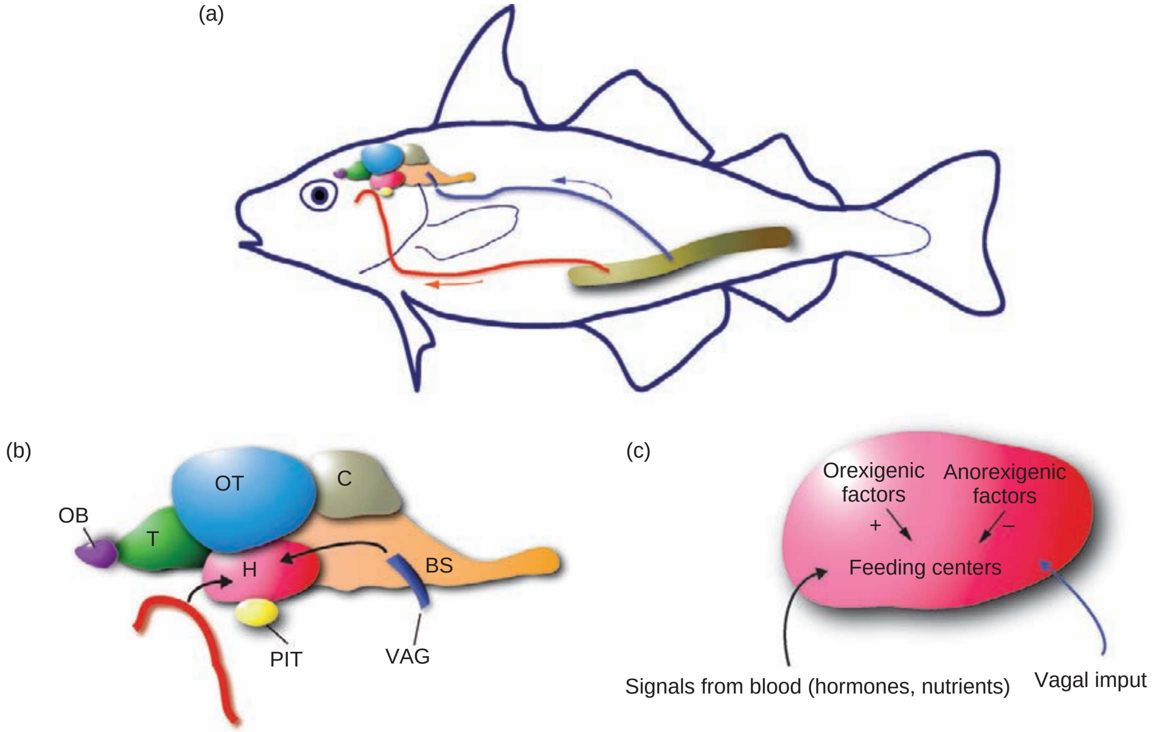

Figure 1 (a) Appetite is controlled by the brain, which integrates information on nutritional status relayed by the blood or by the vagus nerve. (b) Fish brains can be subdivided into hindbrain (which contains the brainstem (BS) and receives inputs from the vagus nerve (VAG)), the midbrain (which contains the cerebellum (C), optic tectum (OT), and hypothalamus (H)), and the forebrain, which is composed of the telencephalon (T) and olfactory bulbs (OB). A pituitary gland (PIT, small endocrine gland) is located at the base of the brain and attached to the hypothalamus. (c) The hypothalamus contains feeding centers that are influenced by hypothalamic orexigenic and anorexigenic factors. These centers are also influenced by neural projections from the vagus nerve as well as by blood-borne nutrients and hormones.

cerebellum, optic tectum, and hypothalamus; and (3) forebrain, which is composed of the telencephalon and olfactory bulbs (**Figure 1**(**b**)).

Signals from the brain consist largely of neurohormones secreted by the hypothalamus. When energy intake exceeds expenditure, anorexigenic (appetite-inhibiting) neurohormones are secreted, whereas when energy expenditure exceeds intake, orexigenic (appetite-stimulating) neurohormones are secreted (**Figure 1**(**c**)). Signals from the peripheral circulation consist of factors released in the blood stream that enter the hypothalamus and bind to hypothalamic receptors, thus acting directly on hypothalamic feeding centers. These factors consist of either nutrients, such as amino acids and glucose, or hormones released by the GI tract during a meal.

Nervous signals arrive to the hypothalamus via innervation from the brainstem, which is a relay center for visceral sensory information carried by the vagus nerve originating from the GI tract. This information consists of both mechanical and hormonal signals (**see also Integrated Function and Control of the Gut**: Endocrine Systems of the Gut, **Gut Anatomy and Morphology**: Gut Anatomy, and **The Gut**: The Gastrointestinal Tract: An Introduction). When the GI tract wall is distended by the presence of food, it activates stretch receptors, which transmit that information to the brain via the vagus nerve. The presence of food also triggers the release of a number of gut hormones, which can either be released in the blood stream (as described above) or bind to receptors on the vagus nerve.

Appetite regulation might be divided into short-term regulation, which pertains to the size and duration of a meal, and long-term regulation, which pertains to weight regulation. Most short-term regulators are hormones released from the GI tract during or after a meal. These so-called satiety factors indicate fullness (or satiety) and terminate a meal. They include cholecystokinin (CCK) and gastrin-releasing peptide (GRP). Long-term regulators, such as leptin and insulin, have levels that vary with adiposity and relay information about long-term energy stores.

Fish as a Model to Study the Mechanisms Regulating Appetite

Besides the same basic brain organization, fish have the same basic mechanisms controlling feeding behavior as other vertebrates, making them a valuable model to study the mechanisms regulating appetite in vertebrates in general.

However, fish also present unique characteristics. Perhaps more than any other vertebrate group, they display a great diversity in feeding habits and consume a large variety of foods (**see also Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics). Depending on the species considered, fish might eat plants (herbivores such as grass carp, *Ctenopharyngodon idella* or tilapia, *Oreochromis niloticus*), fish and large invertebrates (carnivores such as cichlids, trouts, flatfish, or sharks), or both plants and animals and occasional detritus (omnivores, such as common carp, *Cyprinus carpio* and goldfish, *Carassius auratus*). Different feeding habits can be found within one family of fish, as among cyprinidae (carps and goldfish) or bleniidae (blennies). These different feeding habits often translate into morphological (in particular, in the structure of the GI tract and the brain) and behavioral specializations for a particular type of food. For example, carnivorous predators usually have a shorter intestine than herbivores and might have higher development of areas of the brain needed for finding preys. However, a characteristic and originality of these animals are that many fish switch their feeding habits throughout life and most fish can adapt their diet to the available food supply. Feeding habits in fish can thus change with locality, age, sex, and season.

Overall food demand is a direct function of metabolic rate. Fish are poikilothermic (cold-blooded) animals, whose body temperature reflects the ambient temperature. As such, they do not expend energy to maintain a constant body temperature, and usually have lesser metabolic rates and needs – thus less feeding requirements – than homeotherms (warm-blooded animals such as mammals). However, as opposed to most mammals, which have a finite growth, most fish have an indeterminate growth, which means they continue to grow throughout their lives. Fish thus feed not only to maintain their basal metabolism but also to build energy stores to sustain both adequate growth and reproduction throughout their lives. The strategies for energy storage vary among species. For example, carp and salmon store excess energy as lipids in the muscle and as visceral fat, while Atlantic cod and sharks store excess energy in the liver.

Fish also experience a number of environmental changes, and often undergo daily and seasonal cycles in appetite that are entrained by the environment (see the next section).

Studying Appetite in Fish: Methods and Approaches

Several methods and approaches can be used to assess appetite in fish. In wild animals, the choice of techniques is rather limited and food intake is usually estimated by examining stomach or gut contents. In contrast, in laboratory conditions, food intake may be assessed accurately by quantifying the amount of food eaten by individual fish. This can de done directly by visually observing the fish and counting the number of pellets eaten by each individual. Appetite can also be measured by weighting the fish before and after feeding, by measuring the radioactivity of fish fed pellets or prey labeled with radioactive material, or by using X-ray to count pellets in stomachs of fish fed food labeled with opaque beads.

Very often, however, the assessment of appetite for individual captive fish is very difficult or impossible. For example, social and schooling species can become stressed as individuals or in small groups, or conversely in high-intensity aquaculture conditions. For groups of fish, feeding of individual fish can be inferred simply by dividing the amount of food eaten by a group of fish by the number of fish and the average weight of fish. To obtain more accurate quantifications of food intake, ingenious devices have been developed by some researchers. One might either continuously collect and detect uneaten food pellets by underwater infrared sensors, or use acoustic methods to detect sounds emitted by fish during feeding. Some fish species (e.g., rainbow trout, *Oncorhynchus mykiss* and sea bream, *Sparus aurata*) can also be trained to eat on demand using self-feeders. These devices consist of detectors that deliver food when activated by a fish, and allow for the assessment of appetite by counting the number of feed demands.

In order to assess the role of specific appetite-regulating hormones, several methods can be used. A direct method consists of submitting fish to hormone treatments. The hormone can be delivered via several routes, including peripheral (intraperitoneal (IP), or in the body cavity) or brain injections (intracerebroventricular (ICV), or in the brain ventricle system), intraperitoneally implanted pellets or osmotic mini-pumps – which deliver the hormone continuously for several days or weeks – and via oral administration. Food intake is then assessed during and/or following treatment and compared to that of control saline-injected fish to detect a possible orexigenic or anorexigenic effect of the hormone (see **Video Clip 1**).

In vivo injections and feeding behavior observations are not always feasible, as some fish species cannot withstand the stress of the procedure or are too large for injections. In these situations, the role of hormones can be assessed indirectly by examining the effects of feeding conditions (e.g., starvation or lipid-rich diet) on blood or protein/gene expression levels. The assumption is that if, for a given hormone, these levels vary between fish feeding different diets (or not feeding), then the hormone most likely has some role in appetite regulation.

The advent of new technologies such as transgenic animals (that carry a foreign gene, which has been deliberately inserted into their genome) or knockdowns (in which expression of a gene is inactivated) might provide promising new data on the genes involved in the regulation of appetite in fish.

Hormones and Appetite in Fish

A number of hormones have been identified as appetite regulators in fish. **Table 1** summarizes those hormones known to regulate appetite in fish to date. A few major hormones known to regulate appetite are described below.

Hormones from the Brain and Pituitary

Neuropeptide Y (NPY), orexins (orexin A and B), and galanin are three of the major brain hormones that stimulate appetite in fish. As in mammals, orexins appear to increase alertness and locomotor activity in fish. It has been suggested that orexins, rather than stimulating feeding, might promote arousal responses that would allow food seeking/foraging behavior. Corticotropin-releasing factor (CRF) (and a related hormone called urotensin) and the cocaine- and amphetamine-regulated transcript (CART) peptide are the two major hypothalamic appetite inhibitors. In fish, as in all vertebrates, CRF also has an important role in the stress response. All these hormones, although produced mostly by the brain, are similarly produced but in lesser amounts by peripheral tissues such as the gut and the gonads.

Growth hormone (GH) is a hormone secreted by the pituitary gland that stimulates growth. GH appears to be involved in the regulation of feeding in fish as both fish treated with GH and GH transgenic fish (in which the GH gene has been added) display high feeding levels.

Peripheral Hormones

Most of the peripheral appetite-regulating hormones both act as a satiety factor and have aid in digestive processes. Most of these gut peripheral hormones are also produced in lesser amounts by the brain and are therefore often referred to as brain–gut hormones.

In fish, as in mammals, CCK is a major satiety factor produced by the intestine. During a meal, CCK is released from the small intestine into the circulation and stimulates digestion (by decreasing gastric emptying as well as stimulating gallbladder contraction and secretions from the pancreatic and gastric) while suppressing food intake. The actions of CCK are mediated by binding to both hypothalamic receptors and receptors on the vagus nerve.

Table 1 Major hormones known to regulate appetite in fish

Hormone	*Origin (P: peripheral C: central)*	*Major producing site*	*Effect on feeding (+: stimulation, –: inhibition)*
Amylin	P	Brain/GI tract	+
Apelin	P	GI tract/brain	–
Calcitonin gene-related peptide (CGRP)	C	Brain	–
Cholecystokinin (CCK)	P	GI tract	–
Cocaine- and amphetamine-regulated transcript (CART)	C	Brain	–
Corticotropin-releasing factor (CRF)	C	Brain	–
Cortisol	P	Interrenal	–
Galanin (GAL)	C	Brain	+
Gastrin-releasing peptide (GRP)	P	GI tract	–
Ghrelin	P	GI tract	+
Glucagon-like peptide -1 (GLP-1)	P	GI tract	–
Gonadotropin-releasing hormone (GnRH)	C	Brain	–
Growth hormone (GH)	C	Pituitary	+
Insulin	P	Pancreas	–
Intermedin (IM)	C	Brain/pituitary	–
Leptin	P	Liver	–
Melanin-concentrating hormone (MCH)	C	Brain	–
Melatonin	C	Pineal	–
Neuromedin U (NMU)	C	Brain	–
Neuropeptide Y (NPY)	C	Brain	+
Orexins (OX)	C	Brain	+
Pituitary adenylate cyclase-activating polypeptide (PACAP)	C	Brain	–
Prolactin-releasing peptide (PrRP)	C	Brain	–
Urotensin I (UI)	C	Brain	–

Like CCK, GRP is produced by the GI tract and acts as a satiety factor. GRP also regulates gastric functions such as acid secretion and gastric motility.

Amylin is produced by the pancreas. It suppresses nutrient-stimulated glucagon secretion, slows down gastric emptying, and reduces food intake and body weight.

First discovered in mammals, leptin is produced by adipose tissue (fat) and it regulates food intake, energy balance, and reproduction. Although mammalian leptin was first isolated in 1994, the structures of leptin and its receptor in fish were only established recently. Very few similarities are seen between the leptin protein structures of fish and those of mammals. In addition, in contrast to mammals, the liver appears to be the major site for leptin expression in fish, unlike adipose tissue in mammals. Fish leptin is also produced by brain, GI tract, muscle, and fat. To date, the role of leptin in fish appears to be controversial. Leptin appears to have a role in regulation of feeding and metabolism in fish. While treatment with mammalian leptin does not affect appetite in some fish species (coho salmon, *Oncorhynchus kisutch* or channel catfish, *Ictalurus punctatus*), it does decrease food intake in goldfish. Peripheral injections of trout leptin in rainbow trout suppress food intake.

To date, only two peripheral hormones have been shown to increase appetite, ghrelin and apelin, in vertebrates. In fish, as in mammals, ghrelin is predominantly secreted by the stomach (and also by the brain) and stimulates GH release. In mammals, ghrelin stimulates appetite, but its role in the regulation of feeding of fish is still unclear. Indeed, injections of ghrelin stimulate appetite in some fish species but do not in others. Apelin is produced by several tissues, including brain and adipose tissues. Both peripheral and brain injections of apelin increase feeding in goldfish. Apelin also regulates cardiovascular functions in both mammals and fish.

Influence of Feeding Status and Circulating Metabolite Levels on Appetite

As a general rule, states of hunger or nutrient deficiency induce an increase in gene expression and plasma levels of orexigenic hormones, while a well-fed satiated state increases levels of anorexigenic hormones. In fish, the brain expression levels of NPY, orexins, and galanin all increase in hungry fish, both immediately before a meal and during periods of food deprivation. Similarly, fasted fish display higher ghrelin plasma levels, higher stomach and brain gene expression levels of ghrelin, and higher apelin brain gene expression levels than fed fish. Conversely, CART and CCK gene expression levels increase following a meal and decrease following fasting. Fasting apparently induces a decrease in liver and plasma leptin levels in some fish species. Starvation also induces changes in both pituitary GH gene expression and plasma GH levels.

Administration of glucose or amino acids decreases appetite and fat fish appear to eat less than lean fish, suggesting that circulating metabolite levels alter food intake in fish.

Influence of Gender, Reproductive Status, and Genetics on Appetite

Individual differences exist for foraging behavior and growth that are related to gender, sexual maturity, and genetic background. In some fish species, gender-specific differences in the presence and distribution of appetite regulators exist (e.g., galanin and ghrelin). Appetite also varies according to the reproductive state. Appetite is suppressed in some species during the reproductive season. This is especially the case during spawning migrations (e.g., salmonids), courtship, spawning, or nest guarding. Males and females have different profiles of reproductive hormones, in particular gonadal sex steroids (androgens and estrogens), and during a fish reproductive cycle, major changes in the levels of these hormones occur. It has thus been hypothesized that gonadal steroids might influence appetite and the expression levels of appetite regulators.

The hypothalamic hormone gonadotropin-releasing hormone (GnRH) is a major reproductive hormone in vertebrate. It stimulates the pituitary to secrete gonadotropins, which in turn acts on the gonads to stimulate production of gonadal steroids and gametes. In goldfish, brain injections with GnRH decrease appetite, in part by decreasing brain orexin gene expression. Conversely, brain injections of orexin inhibit spawning behavior, in part, by decreasing hypothalamic GnRH gene expression levels. These data suggest that the actions of reproductive hormones and appetite regulators are closely related.

Food intake has been shown to vary among fish strains of different genetic backgrounds. Different strains display variations in feeding activities and patterns, nutrient utilization, and growth, which might relate to genetic variations in appetite-regulating hormones. Recent studies also show that GH transgenesis (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Growth Hormone Overexpression in Transgenic Fish) induces modifications in feeding-related behaviors in both carp and salmon, where transgenic fish display an increase in both food consumption and in time spent foraging in the feeding areas.

Environmental Control of Appetite

In the wild, environmental factors such as temperature and photoperiod can have a dramatic effect on appetite in certain fish species. These environmental factors often act as cues that entrain a seasonal cycle in feeding and reproduction. For example, some temperate fish, such as winter flounder, *Pseudopleuronectes americanus* or Arctic charr, *Salvelinus alpinus*, display a decrease in appetite during winter, when days are short and temperatures are low. Generally, fish tend to increase their appetite and growth rates with rising temperatures. Fish species also vary in their natural daily feeding rhythms, some species being diurnal feeders (Atlantic salmon, *Salmo salar*) and others being nocturnal feeders (channel catfish). Little is known about the hormonal mechanisms regulating these environment-induced changes in feeding, but some data cue to the involvement of appetite-regulating hormones. For example, in Atlantic cod, *Gadus morhua*, brain CART gene expression levels are higher in fish held at 2 °C than in fish held at 15 °C, and in ornate wrasse, *Halichoeres ornatissimus*, fish exposed to constant light conditions display higher orexin receptor hypothalamic expression levels than fish exposed to natural photoperiod. In addition, in Atlantic cod and goldfish, the hypothalamic expression of orexin appears to show daily fluctuations in phase with feeding rhythms.

In captive fish, appetite is influenced by stocking density, in particular in species in which dominant individuals monopolize the available food (e.g., in salmonids; **see also Social and Reproductive Behaviors**: Dominance Behaviors). Tank color also influences feeding and growth. Flounders grow faster in white tanks than in the black tanks.

Most fish eat less and grow slower if stressed by their environment. These situations include drastic changes in temperature, photoperiod, salinity, or low oxygen levels (hypoxia). Excessively high temperature can suppress feeding and can cause severe environment hypoxia, both of which lead to suboptimal growth. Contaminants and disease agents also usually decrease appetite.

Glossary

Autocrine signaling Receptor-mediated transfer of information to a cell by a chemical messenger produced and released by the same cell.

Coping A behavioral response that aims at reduction of the impact of aversive stimuli on physiological homeostasis.

Endocrine signaling Receptor-mediated transfer of information to cells by a chemical messenger (hormone) produced and released by distant cells, and transported via the blood circulation.

Heat shock protein A protein that interacts with other proteins, promoting productive folding pathways to ultimately stabilize cellular proteins and membranes.

Homeostasis The equilibrium or stability of the internal environment of organisms in a changing external environment, maintained by many physiological adjustment mechanisms.

Hormone Signaling molecule released by a cell that either stimulates the cell of origin (autocrine), nearby cells (paracrine), or travels via the bloodstream to distant cells (endocrine).

Metallotheionein A small protein of a group of cysteine-rich proteins with an ability to bind heavy metals.

Neurohormone Hormone produced by the brain that influences neural activity or functioning.

Paracrine signaling Receptor-mediated transfer of information by a chemical messenger produced by a cell toward neighboring cells.

Stress State which extends the adaptive responses developed of an animal beyond of the normal range or the normal functioning as a result of a challenge that attempt to reestablish the physiological equilibrium.

Stressor Any agent generating a situation of stress and inducing a coordinated response involving a transient modification of the physiological regulation.

Urophysis The storage organ of the axon endings of a group of neuroendocrine cells at the distal end of the spinal cord of fishes, releasing the hormones urotensin I and II.

Hormones, Stress and Stressors

Teleost fishes, like many other animals, respond to changes in the external and internal environments by the release of hormones into the blood. Rhythmic changes, such as the daily light–dark cycle and minor changes in the daily routine, are met with adjustments that maintain the dynamic physiological equilibrium of an organism called homeostasis. The hormones involved are dependent on the type of change. In addition to such changes, every animal also meets unexpected and major changes that are threatening its well-being and even survival. Such changes vary from a sudden temperature drop, an encounter with a predator, or a dominant member of the social group, to pollutants such as agrichemicals.

The condition of disturbed homeostasis is defined as stress. If this happens, most vertebrates, including fishes, show a marked, more or less uniform endocrine response, largely independent of the type of stressor. This is the generalized or organismal stress response in which many organs and tissues are involved. It is an adaptive response that, if successful, leads to not only recovery, that is, restoration of homeostasis, but also increased resistance to the same or related types of stressor. The most important hormones and their functions involved in this process are described below. This is done in a generalized way, ignoring many species-specific differences that are found among teleost fishes, a very large group of animals that have colonized all possible aquatic niches.

The term stress is not restricted to the organismal level. Physical and chemical stressors can also act directly at the cellular level, disturbing the cellular physiology. The cellular stress responses, which are manifold and largely stressor specific, include stimulated or induced expression of proteins, such as heat shock proteins, metallotheioneins, and antioxidant enzymes. They occur in all cells, even bacteria, and thus have a much longer evolutionary history than the organismal stress response of the vertebrates. The cellular stress responses are independent of the organismal stress response in the vertebrates, and high levels of, for instance, heat shock proteins cannot be used as reliable indicators of stress at the organismal level.

In the organismal stress response, classically three categories are distinguished: the primary, secondary, and tertiary stress responses. These concern different levels of organization. We will follow this tradition. The primary response results in an often dramatic and therefore easily noticeable increase of the blood levels of the primary stress hormones, the catecholamines (CAs), adrenaline and noradrenaline (**see also Hormonal Responses to Stress**: Catecholamines), and the corticosteroid cortisol (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids). The secondary response comprises the physiological effects of these hormones. The tertiary response includes the physiological and behavioral changes occurring at the whole animal level, which can be restorative, adaptive, as well as pathological. Only the initiation of the primary, secondary, and tertiary responses is sequential in time because the duration of each response is such that it creates temporal overlap once the stress response is underway.

Primary Stress Response

The primary response to the perception of a stressor includes the state of alarm in the brain leading to the release of the primary stress hormones. Key brain areas in the integration of the response are the pallial areas of the telencephalon that are considered the teleost homologs of the mammalian hippocampus, and the brain stem (**see also Brain and Nervous System**: Functional Morphology of the Brains of Ray-Finned Fishes). Central brain monoamines are implicated with a prominent role for serotonin. The messages resulting in the release of CAs and cortisol leave the brain via two major routes (axes; **Figure 1**).

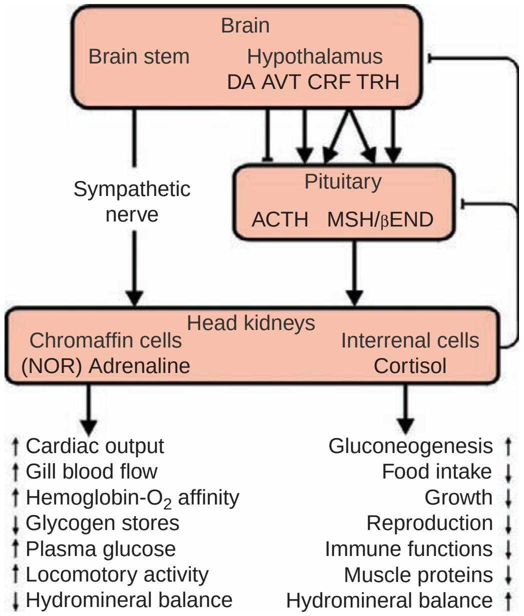

Figure 1 Diagram of the BSC and HPI axes, showing the main neurohormonal and hormonal messengers involved in the organismal stress response, and the major effects of the most important messengers of these axes, adrenaline and cortisol; arrows pointing upward: stimulation; arrows pointing downward: inhibition. AVT, arginine vasotocin; DA, dopamine; betaEND, beta-endorphin

The Brain–Sympathetic–Chromaffin Cell (BSC) Axis

The rise in the blood levels of the CAs starts a few seconds after confrontation with an acute stressor. In fish, adrenaline dominates, with plasma levels up to 10 times higher than those of adrenaline. The CAs are produced and released by the chromaffin cells, which normally are clustered in small groups within the layers of cortisol-producing interrenal cells surrounding the walls of the posterior cardinal veins and their branches (**Figure 2**). Together with the surrounding lymphoid tissue, they form the interrenal glands or head kidneys, the homologs of the mammalian adrenal glands. The chromaffin cells also release other substances, for example, dopamine, enkephalin, and natriuretic peptide, which may have functions related to the release or potentiation

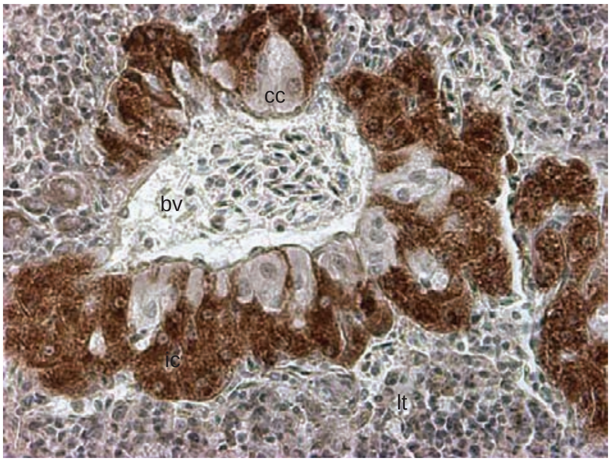

Figure 2 Light microscopic picture of head kidney tissue of carp (*Cyprinus carpio*), showing a blood vessel (bv) with erythrocytes, surrounded by a ring of interrenal cells (ic) immunocytochemically stained with an antibody raised against cortisol (brown deposits in the cytoplasm). Between these cells small numbers of nonstained chromaffin cells (cc) are present. The interrenal cells are surrounded by lymphoid tissue (lt). Courtesy Dr. Gert Flik.

of the CAs. Basal plasma levels of adrenaline are, in general, below 5 nmol. Peak values more than 50 times higher have been reported after acute strong stressors (**Figure 3**). The CA levels rapidly drop after peak levels have been reached, as a result of lowering of the release and a high turnover rate (< 10 min). When the increased CA release continues during chronic stress, the blood levels usually stabilize well below 50 nmol. The CA release is mainly controlled via preganglionic cholinergic fibers of sympathetic nerves terminating around the chromaffin cells. Autocrine and paracrine factors as well as hormones including cortisol may play a modulating role in CA release (**see also Hormonal Responses to Stress**: Catecholamines).

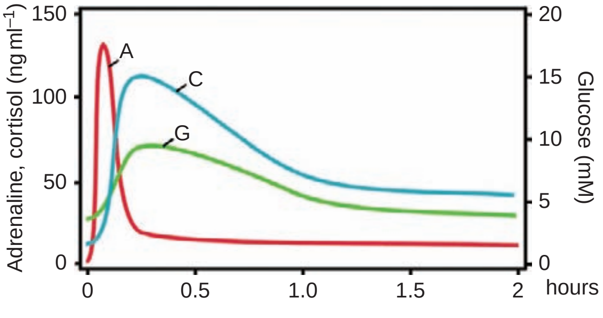

Figure 3 Generalized time course of the blood plasma levels of adrenaline (A), cortisol (C), and glucose (G) following confrontation with an acute stressor (based on observations on carp, *Cyprinus carpio*).

The Hypothalamic–Pituitary–Interrenal Axis

Cortisol is the final messenger of the hypothalamic–pituitary–interrenal (HPI) axis (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids). A key messenger between the brain and the endocrine system during the stress response is corticotropin-releasing factor (CRF), produced by neurons of the preoptic nuclei in the hypothalamus. These CRF neurons project to the pituitary gland and stimulate the release of the adrenocorticotropin hormone (ACTH) from cells in the distal part of the pituitary gland. Arginine vasotocin is also produced in the CRF cells and potentiates the CRF stimulation of the ACTH cells. ACTH is the major stimulant during stress of the interrenal cells for the synthesis and release of cortisol. The tissues producing these messengers are called the HPI axis. CRF is further produced in other areas of the brain, for instance, in the telencephalon and the tectum opticum, where it acts as a neurotransmitter involved in many functions (**see also Brain and Nervous System**: Functional Morphology of the Brains of Agnathans, Functional Morphology of the Brains of Sarcopterygian Fishes: Lungfishes and Latimeria, Functional Morphology of the Brains of Ray-Finned Fishes, and Functional Morphology of the Brains of Cartilaginous Fishes). It is also released into the circulation where it has effects on many organs including the heart (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels and **Design and Physiology of the Heart**: Physiology of Cardiac Pumping) and the immune system. This endocrine function is the reason that CRF is also called the corticotropin-releasing hormone (CRH). The precise roles of CRF in the body have to be defined. CRF signaling is mediated through at least two types of CRF receptors, R1 and R2, with several subtypes. CRFR1 is the principal receptor for the HPI axis. CRFR2 signaling occurs in many organs including the brain. Thyroid-releasing hormone, another hypothalamic neurohormone, has ACTH-stimulating properties in fishes. Apart from ACTH, cortisol is also stimulated by hormones such as urotensin I released by the urophysis and atrial natriuretic peptide.

Following an acute stressor, cortisol release starts after about 5 min (**Figure 3**). This lag time contrasts with the immediate release following the stimulation of the CA-producing cells. The lag time in cortisol release, the rather slow building up of the peak level (up to 1 h), the low turnover rate (cortisol is converted to cortisone; half life is about 1 h), and the rather simple assay procedures make cortisol blood levels the most frequently used stress parameter in fishes. Cortisol values vary from basal levels between 5 and 30 nmol to peak levels of more than 400 nmol during severe acute stress. During chronic stress, cortisol levels usually stabilize at 2–5 times the basal concentration. Up to 80% of the hormone in circulation is protein bound and therefore biologically inert, although a protein specific for cortisol binding in fish plasma is still debatable.

Other Pituitary Hormones Activated during the Primary Response

In addition to the ACTH release, the release of several other pituitary hormones is stimulated by hypothalamic messengers during the primary stress response. In fishes, CRF also stimulates the release of thyroid-stimulating hormone (TSH), leading to elevated thyroid hormone levels during stress. CRF further activates the cells producing alpha-melanophore-stimulating hormone (alpha-MSH) and beta-endorphin. In some, but not all, species investigated, alpha-MSH and beta-endorphin stimulate cortisol release. The sensitivity of the ACTH and MSH cells is modulated by dopamine (ACTH) and endorphin (MSH) from hypothalamic origin. An intriguing hormone released within a few minutes following stressor exposure is somatolactin. It belongs to the growth hormone/prolactin family and has been identified so far only in the pituitary pars intermedia of fishes. The function of somatolactin has been related to, for example, skin pigmentation, acid–base and calcium regulation, and lipid metabolism, but further studies are required to clearly define its role in the stress response.

Secondary Stress Response

Actions of adrenaline and cortisol

The most important physiological actions of CAs and cortisol are summarized in **Figure 1**. The main function of adrenaline is the rapid mobilization of energy to facilitate immediate action of the animal (fight or flight). Adrenaline further stimulates the breakdown of glycogen (glycogenolysis) in the liver, leading to a rapid rise of blood glucose. Furthermore, free fatty acid levels may become elevated. Given the prompt CA release following stressor perception, it is hardly possible to separate the effect of the stressor on plasma CA levels from the stress effects of capture and blood sampling on this parameter. Therefore, the rise in plasma glucose, which develops relatively slowly after stressor detection, is frequently used as an alternative parameter for the effect of a stressor on CA release. Glucose is the primary energy substrate for fish and is, in particular, needed by the brain and the muscles during stress. High-adrenaline levels further increase stroke volume and/or rate of the heart and promote blood flow, in particular, into the brain, muscles, and gills. Furthermore, adrenergic sympathetic innervation of the vascular system is involved. The increased perfusion of the gills stimulates the gas exchange and, together with a higher affinity of hemoglobin for O_2, induced by noradrenaline, facilitates the oxygenation of the tissues, in particular, brain and muscles.

In the first phase of the acute stress response, the actions of cortisol are less prominent than those of adrenaline. The most important functions of cortisol concern the reallocation of energy away from long-term investments in growth and offspring toward activities directed at immediate survival. A second important function concerns the repair of the hydromineral disturbance that accompanies stress in fishes (**see** section Tertiary Response). Thus, in fishes, cortisol functions both as glucocorticoid (GR) as well as mineralocorticoid (MR) hormone. In terrestrial vertebrates, the control of these functions is separated, with corticosterone or cortisol (depending on the species) as the GR, and aldosterone as the MR hormone. This functional separation at the hormone level apparently took place after the water-to-land transition of the vertebrates, around 380 million years ago. Other actions of cortisol are negative feedback control at all levels of the HPI axis. This does not imply that cortisol inhibits its own secretion under all conditions, for instance, during acute stress. In general, negative feedback processes are precisely regulated. For cortisol, the functional details are far from clear.

Receptors Involved in Cortisol Activity

Terrestrial vertebrates have GR and MR receptors for the GRs and aldosterone, respectively (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids and **The Pituitary**: Development of the Hypothalamus-Pituitary-Interrenal Axis). In fishes, receptors with similar structure have been found. Two GR types have been reported, GR1 and GR2. Only one MR has been found so far. Furthermore, splicing isoforms have been described for GR and MR. GR1 have a much lower affinity for cortisol than GR2, indicating that GR1s are functioning at stress levels of cortisol. Expression of the mRNAs of the GRs and MR has been reported for many organs and tissues, including the telencephalon (in pallial areas homologous to the mammalian hippocampus), the CRF neurons in the pre-optic nucleus, and the ACTH cells in the pituitary. Thus, the three cortisol receptor types are all present in the three most important neural and endocrine areas related to the stress response. Their numbers can be manipulated by chronic stressor exposure.

Tertiary Response

If an animal can cope efficiently with a stressor through adaptation, or if the stressor is of short duration, homeostasis can be restored without serious consequences for the animal. The effects can be limited to improved performance in the future, such as increased predator avoidance capacity or disease resistance. In such cases, a tertiary response can hardly be observed. If the stressor has a chronic nature, and the adaptation to the stressor is laborious or even absent, the tertiary stress response is long-lasting and disabling. This was called distress by the pioneer of the field, Hans Selye, and distinguished from eustress, the stress that can be mastered successfully. In humans, eustress is challenging, rather than depressing. It makes humans and animals more resistant to the same or similar type of stressor, and this is the biological, adaptive function of the stress response.

During the tertiary response, the adrenaline and cortisol concentrations of the blood can vary from slightly to well above basal levels, much lower than the peak levels during acute stress. The chronically elevated adrenaline levels lead to depletion of the glycogen stores of liver and muscles, and to cardiovascular problems.

During chronic stress, the effects of cortisol are much more prominent than in the acute phase of the secondary response. The most important actions relate to energy balance, in particular, the replenishment of energy stores. This is performed by the diversion of energy substrates away from anabolic processes, in particular, growth and reproduction, and by the partial inhibition of the immune response. Whereas these actions occur in all vertebrates, one important action of cortisol is typical for fishes and concerns the hydromineral balance. All these actions of cortisol, which will be discussed briefly below, already start during the secondary stress response, but their effects become fully visible during the tertiary response.

Cortisol, Appetite, and Growth

Growth is inhibited rapidly during stress, via inhibition by cortisol of the pituitary growth hormone cells and the insulin-like growth factors (IGFs) produced by the liver. Food intake and food conversion efficiency are reduced. In trout, hypothalamic CRF mRNA levels are negatively correlated with food intake, as are the urotensin-1 mRNA levels in the urophysis. Leptin, the mediator produced by the liver that reduces appetite, may be involved. Growth can become negative by the catabolic activity of chronically high cortisol levels, which promote gluconeogenesis at the detriment of muscular proteins. This can lead to reduced scope for activity, emaciation, gastric and intestinal atrophy, and, finally, death (**see also Hormonal Responses to Stress**: Stress Effect on Growth and Metabolism).

Cortisol and Reproduction

Stress, in particular when it is chronic, leads to inhibition of the reproductive hormones at all levels of the hypothalamo-pituitary-gonadal axis. In juvenile fishes, the onset of puberty is delayed. In sexually mature fishes, reproduction is decreased, or suppressed completely, as a result of delay or failure of egg development and ovulation, of suppressed spermatogenesis, and of disruption of courtship behavior. Reproductive success can be further affected by deleterious effects transmitted by elevated maternal cortisol levels on the survival changes of the offspring (see below). Inhibitory effects of cortisol have been demonstrated at all levels of the reproductive axis (although not studied in all species): the gonadotropin-releasing hormone (GnRH) producing neurons in the hypothalamus, the pituitary cells producing the gonadotropins I and II, and the gonadal cells producing the sex steroids (**see also Hormonal Responses to Stress**: Impact of Stress in Health and Reproduction).

Cortisol and Hydromineral Regulation

In fish, stressors have profound disturbing effects on hydromineral regulation, with substantial metabolic costs for its restoration. This is an important difference between fish and terrestrial vertebrates, connected with the aquatic lifestyle of fishes. Stressors affect hydromineral balance directly as well as indirectly (**see also Hormonal Control of Metabolism and Ionic Regulation**: The Hormonal Control of Osmoregulation in Teleost Fish). Toxic stressors can act directly by damaging the osmoregulatory organs. In particular, toxic metal ions in the water can inhibit active ion transport mechanisms, for instance, NaKATPase, the biochemical equivalent of the sodium pump, and high-affinity CaATPase, the calcium pump, or can block ion channels. The gills (the main organs for ion exchange with the water), the gut (the location of water uptake in seawater fishes), and the kidneys are the main targets.

All stressors affect hydromineral regulation indirectly, via the adrenaline. The high-adrenaline levels, typical for stressed fish, do not only increase blood pressure, but also increase the permeability to water and ions of the respiratory surface, represented by the membranes lining the branchial lamellae. The blood spaces of the lamellae are separated from the water by thin endothelial and epidermal layers. This facilitates oxygen uptake and removal of carbon dioxide, but these delicate structures also make the gills a weak spot in the body surface. High-adrenaline levels increase the passive water and ion fluxes across the gill membranes, inducing hemodilution by increased ion losses and water inflow in freshwater fish, and, in marine fish, hemoconcentration by ion inflow and water outflow.

The mineralocorticoid functions of cortisol are focused on the stimulation of NaKATPase activity in gills, gut, and kidneys. The proliferation and differentiation of the branchial ionocytes (also called chloride cells, showing high NaKATPase activity) during stress are mediated by cortisol (**Figure 4**). Although originally

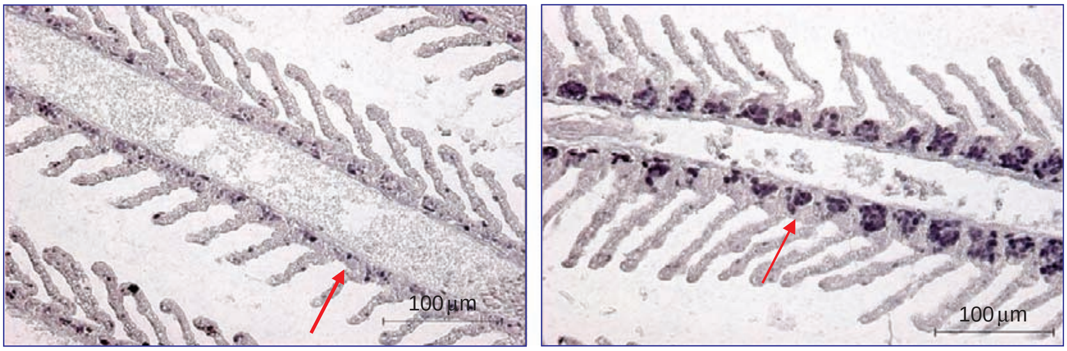

Figure 4 Gill filaments of Atlantic salmon (*Salmo salar*) immunologically stained with a monoclonal antibody raised against proliferating cell nuclear antigen (PCNA or cyclin), a molecule expressed in the nuclei of proliferating cells. Stained nuclei (arrows) are scarce in gills of control fish (left) and numerous in the gills of fish stressed by infestation with salmon lice (*Lepeophtheirus salmonis*; about 15 per fish). Almost all nuclei belong to cells differentiating into ionocytes (ion-transporting cells).

cortisol was considered to be primarily a hormone for hydromineral regulation in seawater, it is now generally accepted as equally important for marine and freshwater fishes, and for facilitating the hydromineral adaptations during migrations between freshwater and seawater (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction).

The disturbing effects of stressors on passive water and ion movements in fish also stimulate the release of other hormones with hydromineral actions. In seawater fish, growth hormone promotes NaKATPase activity in the gills and gut. In freshwater fish, prolactin is the major hormone controlling the permeability to water and ions of several epithelia, including the branchial membranes. This function explains the stimulation of prolactin release that has often been reported in stressed freshwater fish. Both the osmotic uptake of water in freshwater fish and the osmotic loss of water in marine fish require compensatory actions by the kidneys, resulting in a urine flow that is high in freshwater and low in seawater. This means that the hormones controlling renal activity (e.g., natriuretic peptides), the neuropeptides vasotocin and isotocin, and the renin-angiotensin system are also indirectly implicated in the stress response. This also applies to stanniocalcin and calcitonin, hormones controlling the branchial calcium uptake, plasma calcium levels, and bone formation, and urotensin II, a hormone produced in the urophysis that has vasoconstrictor properties and stimulates the intestinal ion uptake in seawater (see also **Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels).

Factors Modifying the Stress Response

Although the organismal stress response is essentially a uniform response to all kinds of stressors, within and between populations of animals, a great variety can be observed in the intensity and character of the responses to the same stressors. This variety is the result of the impact of several modifying factors acting at the individual or population level. Important factors are life stage, past experiences and acquired adaptations, genetic differences, maternal influences, and disturbance of the stress system by pollutants. Here, the focus is on the last three factors, since they have a direct relation with the stress hormones.

Innate Individual Variation: Proactive and Reactive Stress Coping Styles

Individuals within a population of animals show a great variety in the intensity and character of several behavioral and physiological aspects of the stress response. In many mammals, and in some bird and teleost species, a very similar bimodal distribution of this variety has been demonstrated, with individuals showing either a distinct proactive (bold) or reactive (shy) style, and others with a mix of intermediate behavior (**see also Social and Reproductive Behaviors**: Dominance Behaviors). Proactive animals show a shorter response interval to stressors, a higher locomotory activity and more aggression, and are more active in facing or avoiding stressors than reactive animals, which play a more waiting game. These individual differences in the style of coping with a stressor are normally consistent over lifetime, and connected with differences in brain activity and hormonal responses. Proactive animals show a relatively high-brain serotonin turnover and a high-BSC and modest HPI activity, resulting in high-CA and low-cortisol release during stress. Reactive animals show the reverse: lower brain serotonin turnover, lower BSC activity, and CA release, and a higher HPI-axis activation with a firm cortisol response (**Figure 5**). In animals living in a social group, proactivity is usually linked to both dominant behavior and

	Proactive (bold)	Reactive (shy)
Brain serotonin turnover	High	Low
Plasma adrenaline levels	High	Low
Cardiac output	High	Low
Reactivity	High	Low
Aggression level	High	Low
Locomotory activity	High	Low
Risk	Taking	Avoiding

Figure 5 Characteristics of the two coping strategies in fishes. Relative differences between pro-active and reactive individuals in physiological and behavioral responses to an inescapable stressor.

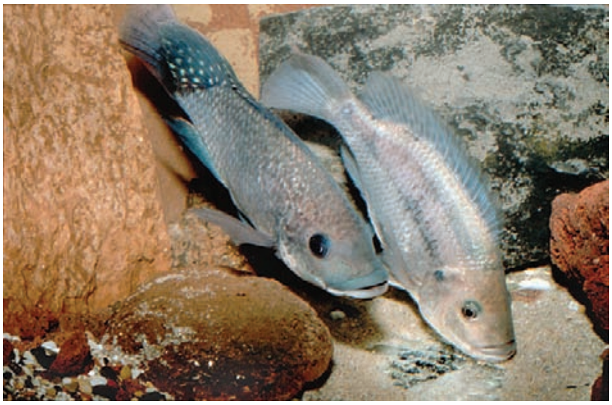

Figure 6 Two male tilapia (*Oreochromis mossambicus*). In confrontations the right fish, with the dark skin color and broad lips typical for dominant males (which have a higher testosterone level), showed a proactive, and the left fish, with the skin colour of lower ranks (and a lower testosterone level), showed a reactive type of behavior.

a high place in social hierarchy. In males, this is correlated with a high-testosterone level (**Figure 6**). A reactive coping style to stressors is typical for the lower subordinate ranks. These animals normally show less exploratory activity, have lower testosterone levels, are less aggressive, and have lower reproductive success. In mangrove killifish (*Kryptolebias marmoratus*) for instance, pre-fight cortisol levels relate negatively, and pre-fight testosterone positively, for initiating and winning a confrontation.

The coping style of a fish can be changed by cortisol administration from proactive to reactive, but it is clear that the stress-coping styles in fish have a firm genetic basis, as in mammals and birds. A selection program on trout has resulted in strains of low-cortisol responders with high-brain serotonin and CA-activity and a proactive stress-coping style, and high-cortisol responders with lower serotonin turnover and higher HPI activity and a reactive way of coping with stressors. Compared to mammals, in fishes, this type of research is still in its infancy. Nevertheless, it has become clear that these innate coping styles have an evolutionary history starting before the water-to-land transition of the vertebrates. This points to a high-survival value for both coping styles. Whereas, under some conditions, a proactive style with higher-testosterone levels may result in higher reproductive success, in other conditions, a reactive style may be advantageous. **Figure 7** shows the results of exposure of trout (*Oncorhynchus mykiss*) to water with a low-oxygen concentration. The fishes that recovered from a period of low oxygen had lower adrenaline and higher cortisol levels during hypoxia than the animals that did not recover. The swimming activity during that period was also significantly lower in the surviving fish. Moreover, the more risky behavior of proactive animals may reduce their lifetime, and this can imply that their total offspring is certainly not always higher than that of reactive animals. Research on mammals has shown that mixed populations of proactive and reactive animals are socially more stable than groups of only proactive or reactive animals.

Maternal Stress and Development of Offspring

Cortisol production probably starts already in the embryonic stage (see above). However, even unfertilized fish eggs contain cortisol, since this is transmitted from the mother to the yolk in the eggs of the developing gonads. When the mother shows elevated circulating cortisol levels, the eggs will also receive their share. If the mother is chronically and severely stressed, this will lead to absorption of the eggs and involution of the gonads. If the stress is not sufficiently high for the suppression of spawning, the eggs will receive elevated cortisol levels. Since elevated GRs can interfere with early development in many vertebrates, stress in the mother can affect the quality of the eggs and embryos, thereby reducing the chances of survival for the offspring, and lower the threshold of the stress response. Evidence from fishes, although limited, shows that developing eggs of stressed mothers,

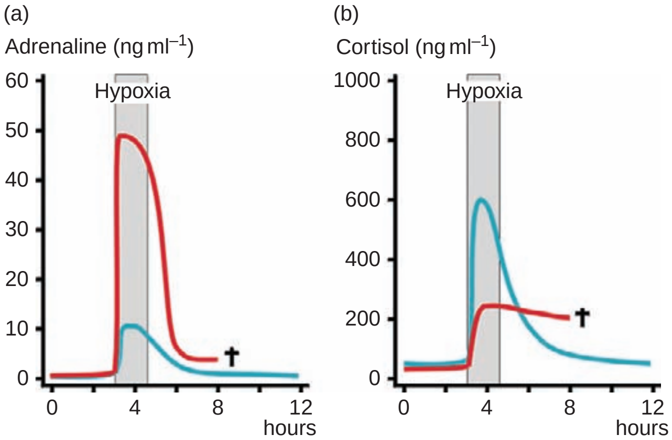

Figure 7 Concentrations of adrenaline (a) and cortisol (b) in blood plasma of recovering (r) and nonrecovering (nr) rainbow trout (*Oncorhynchus mykiss*) exposed to 90-min hypoxia at 4.8 kPa. This experiment shows that a high-adrenaline/low-cortisol response as in proactive fish is a disadvantage for surviving low-oxygen conditions (these fish did not recover), compared with a low-adrenaline/high-cortisol response as in reactive fish. Reproduced from van Raaij M, Pit D, Balm P, Steffens A, van den Thillart G (1996) Behavioral strategy and physiological stress response in rainbow trout exposed to hypoxia. *Hormones and Behavior* 30: 85–92, with permission from Elsevier.

or mothers experimentally exposed to high-cortisol levels, display faster depletion of energy resources in the eggs, lower growth rate, accelerated hatching, increased larval mortality, and abnormalities such as increased heart rates and asymmetrical otoliths (**see also Social and Reproductive Behaviors**: Dominance Behaviors, Sexual Behavior in Fish, and Socially Controlled Sex Change in Fishes).

Endocrine Disruption

Specific toxic effects of pollutants on the endocrine system may lead to disturbance of the endocrine-control mechanisms, a process called endocrine disruption. Cadmium inhibits cortisol synthesis via blocking of calcium channels in the membranes of the interrenal cells. Xenobiotics acting via the aryl hydrocarbon receptor can inhibit interrenal steroidogenic acute regulatory protein activity (the rate-limiting step in cortisol biosynthesis) as shown, for example, alpha- and beta-naphthoflavone. Other examples of endocrine disruption are GR downregulation by polychlorinated biphenyls and the effects of salicylate and other anti-inflammatory agents that disturb cortisol synthesis. The result is a diminished cortisol response to stressors and hydromineral challenges such as seawater adaptation, as has been demonstrated for fishes from many polluted surface waters. Furthermore, atrophied pituitary ACTH cells have been reported for such animals (**see also Hormonal Responses to Stress**: Impact of Stress in Health and Reproduction, **Toxicology**: The Toxicology of Organics in Fishes).

Concluding Remarks

In fishes, like in other vertebrates, stressors modify the activity of virtually all hormones and lead to adjustments of almost all aspects of physiology. Many hormones are produced at multiple sites and have multiple functions. Their interactions represent an intricate network firmly controlled by the brain. However, the focus of the primary stress hormones is on energy mobilization for activities directed at increasing chances of survival. When stress becomes chronic, the inhibition of other body functions may eventually lead to damage and atrophy in many organs, and reduced performance capacity. Although the response to a stressor is general rather than stressor specific, modifying factors give every stress response a unique character.

Glossary

Adrenergic A general term pertaining to processes or structures related to catecholamines. For example, neurons that release noradrenaline as transmitter; catecholamines binding to adrenergic receptors (adrenoceptors), and adrenergically activated (catecholamine-activated) physiological processes.

Catecholamine-release threshold The point at which catecholamines are abruptly released into the blood (i.e., plasma catecholamine levels rise). The release threshold is usually defined in terms of the arterial oxygen partial pressure or the arterial oxygen content/concentration/oxygen-hemoglobin saturation level.

Cholinergic A general term pertaining to processes or structures related to acetylcholine. For example, neurons that release acetylcholine as transmitter. Nicotinic and muscarinic receptors are cholinergic receptors because they bind acetylcholine. Cholinergic synapses are found in both the central and peripheral nervous systems.

Chromaffin cells Cells from the sympathetic–adrenal lineage that synthesize and store catecholamines as well as release them into the blood (via the extracellular fluid).

Exocytosis The process by which neurotransmitters or hormones, which are stored in secretory vesicles or granules, are released from a nerve or endocrine cell when these storage granules fuse with the plasma membrane.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Hypoxemia A reduction in the oxygen content/concentration of the blood. Blood can be hypoxic without being hypoxemic.

***In vitro* perfused posterior cardinal vein (PCV) preparation** An experimental preparation used to measure the release of catecholamines from chromaffin cells within the walls of the posterior cardinal vein. The PCV is perfused with saline. The effects of various drugs or electrical nerve stimulation on catecholamine release can be assessed by measuring catecholamine levels in the outflowing perfusate.

Non cholinergic A term used to describe mechanisms of catecholamine release that occur independently of acetylcholine acting on nicotinic or muscarinic receptors.

P_{50} The oxygen partial pressure at half-maximal oxygen saturation of blood or hemoglobin.

Biosynthesis of Catecholamines

The catecholamine hormones, dopamine, noradrenaline (norepinephrine), and adrenaline (epinephrine), are synthesized and stored within adrenergic neurons and adrenal chromaffin cells where they function as neurotransmitters (dopamine and noradrenaline) and circulating hormones (noradrenaline and adrenaline), respectively. Catecholamine biosynthesis occurs via the Blaschko pathway beginning with the amino acid precursor, tyrosine (**Figure 1**). Tyrosine is hydroxylated by the enzyme tyrosine hydroxylase (TH) to form dihydroxyphenylalanine (DOPA) in the rate-limiting step in catecholamine synthesis. TH activity is both under negative feedback control from dopamine and noradrenaline and under regulation by a variety of neuronal and hormonal factors.

DOPA is hydroxylated by amino acid decarboxylase (AADC or DOPA decarboxylase) to form dopamine. This enzyme is present in sufficient quantities that DOPA does not accumulate to any substantial extent. The first two steps of the pathway occur within the cytosol. Dopamine is then transported into secretory vesicles (granules) where it is hydroxylated by dopamine β-hydroxylase (DBH) to form noradrenaline. In some chromaffin cells, noradrenaline is transported from the secretory vesicle, back into the cytoplasm, where it is methylated to form adrenaline by the enzyme phenylethanolamine N-methyltransferase

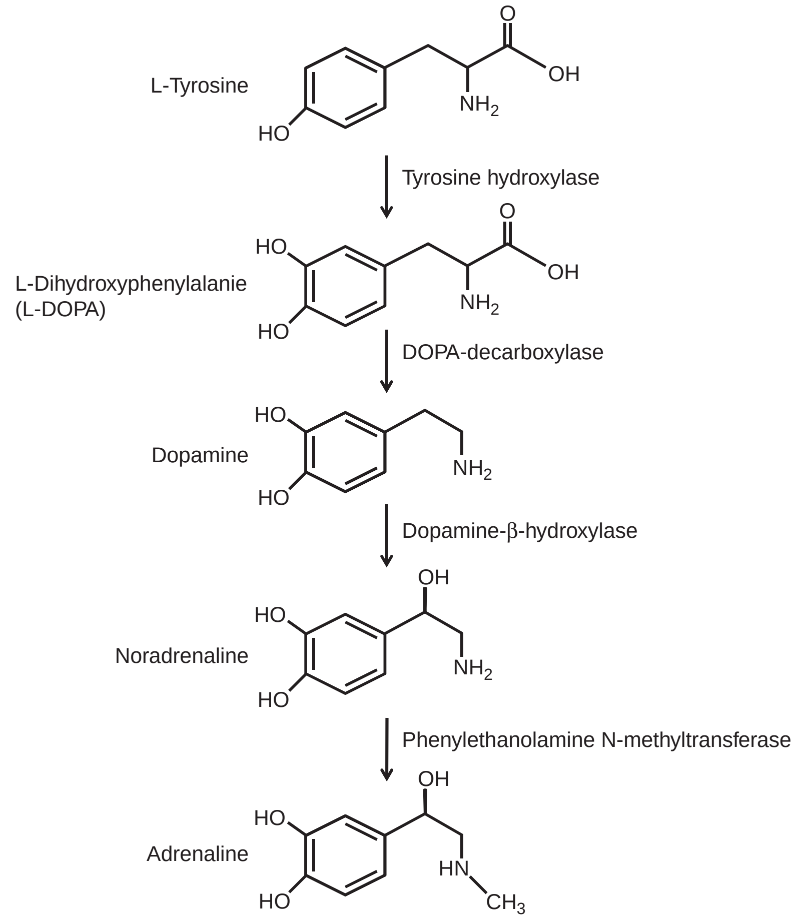

Figure 1 The catecholamine biosynthetic pathway.

(PNMT). Alternately, once synthesized, noradrenaline may remain within the secretory granules; and once synthesized within the cytosol, adrenaline is transported into secretory granules prior to release.

Sites of Catecholamine Synthesis and Storage

In fish, as in other vertebrates, catecholamines are synthesized within, and released from, chromaffin cells. The arrangement of chromaffin cells differs greatly among species. In mammals, chromaffin cells are found within the core of the adrenal gland, the adrenal medulla surrounded by the steroidogenic interrenal cells within the adrenal cortex. In birds and reptiles, chromaffin cells are closely intermingled with interrenal cells within an adrenal gland. In urodele amphibians, chromaffin cells are located within segmented bodies associated with sympathetic nerves on the ventral side of the kidney, while, in anuran amphibians, chromaffin cells form a distinct mass on the surface of the kidney.

Among different classes of fish, the arrangement of chromaffin cells also exhibits substantial diversity. In cyclostomes and agnathans (hagfish and lamprey; **see also Hagfishes and Lamprey**: Hagfishes, Lampreys: Energetics and Development, and Lampreys: Environmental Physiology), chromaffin cells are distributed within the systemic and portal hearts and in large veins and arteries. In elasmobranchs (sharks and rays; **see also Chondrichthyes**: Physiology of Sharks, Skates, and Rays), chromaffin cells are associated with paravertebral ganglia. The axillary bodies, comprising chromaffin cells in association with gastric ganglia, are the primary source of circulating catecholamines in these fish. In teleost (bony) fish, chromaffin cells are located within the walls of the posterior cardinal vein (PCV) and its branches within the kidney tissue, primarily in the anterior regions of the kidney (head kidney; **Figure 2**; **see also Role of the Kidneys**: Histology of the Kidney).

Most fish release adrenaline and noradrenaline into the blood under the appropriate conditions. The relative amount of adrenaline versus noradrenaline varies,

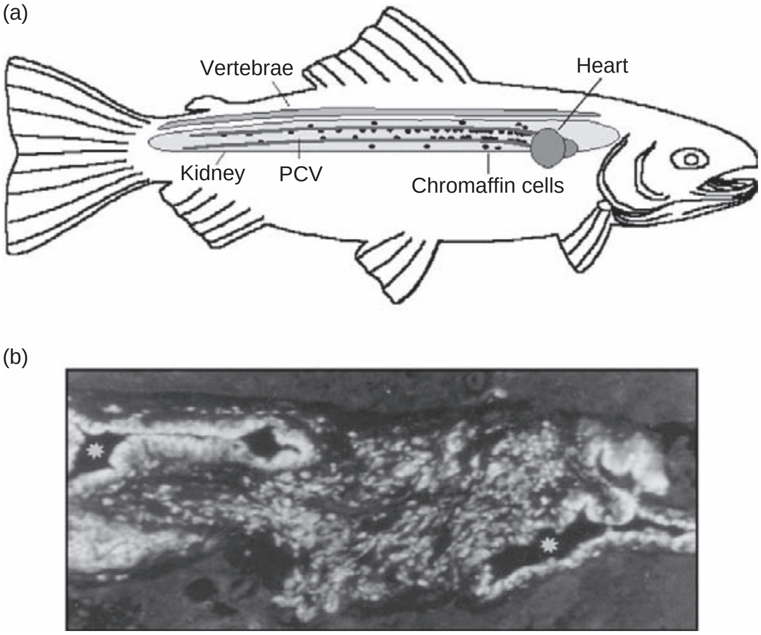

Figure 2 (a) The location of the catecholamine-containing chromaffin cells in a generic teleost fish. Chromaffin cells are found in the walls of the posterior cardinal vein (PCV) and scattered throughout the kidney tissue. (b) A cross section of the kidney and PCV from an Atlantic cod. (a) Modified from Reid SG, Bernier NJ, and Perry SF (1998) The adrenergic stress response in fish: Control of catecholamine storage and release. *Comparative Biochemistry and Physiology – Part C* 120: 1–27.

depending upon the species and the situation eliciting catecholamine release. As with other vertebrates, adrenaline and noradrenaline in fish are also stored in separate populations of chromaffin cells, although these populations are usually intermixed. Some chromaffin cells contain only adrenaline, whereas others contain only noradrenaline. Adrenaline-containing cells appear to contain the enzyme PNMT, whereas the noradrenergic cells do not.

Situations Eliciting the Release of Catecholamines into the Circulation

Catecholamine Release during Hypoxia

In teleosts, numerous stressful situations result in an elevation of plasma catecholamine levels. Conditions such as hypoxia (a decrease in the level of inspired oxygen in the water; **see also Hypoxia**: The Expanding Hypoxic Environment), hypercapnia (an increase in water CO_2 levels), exhaustive exercise, predation, ionoregulatory disruptions, and exposure to air usually lead to the release of catecholamines into the blood.

One of the most potent stimuli for catecholamine release in fish is exposure to environmental hypoxia. Hypoxic conditions are sensed by chemoreceptor cells (**see also Control of Respiration**: Oxygen Sensing in Fish) on the gills which then activate pathways ultimately leading to catecholamine release from the chromaffin cells. A number of studies, in a variety of teleost species, indicate that catecholamine release during hypoxia occurs when the oxygen content of the blood (or oxygen-hemoglobin saturation) decreases by approximately 50% (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). In other words, catecholamines are released when the partial pressure of oxygen in the arterial (Pa_{O_2}) blood reaches the P_{50} value (P_{50} is defined as the Pa_{O_2} level at which blood oxygen content is reduced to 50% of the maximal value; **Figure 3**(**b**)).

In experiments demonstrating this phenomenon, fish were exposed to varying levels of water P_{O_2} (Pw_{O_2}), usually between 30 and 150 mmHg. Blood samples were taken to measure arterial oxygen content, Pa_{O_2}, blood (hemoglobin) and plasma catecholamine levels. In all cases, the general profile of plasma catecholamine appearance in the plasma is very similar (**Figure 3**(**a**)). When water P_{O_2} is high or moderate, plasma catecholamine levels remain low (i.e., baseline levels). However, in all cases, a threshold is reached at which point plasma catecholamines increase. When plasma catecholamine levels are plotted as a function of blood oxygen content, the threshold at which catecholamines are elevated is approximately the same in all species of fish (i.e., at approximately a 50% reduction in blood oxygen content). When the same catecholamine data are plotted as a function of Pa_{O_2}, the release threshold is different among the

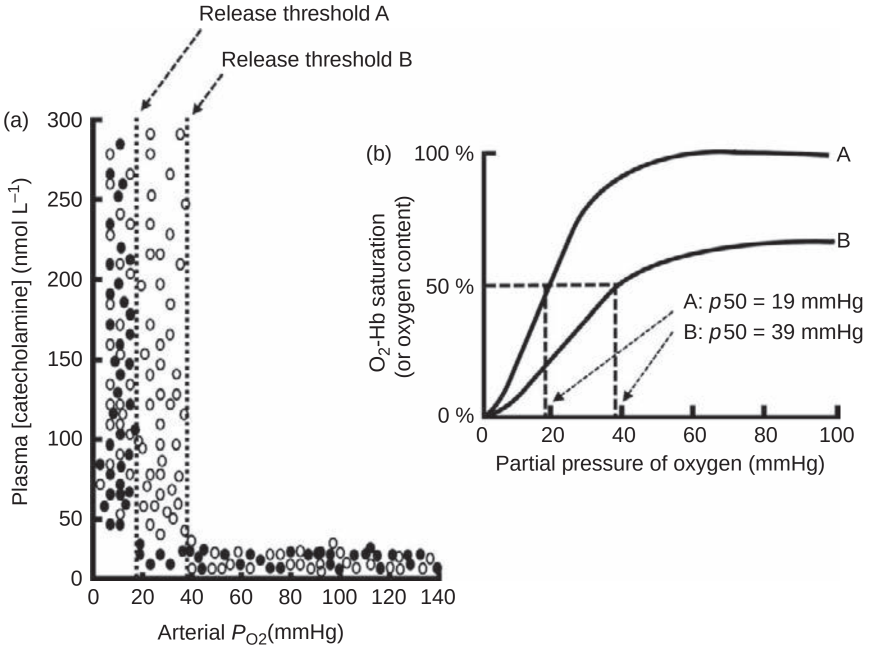

Figure 3 (a) The general relationship between plasma catecholamine levels and the partial pressure of oxygen in the arterial blood (P_{O_2}). (b) Generic oxygen equilibrium curves illustrating the relationship between the level of oxygen-hemoglobin saturation (or oxygen content) and the partial pressure of oxygen in the arterial blood in two groups of fish, group A and group B. The black symbols in (a) represent data points from group A, while the open symbols represent data points from group B. The dashed lines in (a) indicate the catecholamine release thresholds for both groups of fish (left line, group A; right line, group B). The higher affinity of hemoglobin for oxygen in group A results in a lower threshold for catecholamine release compared to group B.

species and correlates approximately to the P_{50} value for that species. The relationship between the Pa_{O_2} release threshold and the P_{50} value (from different fish) has a slope of approximately 1, indicating that catecholamines are being released when the oxygen content has fallen to approximately 50% (**Figure 4**).

Catecholamine Release during Hypercapnia and Exercise

Exposure to environmental hypercapnia frequently results in an elevation of plasma catecholamines. However, it is likely that it is due to an indirect effect of hypercapnia-

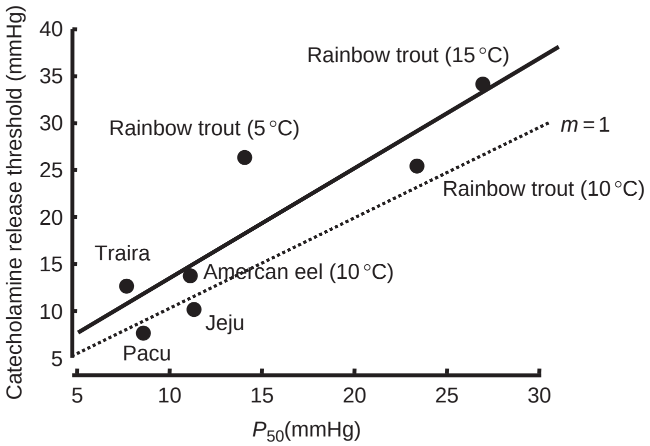

Figure 4 The relationship between the arterial P_{O_2} catecholamine release threshold (mmHg) and the P_{50} value (mmHg) using data from traira, pacu, jeju, American eel, and rainbow trout (at three different temperatures). The dashed line is a line of unity (slope = 1). The relationship between the catecholamine release threshold and the P_{50} value is very close to having a slope of 1, indicating that catecholamines are released into the blood when the arterial P_{O_2} falls to approximately the P_{50} level (i.e., at the point where blood oxygen content is reduced to 50%).

induced hypoxemia rather than a direct effect of hypercapnia *per se*. Hypercapnia is usually accompanied by a respiratory acidosis as CO_2 is hydrated to form an H^+ ion and a HCO_3^- ion (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion). Both CO_2 and H^+ ions compromise the ability of hemoglobin to bind oxygen and reduce the oxygen-carrying capacity of blood. As such, any elevation of plasma catecholamines during hypercapnia may simply result from CO_2 and H^+ ions reducing blood oxygen content – a known stimulus for catecholamine release (see above). However, nicotinic receptor-induced catecholamine release (see below) can be augmented by an acidic environment around the chromaffin cells or exposure of a fish to hypercapnia.

During exhaustive or strenuous exercise, catecholamine release serves to mobilize energy stores in an effort to increase plasma glucose levels. Within the liver, glycogenolysis and gluconeogenesis are stimulated, whereas glycolysis is inhibited. Catecholamines also assist in delivering oxygen to muscles by enhancing blood-oxygen-carrying capacity. Ionoregulatory disruptions, such as exposure to soft water, produce a thickening of the gills via proliferation of mitochondrial-rich (chloride) cells which, in turn, leads to a reduction in Pa_{O_2} and, possibly, blood oxygen content. Catecholamines may play a role in enhancing oxygen transport during initial exposure to soft water but chronic exposure may blunt any effects due to desensitization of the catecholamine release process and adrenergic receptors on effector cells such as the red blood cell.

Mechanisms of Catecholamine Secretion

Cholinergic Control of Catecholamine Release

Numerous mechanisms have been identified which can trigger, modulate, or inhibit the release of catecholamines from fish chromaffin cells. An extensive body of literature also exists on the mechanisms of catecholamine secretion in mammalian species. Near the end of the twentieth century, it was still, in general, dogmatic to state that there was little doubt that the primary mechanism leading to the release of catecholamines from chromaffin cells in fish (and other vertebrates) is stimulation of the chromaffin cells by acetylcholine (ACh) released from sympathetic nerves. In addition, in most species, it was thought that cholinergic-induced catecholamine release was mediated by ACh-activating nicotinic cholinergic receptors on the chromaffin cell (**Figure 5**). This leads to membrane depolarization, an

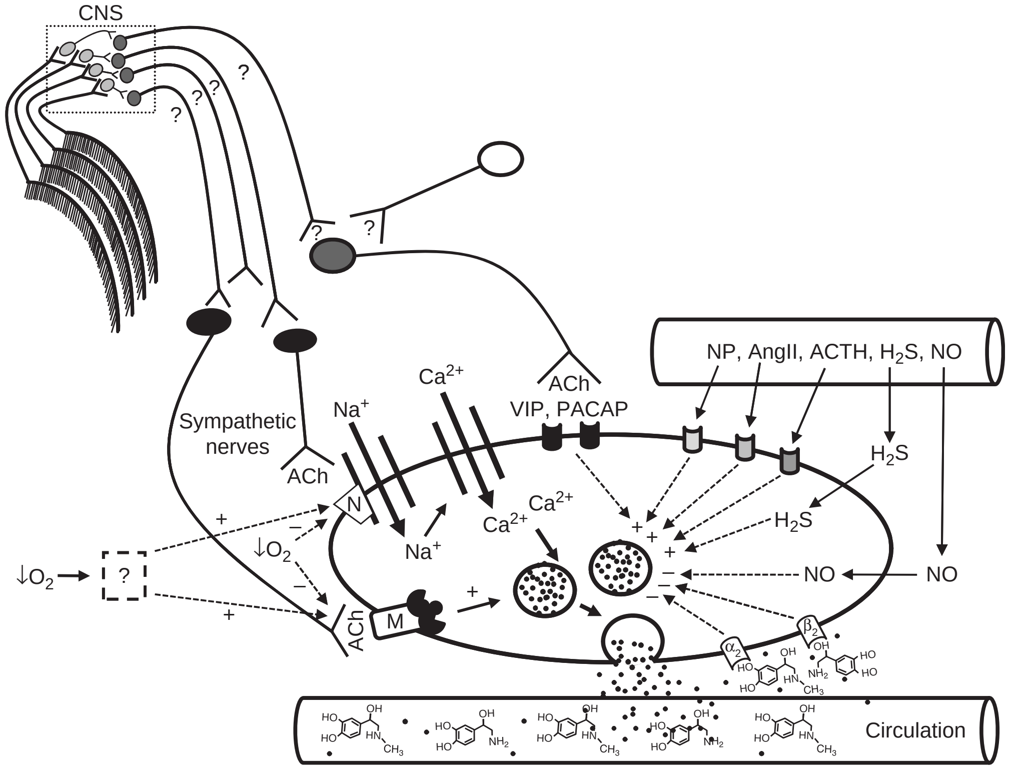

Figure 5 Cholinergic and non-cholinergic mechanisms of catecholamine secretion from a generic fish chromaffin cell. α_2, alpha-2-adrenoceptor; Ach, acetylcholine, ACTH, adrenocorticotropic releasing hormone; AngII, angiotensin II, β_2, beta-2-adrenoceptor; CNS, central nervous system; H_2S, hydrogen sulfate; M, muscarinic receptor; N, nicotinic receptor; NP, natriuretic peptide; NO, nitric oxide; PACAP, pituitary adenylyl cyclase-activating polypeptide; VIP, vasoactive intestinal polypeptide.

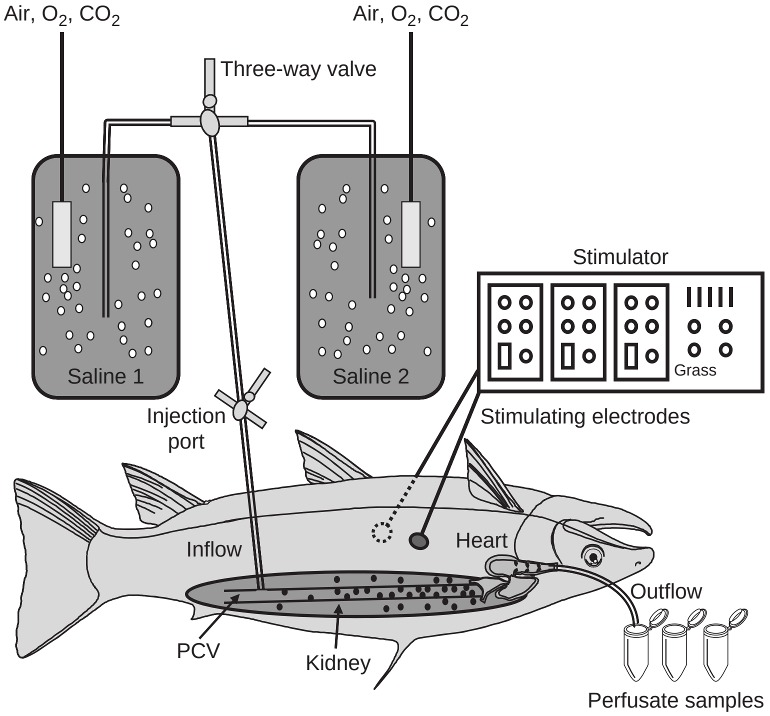

Figure 6 The *in vitro* (*in situ*) saline-perfused posterior cardinal vein (PCV) preparation used to study catecholamine release in fish.

influx of Ca^{2+} from the extracellular fluid, the fusion of catecholamine-containing secretory vesicles with the plasma membrane, and the release of their contents via exocytosis.

However, further studies have identified mechanisms other than nicotinic receptor stimulation that cause catecholamine secretion from fish chromaffin cells. Many of these studies have employed an *in vitro* saline-perfused PCV preparation (**Figure 6**). In this preparation, the PCV is cannulated near its caudal end to serve as an inflow, whereas the ventricle is cannulated to serve as an outflow. Saline is perfused through the inflow cannulae, flows through the PCV, across the chromaffin cells, and is collected in sample tubes via the outflow cannulae. Various pharmacological agents (e.g., receptor agonists and antagonists) can be added to the perfusion saline or given as bolus doses via an injection port. The effect of these agents on catecholamine secretion can be assessed by measuring catecholamine levels in the outflowing perfusate. A variation of this preparation uses an electrical stimulation technique to stimulate the sympathetic nerves that innervate the chromaffin cells.

Techniques such as these have revealed that direct activation of muscarinic receptors, by acetylcholine released from sympathetic nerves, can augment nicotinic receptor-induced catecholamine release from trout chromaffin cells and may also exert a direct secretory effect. On the other hand, studies on American eel chromaffin cells indicate that whereas nicotinic stimulation triggers catecholamine release, muscarinic receptor stimulation has a slightly inhibitory effect on noradrenaline release.

Cholinergic control of catecholamine secretion can be regulated or modified by a variety of factors. For example, perfusion of the *in vitro* PCV preparation with either adrenaline or noradrenaline prevented nicotinic or muscarinic receptor activation from triggering catecholamine release while reducing the ability of electrical stimulation to trigger release. These responses were mimicked by treatment with agonists of the adrenergic β_2 and α_2 receptors, respectively (**Figure 5**). Conversely, treatment with β_2 and α_2 receptor antagonists augmented catecholamine release triggered by nicotinic and muscarinic receptor stimulation. These studies illustrate that circulating plasma catecholamines can have feedback effects on the chromaffin cells, attenuating further release.

Exposure to environmental hypoxia can also regulate the release of catecholamines from fish chromaffin cells, albeit in a complicated manner. For example, perfusion of the *in vitro* PCV (chromaffin cell) preparation with hypoxic saline reduces catecholamine release in response to electrical field stimulation and activation of muscarinic and nicotinic receptors. On the other hand, if nicotine is injected into hypoxic fish *in vivo*, then the increase in plasma catecholamine levels is greater than that in normoxic fish following a nicotine injection. These opposite results indicate that regulatory processes at a site other than the chromaffin cells are modulating catecholamine release during hypoxia and overriding the inhibitory effects of hypoxia at the direct level of the chromaffin cell (**Figure 5**). Exposure to chronic hypoxia can also modify catecholamine release patterns by enhancing the sensitivity of the release process to cholinergic stimulation.

Noncholinergic Control of Catecholamine Release

Exposure to environmental hypoxia is one of the strongest triggers for catecholamine release in fish. However, nicotinic receptor stimulation is not absolutely required to trigger release under these conditions. If nicotinic receptors are experimentally desensitized by prolonged treatment with nicotine, catecholamine release during hypoxia still occurs. It is apparent that many mechanisms, noncholinergic in nature, can trigger catecholamine release from fish chromaffin cells. Indeed, in the most primitive group of extant fish, the cyclostomes, plasma catecholamine levels are elevated during stress despite the chromaffin cells receiving no innervation. In these animals, there must be humoral or paracrine processes that trigger the secretion of catecholamines. In 1998, Reid and colleagues published an extensive review on the mechanisms of catecholamine release in fish, describing the effects of humoral agents such as serotonin, angiotensins, natriuretic peptides (NPs), adrenocorticotropic hormone (ACTH), cortisol, opioids, assorted peptides, adenosine, histamine, and catecholamines. Since that time, a number of studies have continued to examine noncholinergic mechanisms of catecholamine secretion in fish (**Figure 5**), including regulation by angiotensin, vasoactive intestinal polypeptide (VIP), pituitary adenylyl cyclase-activating polypeptide (PACAP), and NPs and gasotransmitters such as nitric oxide (NO) and hydrogen sulfide (H_2S).

Angiotensin

In fish, as in other vertebrates, the renin–angiotensin system (RAS) is activated during periods of hypotension in order to restore blood pressure. When blood pressure drops, specialized cells in the kidney release an enzyme called renin, which converts a circulating peptide called angiotensinogen into angiotensin I. Angiotensin I is converted into angiotensin II by angiotensin-converting enzyme (ACE). Both angiotensins I and II can exert pressor effects although angiotensin II is the more potent form. Recent studies on trout have demonstrated that some of the pressor effects attributed to angiotensin II can actually be attributed to catecholamines that were mobilized by an angiotensin II-triggered mechanism. Histological studies have found the presence of angiotensin II receptors on rainbow trout chromaffin cells. Physiological studies have demonstrated that angiotensins I and II can trigger catecholamine release from trout and dogfish chromaffin cells. The RAS also appears to contribute to the maintenance of basal plasma catecholamine levels as inhibition of ACE causes a reduction in these levels. On the other hand, angiotensin II does not cause catecholamine release in the American eel nor do circulating catecholamines play a role in blood pressure restoration during hypotension in this species.

VIP and PACAP

In mammals, VIP and PACAP are often located in sympathetic nerve fibers where they function alongside acetylcholine as co-transmitters. Histological studies have identified the presence of VIP and PACAP in nerves innervating chromaffin cells in Atlantic cod, rainbow trout, European eel, and spiny dogfish. VIP-binding sites (that appear to be the VPAC receptor for VIP) are located on PNMT-positive and PNMT-negative chromaffin cells of rainbow trout. Both VIP and PACAP trigger adrenaline (but not noradrenaline) release from trout chromaffin cells with a similar degree of potency. This response can be abolished by antagonism of VIP receptors but not by antagonism of PACAP receptors. Electrical stimulation experiments demonstrated that VIP/PACAP-induced catecholamine release is triggered at low stimulation frequencies, whereas cholinergic mechanisms are activated at higher frequencies. If nicotinic receptors are desensitized by constant nicotine treatment, catecholamine release in response to low-frequency neural stimulation is not affected while release in response to high-frequency stimulation is reduced. The low-frequency-induced catecholamine release is not altered by treatment with muscarinic or nicotinic receptor antagonists but is reduced by treatment with a VIP receptor antagonist. VIP and PACAP, therefore, appear to function as co-transmitters in nerves innervating fish chromaffin cells and they trigger catecholamine release under mild-to-moderate stressful conditions when the nervous stimulation of the chromaffin cells is likely to be relatively low.

Natriuretic peptides

NPs are released into the blood in response to elevated blood pressure or plasma sodium levels. NPs are produced in the heart, brain, and chromaffin cells. Histological studies have found evidence for the presence of atrial natriuretic peptide (ANP) immunoreactivity in teleost chromaffin cells. Experiments on rainbow trout and American eels suggest that NPs cannot directly stimulate catecholamine secretion by direct actions on the chromaffin cells. However, in dogfish, NPs trigger noradrenaline release by mechanisms (on either the chromaffin cells or elsewhere) that depend, ultimately, on α-adrenoceptor stimulation.

Gasotransmitters

Gasotransmitters are small gaseous molecules that function as neurotransmitters. This family of neurotransmitters consists of nitric oxide (NO), carbon monoxide (CO), and H_2S. Gasotransmitters are not stored within secretory vesicles in nerve terminals but, rather, are produced when required. They diffuse from the nerve terminal into the target cell where they exert effects mediated by second-messenger systems. Both NO and H_2S have been shown to alter catecholamine release from fish chromaffin cells. For example, NO, derived from neuronal nitric oxide synthase (nNOS), inhibits catecholamine release in rainbow trout. This was demonstrated by introducing a NO donor into the *in vitro* PCV preparation and observing the abolition of electrically induced catecholamine release. Conversely, electrical-induced catecholamine release is augmented by the NOS inhibitors, L-NAME and 7-NI.

Repetitive hypoxia over a period of days decreases the capacity of rainbow trout to elevate plasma catecholamine levels in response to acute environmental hypoxia. This is due, at least in part, to hypoxia-induced increases in plasma NO, which in turn inhibit catecholamine release

from chromaffin cells. Further evidence in support of NO-induced inhibition of catecholamine release during repetitive hypoxia comes from *in vitro* PCV preparations taken from fish exposed to repetitive hypoxia. Electrically stimulated catecholamine release in these preparations was reduced although this effect could be reversed by nNOS inhibitors.

H_2S can directly stimulate catecholamine secretion from trout chromaffin cells via membrane depolarization and calcium-evoked exocytosis. During exposure to environmental hypoxia, plasma H_2S levels increase as do plasma catecholamines. Furthermore, chromaffin cells will synthesize H_2S when incubated with L-cysteine, the precursor to H_2S, and H_2S is co-released from the chromaffin cells with catecholamines, suggesting an autocrine mechanism of augmenting catecholamine release.

Effects of Plasma Catecholamines and Mechanisms of Action

Although circulating catecholamines exert numerous effects on many different target tissues, the overall effect of these hormones is to reduce the detrimental effects of stress by optimizing cardiovascular and respiratory function while also mobilizing energy supplies. These effects are initiated by the binding of catecholamines to adrenergic receptors located on target tissue cell membranes. These receptors are generally classified as α_1, α_2, β_1, and β_2 adrenoceptors. Some of the key effects of plasma catecholamines are illustrated in **Figure** 7(**a**) and are described in detail in a 1992 review by Thomas and Perry and a 1998 review by Reid and colleagues.

Circulating catecholamines act on the heart to increase both heart rate and stroke volume and on blood vessels to alter blood pressure and flow (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels and Design and Physiology of the Heart: Physiology of Cardiac Pumping). At the level of the gills, catecholamines can enhance O_2 uptake from the water into the blood; at the red blood cell (see below), catecholamines increase both the affinity and capacity of the blood to carry oxygen while catecholamine-induced contraction of the spleen increases the amount of red cells in the circulation (**see also Blood**: Cellular Composition of the Blood). All of these effects serve to optimize cardiorespiratory function to ensure adequate delivery of oxygen to the tissues. At the liver, catecholamines stimulate gluconeogenesis and glycogenolysis, while at adipocytes they stimulate lipolysis. These actions increase the levels of circulating glucose and free fatty acids, respectively, to ensure adequate energy (fuel) supplies for metabolically active tissues (**see also Hormonal Responses to Stress**: Stress Effect on Growth and Metabolism).

One of the most important physiological responses triggered by plasma catecholamines (at least in bony fish) is to increase the hemoglobin-oxygen-binding affinity as well as the carrying capacity of hemoglobin for oxygen (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbonic Anhydrase in Gas Transport and Exchange). The primary mechanism leading to these changes is adrenergically activated Na^+–H^+ exchange on the plasma membrane of red blood cells (**Figure** 7(**b**)). Both adrenaline and noradrenaline can activate β_2 adrenergic receptors on the red cell, which leads to the activation of adenylyl cyclase and cyclic adenosine monophosphate (cAMP) production. In turn, this leads to activation of Na^+–H^+ antiporters on the cell membrane that remove an H^+ ion from the red cell in exchange for a plasma Na^+ ion. This results in an acidification of the plasma and an alkalinization of the red cell. This increase in intracellular pH leads to increases in both the affinity of hemoglobin for oxygen (Bohr effect) and the maximal oxygen-carrying capacity of the blood (Root effect) (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange). Catecholamines can also elevate blood-oxygen-carrying capacity by triggering splenic contraction and the release of additional erythrocytes into the blood (**see also Blood**: Cellular Composition of the Blood).

The adrenergic stress response is terminated (deactivated) by the uptake of circulating catecholamines into neuronal and non-neuronal tissue where they are converted to methylated and deaminated derivatives prior to excretion in the urine (**Figure 8**).

Glossary

Gluconeogenesis The metabolic pathway responsible for glucose production from three-carbon precursor molecules, for example, amino acids.

Glycogenolysis The production of glucose from glycogen.

Hypothalamic–pituitary–interrenal (HPI) axis The HPI axis is the anatomical arrangement, whereby neuro-signals generated in the hypothalamus initiate the release of factors from the pituitary that move within the blood to the interrenal tissue to release glucocorticoids, subject to control by negative feedback loops at each level of this interactive system.

Signal transduction A process by which an extracellular signal (e.g., a hormone, the first messenger) initiates intracellular processes; generally involves a receptor, linking proteins, an enzyme that generates a second messenger (e.g., cyclic adenosine monophosphate), that activates downstream protein kinases which alters regulator-phosphorylation patterns.

Steroidogenesis The metabolic pathway by which steroids are enzymatically generated from cholesterol in cell types including the gonads and interrenals.

Introduction

This article examines metabolism and growth in fish as impacted by stress. Both factors are part of the organismal stress response with metabolism being important in terms of the secondary response, and growth being part of the tertiary response (**see also Hormonal Responses to Stress**: Hormone Response to Stress). When confronted by a stressor, the fish must respond and it does so by re-partitioning its energy between survival mechanisms and processes, such as growth and reproduction that are considered long-term commitments. A complex suite of nervous and endocrine functions are responsible for these re-partitioning activities and although we are now beginning to better understand these processes in mammals, our studies with fish remain primitive by comparison. To better understand the issues, the catecholamine (CA) and glucocorticoid pathways are briefly reviewed for their impacts on metabolism and growth.

Catecholamines

The CAs adrenaline (Adr) and noradrenaline (NAdr) are released from chromaffin cells (CCs) located to various body locations depending upon the fish group; within the advanced teleost fishes, these cells are primarily located within the walls of the posterior cardinal vein (PCV) in the anterior or head kidney generally intermixed with the steroidogenic interrenal cells (**see** section Glucocorticoids). The synthesis of Adr and NAdr within the CCs is discussed elsewhere (**see also Hormonal Responses to Stress**: Catecholamines), but suffice it to say that CAs are generally released from CCs to overcome acute cardiorespiratory and metabolic disruptions. Numerous stressors initiate such disruptions including hypoxia, anemia, acidosis, exhaustive exercise, and general physical disturbances.

Catecholamine Release and Content

Teleost fish CCs are innervated by sympathetic nerve fibers that release acetylcholine onto the cells ultimately releasing CAs from vesicles by Ca^{2+}-induced exocytosis into the PCV. Release can be induced using the mixed nicotinic/muscarinic agonist carbachol in rainbow trout (*Oncorhynchus mykiss*), but the specificity of cholinergic receptors on the CC shows significant species variability. A variety of noncholinergic agents are also known to elicit CA release in some fish species. Humoral agents, including serotonin (5-hydoxytryptamine (5-HT)-containing cells, are intermixed within the interrenal CCs), angiotensins, natriuretic peptides, adrenocorticotropic hormone (ACTH; **see** section Cortisol Release and Mechanisms of Action), opioid peptides, and CAs themselves have been shown to result in CA release. Probably, the most interesting and relevant nonhumoral factor is oxygen concentration (**see also Hormonal Responses to Stress**: Catecholamines).

Resting total Adr and NAdr levels in blood are generally $<20\,\mathrm{nmol{\cdot}l^{-1}}$, while stress-induced levels vary enormously across fish species being minimal in some Antarctic species to large in the salmonids ($>300\,\mathrm{nmol{\cdot}l^{-1}}$). These differences in levels between species result from factors including numbers of CCs and storage content, stress intensity, and turnover rates. Significant stress intensity is required to raise blood CA levels above the background in fish and, generally, this is correlated with a decrease in blood oxygen content.

Role of Oxygen

CA release is linked to a threshold PaO_2. Thus, the differences noted between fish species may reflect specific differences in hemoglobin-oxygen (Hb-O_2) binding affinities of blood (**see also Hormonal Responses to Stress**: Catecholamines). Examination of a variety of fish species has generally supported the link between hypoxemia, Hb-O_2 binding affinity (measured as P_{50}; **see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin), and CA release (**Figure 1**). Generally, teleost fish Hb has as low specific buffering capacity in part to

regulate the oxygen content of the swimbladder needed for neutral buoyancy. To ensure appropriate red blood cell (RBC), intracellular pH (pH_i) regulation and Hb-O_2 affinity, a novel CA-activated Na^+/H^+-exchanger (NHE) is located to the RBC membrane of many teleost fish and especially salmonids called the β-adrenergic NHE or simply the βNHE. Adr/NAdr binding to the βNHE initiates a signal transduction process that increases intracellular cyclic adenosine monophosphate (cAMP) content, activation of protein kinase A (PKA), phosphorylation of the βNHE, and activation of Na^+ influx and H^+ efflux. Physiologically, this process results in a rapid, but temporary RBC swelling and, importantly, increases pH_i and thus Hb-O_2 affinity and oxygen transport by Hb to metabolically active tissues. This β-adrenergic response specifically links changes in peripheral tissue metabolism to O_2 availability.

Metabolism and Catecholamines

Clearly, an acute stressor that reduces blood oxygen content results in the rapid release of CA. These circulating CAs affect tissue metabolism by binding to adrenergic receptors or adrenoceptors (ARs) located on membranes of responsive tissues to initiate signaling cascades (**Figure 2**). ARs are members of Family A (rhodopsin/β_2-adrenergic receptor-like) of the seven-transmembrane domain, G-protein-coupled receptor (GPCR) superfamily and evidence supports that the existing multiple AR subtypes (β_1-, β_2-, β_3-, α_1-, and α_2-ARs) arose during duplication events within the evolution of vertebrates. Fish ARs are similar to their homologs found across the vertebrates and especially within the well-characterized mammalian system.

CAs alter both carbohydrate and lipid metabolism in numerous fish species, both in the intact fish and in isolated hepatocytes. The most well-studied tissue is the liver and downstream of the hepatic ARs all components of the classic adenylate cyclase (ACase)/cAMP/PKA and inositol-phosphate/Ca^{2+}/protein kinase C pathways exist, leading to tissue metabolic changes (**Figure 2**). Changes may be modest, but this may be related to the timing of these changes, which generally are rapid and transient. CA concentrations giving 50% maximal hepatocyte glucose release can be as high as $\sim 1\ \mu\text{mol}\cdot\text{l}^{-1}$ and as low as $10\,\text{nmol}\cdot\text{l}^{-1}$. These values are generally above those reported for CA levels even in salmonids, but well above affinity values reported in fish AR binding studies ($1\text{–}20\,\text{nmol}\cdot\text{l}^{-1}$). Rainbow trout, bullhead catfish (*Ameiurus melas*; *A. nebulosus*), and American eel livers are classic β_2-AR-linked systems and incubations of primary hepatocytes from these species with β_2-agonists increase glycogen mobilization (glycogenolysis) through increases in cAMP and PKA activities activating glycogen phosphorylase a (GPase a); general β_2-antagonists (propranolol) block this response. Rainbow trout implanted with cortisol respond by increasing β-AR numbers on hepatocytes and production of cAMP. Although agonist-induced downregulation of ARs is common in mammalian studies, this is less so in fish possibly due to limited numbers of AR phosphorylation sites. Modest increases in gluconeogenesis from lactate and alanine are reported in some species, although this increase can be relatively large (common carp; *Cyprinus carpio*). The hyperglycemic effects of CA are enhanced by fasting and by chronic glucocorticoid application. Generally, these effects are more responsive to Adr than NAdr, with the possible exception of the copper rockfish (*Sebastes caurinus*) that is unusually responsive to NAdr.

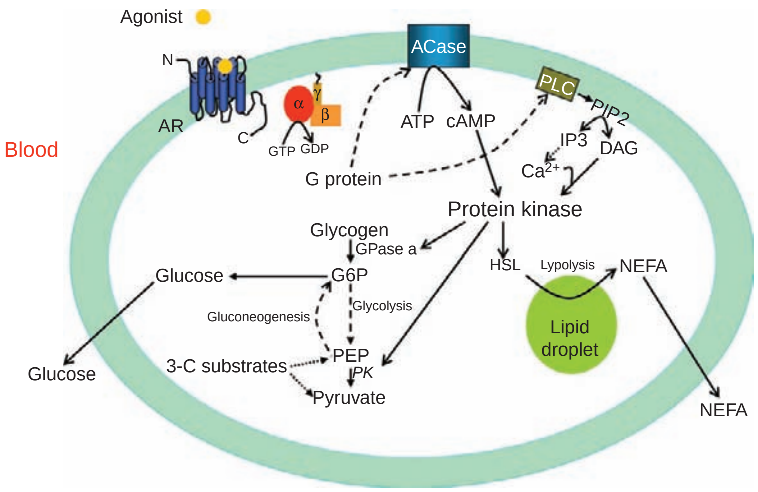

Figure 2 General cartoon for the action of a catecholamine agonist binding to a G-protein-coupled receptor (GPCR) in this case an adrenoceptor (AR) on a composite cell. The G protein is activated leading to the buildup of second messengers (cAMP, IP_3, DAG), which activate protein kinases that phosphorylate specific enzymes of glycolysis/gluconeogenesis and lipolysis. See text for description.

CAs stimulate plasma nonesterified fatty acid (NEFA) levels in mammals primarily by stimulating hormone-sensitive lipase (HSL) activities in adipose tissue (**Figure 2**). This effect is not always observed in teleost fishes, where both liver and adipose tissues can contribute to plasma lipid dynamics; Adr increases NEFA levels in some, but not all, fish while NAdr consistently lowers plasma NEFA in species where investigated. These differences may be related to stress intensity, predominant CA levels in the fish, AR-subtype composition and numbers on liver and adipose tissue, and the apparent high level of lipid mobilization and re-esterification found in some fish species. Certainly, all evidence points to a very different regulation of lipid mobilization in fish compared with mammals. The opposing adrenergic effects on NEFA metabolism in fish have been linked to hypoxia survival; fatty acid oxidation requires oxygen and by inhibiting NEFA mobilization at high CA concentrations, which in many fish represents NAdr content, NEFA and their oxidation intermediates will not compromise metabolic processes.

Muscle is the largest body tissue in fish. Swimming performance is reduced when circulating CA release is blocked by an antagonist. This antagonism can then be overcome by infusing Adr. Precisely how Adr is involved in contraction is unclear, although it may be related to shortening the twitch-relaxation cycle of skeletal muscle, or it may be indirect due to CA effects on other tissues important to swimming such as the heart. Exhaustive swimming generally results in muscle glycogen depletion and at least in some fish species increases in %GPase a, but there is no indication that this is linked directly to CA stimulation of β–ARs that do exist on fish muscle (**see** section Growth and CAs). Blood and muscle lactate pools are generally not in equilibrium in fish after exercise and evidence exists that the muscle lactate pool may contribute significantly to postexercise muscle glycogen recovery; the precise mechanisms for this glycogenesis and the role played by CA remain to be fully elucidated.

In summary, evidence supports a CA-induced increase in plasma glucose and NEFA content to provide tissues with energy needed during the stress response. This increase occurs primarily by Adr occupying β_2-ARs on tissue membranes. Under intense stress conditions as with deep hypoxia, NEFA mobilization is inhibited by NAdr preventing any negative affects of NEFA intermediates on metabolism. The precise metabolic role of CA in fish muscle remains to be elucidated.

Growth and CAs

Growth is generally compromised under both acute and chronic stress. However, there is little evidence for CA directly affecting growth at least in the short term. NAdr, along with numerous other humoral agents, directly inhibits growth hormone (GH) secretion from goldfish (*Carassius auratus*) pituitary cells *in vitro*, but NAdr is undetectable in the goldfish pituitary questioning the physiological importance of this observation.

Specific AR receptors (β_2-AR) exist on red and white skeletal muscle membranes of rainbow trout that, when occupied by β-agonists, increase cAMP intracellular concentrations, which suggests a classic cAMP/PKA signaling cascade. Feeding β-agonists to domestic animals increases muscle protein accretion, but studies in fish are equivocal and drug concentrations used far exceed levels found even under the most severe stress conditions. β_2-Antagonists are used as human drugs to treat cardiovascular problems and these drugs are now found in the aquatic environment; there is no indication to date that existing concentrations are adequate to affect the physiology of fish. There is some indication that CA may coordinate skeletal muscle recovery from exhaustive exercise at least in trout, but the precise mechanisms to account for this are not understood.

Glucocorticoids

The principal glucocorticoid in fish is cortisol (hydrocortisone). It is considered to be the primary indicator of the stress response, as unlike CA, basal and stress-induced levels can be easily measured. Cortisol is a multifaceted hormone expressing huge varieties of physiological and metabolic functions alone and in connection with other hormones (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids). Depending upon the fish species, the nature and intensity of the stressor, the affects of cortisol may differ. Certainly, stress-induced increases in plasma cortisol will directly affect glucose production, feeding responses, and, thus, growth, the immune response, hydromineral balance, and reproduction. Although cortisol is produced on demand at the level of the steroidogenic interrenal cells located to the head-kidney, the release process is initiated by a complex interaction within the HPI axis.

Cortisol Release and Mechanisms of Action

The principal interrenal secretagogue of cortisol is ACTH under the control of the hypothalamic factor corticotrophin-releasing factor/hormone (CRF/H). ACTH moves through the blood and binds to the melanocortin 2 receptor (MC2R), which belongs to the superfamily of GPCR linked to the ACase/cAMP/PKA signaling cascade ultimately increasing cortisol synthesis following stress. Levels of plasma ACTH rise prior to those of cortisol, but both are key indicators of responses to stressors including handling and confinement, crowding, thermal and osmotic shock, and chemical exposure in many species of fish. Cortisol

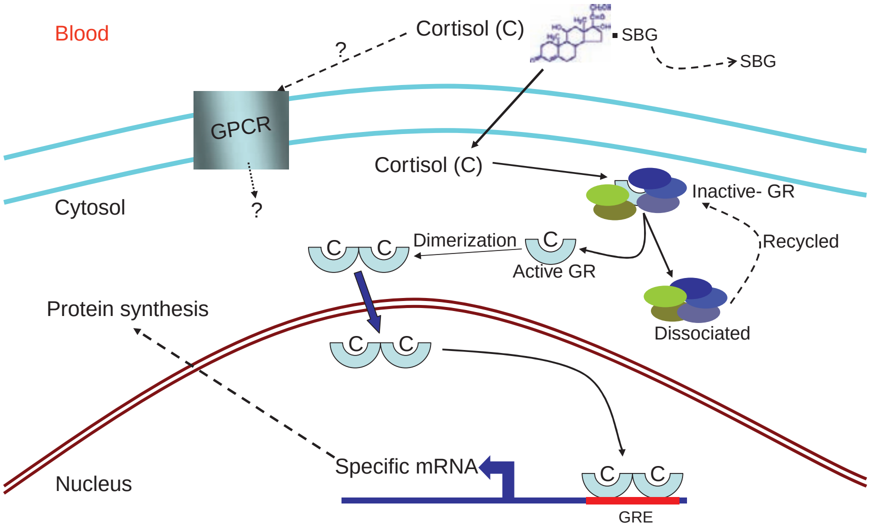

Figure 3 General cartoon of cortisol actions on a cell. Cortisol activates a cytosolic-localized nuclear receptor by displacing Hsps and other factors from it receptor (here a GR), that homodimerizes, moves to the nucleus where it binds to the GRE, located principally upstream of glucocorticoid responsive genes. The result is synthesis of gene-specific mRNA and ultimately proteins responsible for cortisol-induced metabolic changes. Some evidence exists for the rapid activities of cortisol by a membrane GPCR (G-protein-coupled receptor).

acts on cells by binding to corticosteroid receptors (CRs) that are ligand-activated transcription factors (TFs) located as complexes with other protein, including heat shock proteins (Hsps) in the cytosol (**Figure 3**). The phylogeny of CRs is complex but duplication events during evolution resulted in a glucocorticoid receptor (GR) and a mineralocorticoid receptor (MR). This phylogeny is discussed in detail elsewhere (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids).

As TFs, once cortisol binds to its CR, the complex moves to the nucleus where it is thought to homodimerize and bind to glucocorticoid response elements (GREs) generally found in the 5′ promoter sequence of glucocorticoid-sensitive genes (**Figure 3**). Putative GREs are reported on a number of fish genes (e.g., GH, myostatin, metallothionein, aromatase, and Na^+, K^+-ATPase subunit genes).

Cortisol and Metabolism

Generally, plasma cortisol levels rise with an acute stress, but the response is highly dependent upon the species and stress intensity. Handling or confinement, exhaustive exercise, and toxicant exposure will often elicit increases in plasma cortisol levels. Cortisol will be either free and thus physiologically available or bound to plasma steroid-binding globulins (SBGs) and thus not available (**Figure 3**); additionally, cortisol is metabolized within the liver and metabolic clearance rates (MtCRs) will additionally affect plasma levels. Free-cortisol content generally increases with acute stress and MtCR generally increases with chronic stress, leading to decreases or nonstressed levels of plasma cortisol.

Plasma glucose release is considered a secondary indicator of stress in vertebrates, but stress in fish can increase, decrease, or not change plasma glucose levels. In mammals, the rate-limiting gluconeogenic enzyme phospho*enol*pyruvate carboxykinase (PEPCK) contains a GRE, and cortisol or dexamethasone (DEX; a potent synthetic glucocorticoid) treatment stimulates PEPCK activity and stabilizes PEPCK messenger RNA (mRNA), and reduces hepatic glycogen content. The end result is an increase in gluconeogenesis and glycogenolysis (by activating GPase), ultimately increasing blood glucose (see **Figure 2**). In fish, there are significant interspecies differences in both glucose and hepatic glycogen and separating a stressor-specific effect by simply collecting the blood or tissue is extremely difficult. Using cortisol implants and isolated hepatocytes, the consensus is that cortisol or DEX treatment does increase hepatic gluconeogenic enzyme activities (including PEPCK), at least in some species. Some of the interspecific differences may arise from the apparent dissociation found between glucose content and the regulation of gluconeogenic enzymes (both activity and mRNA levels) observed in carnivorous fish species. However, tilapia (*Oreochromis mossambicus*) and rainbow trout hepatocytes do show a dose-dependent effect between cortisol and medium glucose in the absence of changes in glycogen, suggesting the primary cortisol affect is on gluconeogenesis. In rainbow trout with cortisol implants, GR downregulation does occur, which is thought to be associated with an increase in GR destruction by activation of proteosome activities.

GR mRNA is expressed in a variety of tissues including skeletal muscle. Reports exist that both cortisol and CAs may affect glycogenesis in fish skeletal muscle (**see** section Metabolism and CAs). Although controversial, glycogen production from lactate in fish white skeletal muscle is reported and, depending upon the glycogen content remaining following an exercise bout, both cortisol and Adr either increase glycogen production by increasing activities of glycogen synthase (at low glycogen) or increase glycogen breakdown by increasing activities of glycogen phosphorylase (at high glycogen). Both autoregulation of glycogen content by the prior glycogen status and the idea of a threshold value for this regulation are reported in mammals, but its precise role and its mechanistic basis remain to be explored in fish.

There is also general agreement that cortisol exerts a proteolytic function in fish white muscle and possibly liver; this action could fuel the gluconeogenic increases noted above. As mentioned earlier, direct evidence for this function is generally indirect or comes from studies of extreme or exaggerated behaviors (Pacific salmon migration, starvation, and exhaustive exercise) when cortisol levels rise. In general, plasma amino acid levels and hepatic amino acid transaminase activities rise in fish with cortisol implants. These amino acids are thought to be derived from white muscle proteolysis, which is extensive in migrating salmon; however, under normal conditions, where muscle represents >50% of total body mass, changes in muscle protein content are lost against very high background levels. To overcome this mass issue, other parameters are sometimes examined including ammonia output, which in theory, should rise with increased amino acid utilization. This does not always happen, although in resting Gulf toadfish (*Opsanus beta*) a highly significant correlation exists between increases in nitrogen excretion and plasma cortisol concentrations within normal resting levels (2–20 $\text{ng}\cdot\text{mL}^{-1}$). Mammalian tyrosine aminotransferase (TAT) contains a GRE that is considered the model for glucocorticoid action, but TAT activities do not increase with cortisol in most fish species. Alanine oxidation and gluconeogenesis do increase with cortisol in at least some fish hepatocyte preparations.

Lipids are a predominant fuel for normal fish metabolism and levels of all lipid classes are found in fish plasma and, as noted in section Metabolism and CAs, fish demonstrate very high resting lipolytic and re-esterification rates compared with mammals. Generally, increased cortisol increases plasma NEFA and peripheral lipolysis, and studies with salmon report cortisol activation of triacylglycerol lipase in mesenteric fat, red muscle, and liver. This latter effect was not seen in coho salmon (*O. kisutch*) smolts that already are naturally hypercortisolemic. Concurrent changes in some tissue lipid enzymes occur, but the precise role of these changes is not understood. In conditions of natural hypercortisolemia as during smoltification, these increases may relate to the intense restructuring of plasma membranes required during such events. Recent reports in mammals suggest that the increases in NEFA with cortisol are directly related to upregulation of lipase mRNA levels and activities, but also with cortisol acting permissively with other hormones. A detailed view of cortisol on lipids in fish is yet to be undertaken.

Cortisol and Growth

Cortisol is generally considered to decrease somatic growth in fish, but precisely how this comes about continues to be explored. Fish growth is a complex process modulated by the GH-insulin-like growth factor (IGF) axis and the neuroendocrine control of feeding. One or more GREs are reported within the promoter region of GH genes of numerous fish species, and using reporter gene assays, DEX stimulates transcriptional activities of the rainbow trout GH gene promoter, possibly through a cAMP response element. IGF is known to activate growth but plasma levels are kept low by a suite of hepatic-derived IGF-binding proteins (IGFBPs) and one of these (IGFBP-1) is very sensitive to stress and metabolic status. DEX was found to increase coho salmon hepatocyte IGFBP-1 mRNA and medium protein levels; increases in IGFBP-1 levels are known to decrease circulating IGF-I levels, the primary mitogen in fish. Confinement of gilthead sea bream (*Sparus aurata*) resulted in decreased IGF-I plasma levels consistent with decreased plasma GH levels and hepatic GH-receptor mRNA and suggested additional mechanisms to account for decreased growth during stress. In addition, chronic high-level increases in cortisol inhibit food intake in rainbow trout and goldfish while lower levels may actually increase food intake. The principal central and peripheral pathways responsible for such effects in fish are yet to be defined, but they may be related to cortisol effects on gut absorption or its affect on triiodothyronine (T3) levels.

In summary, cortisol affects many aspects of metabolism and growth, which in most cases are dependent upon the physiological status of the fish. In general, cortisol increases glycemia and aminoacidemia, and suppresses growth. These effects occur as a result of the peripheral action of cortisol binding to its receptor and activating transcription of key cellular proteins.

Other Related Hormones

Stressors and the stress response affect many fish tissues and multiple signaling systems, and not simply CAs and glucocorticoids. For example, CRF/H the principal secretagogue of ACTH by the pituitary can also activate secretion of melanocyte-stimulating hormone (αMSH) and even thyroid-stimulating hormone, both of which may act on tissues in quite different ways from ACTH. The best indication of this is the recent fish transcriptomic analysis done using low-density custom or high-density DNA microarrays for which a large number are presently available. Issues remain with the use of these arrays, but rainbow trout exposed to a moderate acute handling stress significantly increased a number of hepatic transcripts for hormone receptors and metabolic genes. These included receptors for testosterone, insulin, IGF and GH, glucose transporters, glucokinase, pyruvate kinase and, of course, PEPCK to note just a few. Using these new molecular techniques, it is clear that our initial view of the stress response in fish may need to be expanded to understand the full extent of the metabolic and growth interactions.

Glossary

Atresia Any of a class of amines derived from a catechol that acts as chemical messengers (a hormone or neurotransmitter). The main catecholamines are dopamine, adrenaline, and noradrenaline and these are secreted by neurons of the autonomic nervous system or specific chromaffin cells of the head kidney.

Catecholamine Any of a class of amines derived from a catechol that acts as chemical messengers (a hormone or neurotransmitter). The main catecholamines are dopamine, adrenaline, and noradrenaline and these are secreted by neurons of the autonomic nervous system or specific chromaffin cells of the head kidney.

Complement system Series of proteins of the innate immune system that are sequentially activated resulting in the release of cytokines and pathogen clearance through the membrane attack complex.

Cytokine Chemical messenger that activates or suppresses mechanisms of the immune system and may often influence other physiological regulatory systems.

Cytotoxicity Defense mechanism of the immune system producing cell death, mainly bacteria.

Glucocorticoid Molecule of lipidic nature secreted by the interrenal tissue in fish as a result of the activation of the hypothalamic–pituitary–interrenal axis after stress. The main glucocorticoid in fish is cortisol and it can mobilize glucidic reserves.

Gonadotropin Hormone produced in the pituitary gland that regulates the reproductive process in vertebrates. The main gonadotropins are the follicle-stimulating hormone and the luteinizing hormone.

Gonads Structures specialized in the production and feeding of gametes and synthesis of reproductive hormones.

Granulocyte A medium-sized white blood cell with variously shaped nuclei and a cytoplasm-containing granules that can perform phagocytosis.

Head kidney Cephalic portion of the kidney of fish in which several key functions during stress are performed, such as hematopoiesis, maturation of immune cells, and hormone secretion.

Hormone Signaling molecule released by a cell that either stimulates the cell of origin (autocrine), nearby cells (paracrine), or travels via the bloodstream to distant cells (endocrine).

Humoral immunity Array of defense mechanisms based on molecules, mainly proteins, that are found in the blood plasma.

Immune suppression Relevant reduction or disappearance of the capacity of response of one or several immune mechanisms.

Immunoglogulin An antibody playing a critical role in immunity.

Innate immunity A number of immune defense mechanisms that defend the host from infection by other organisms, in a nonspecific manner. These mechanisms do not depend on a previous recognition process and do not confer long-lasting or protective immunity to the host.

Interrenal cell Cell found in the head kidney of teleost fish that synthesizes and releases cortisol.

Lymphocyte A type of white blood cell involved in cellular defense and immunity. Granular lymphocytes are called natural killer cells and small lymphocytes produce immunoglobulins (B cells) or toxic granules to pathogens (T cells).

Lysozyme Protein that can be found in plasma, mucus, and other fluids of the animals, involved in the immune defense due to its lytic properties against bacterial cell walls.

Macrophage Specialized white blood cell matured from the monocyte that are able to perform phagocytosis.

Melanocyte-stimulating hormone (MSH) A peptide hormone synthesized in and secreted by the pars intermedia of the pituitary. It induces intracellular dispersion of melanosomes, resulting in skin darkening, and dispersion of xanthophore pigments, as well as longer-term morphological increases in melanophores and their melanogenesis.

Monocyte The largest white blood cell, produced in the head kidney that will be mobilized as a response to inflammatory signals and mature to macrophages.

Neuroendocrine axis Functional connection between structures of the brain, namely hypothalamus, and the pituitary gland that regulates physiological functions such as reproduction, growth, or stress response.

Neuropeptide Any member of a class of protein-like molecules released by the nervous system. They consist of short chains of amino acids, functioning as neurotransmitters (direct synaptic effects) or hormones (indirect modulatory effects).

Oocyte The female germ cell (gametocyte) from which an egg develops. After the onset of meiosis, oogonia become oocytes.

Pituitary An area of the brain involved with the release of regulatory hormones including adrenocorticotropic hormone.

Steroid Lipid compound consisting of a four-ring carbon skeleton (derived from cholesterol) and attached chemical groups. Some steroids act as hormones (17b-estradiol, 11-ketotestosterone) but others do not (cholesterol).

Stress State which alters the physiological equilibrium as a result of a challenge; the adaptive responses of an animal beyond the normal range or the normal functioning.

Stressor Any agent generating a situation of stress and inducing a coordinated response involving a transient modification of the physiological regulation.

Stressors cause a diverse array of consequences in animals depending on the type of stressor, its intensity, duration, and environmental circumstances. These consequences can be species specific. This article deals with these consequences in two areas, health and reproduction, as these two physiological systems can be significantly affected by stressors. Reproduction involves an increase in production of structures in the gonads and, sometimes, also elicits complex behaviors related to movement and aggression. Similarly, the production and maturation of immune cells and the increase of the synthesis of proteins, such as immunoglobulins, involve a delivery of energetic resources to support these processes. Therefore, stressful episodes may affect the correct or full function of these systems as resources are diverted to cope with the stress, thus compromising the reproductive ability and the immunocompetence.

Impact of Stress on Reproduction

Stressors in the natural fish populations may impair the reproductive process, therefore reducing the number of individuals (**Figure 1**). Many species that are cultured in captivity do not spontaneously ovulate or spermiate, although some of them may experience gonadal maturation. This indicates that the conditions must be optimal in order to fully reach the completion of the reproductive process (**see also Reproduction**: The Diversity of Fish Reproduction: An Introduction), otherwise, it is necessary to use artificial methods (exogenous hormones or abdominal stripping). From this observation, it is assumed that stress directly affects reproductive performance and that some stressors, either related to husbandry or simply because of captivity conditions, impair reproduction.

A number of studies have shown that stress induces a negative effect on reproductive fitness. However, not all stressors have been shown to alter reproduction (e.g., handling stressors), suggesting that the effects of stress on reproductive fitness strongly depends on the type of stressor, especially concerning the gamete quality. Even so recent studies indicate that, as with other performance activities, the deleterious nature of stress depends on the balance between input resources (food and reserves), the maintenance costs (standard metabolism, digestion, and exercise), and the reproduction-associated costs (see **Figure 2**). These reproductive costs will include the maturation processes (growth of gonads and

gametes) and reproductive activity (behavioral reproduction and spawning). Since stressors may impose an overload on resource expenditure to cope with the situation, this balance can be maintained if the energy available is sufficient. In this case, no deleterious effects may be observed; otherwise suppressive effects would take place impairing the reproductive performance. This would explain why, under stress, some studies do not observe changes, for instance, in the vitellogenin production, whereas others show oocyte atresia (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction).

Nevertheless, the reports on effects of stressors mostly show alterations in the reproductive performance. Thus, manipulations including confinement and capture may produce ovarian atresia. Handling results in lowered levels of reproductive hormones, such as 17β-estradiol (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction), fewer oocyte numbers (after stripping), and reduction of egg quality. Chronic or repeated handling stressors produce smaller eggs and reduce spermatic quality. Starvation decreases the levels of plasma and pituitary gonadotropins, and changes in the gonadosomatic index are observed in fish under low water oxygen conditions. Sudden alteration of the environmental temperature may induce reduced somatic condition and modifications in gonadal maturation.

Chemical stressors can greatly impair the reproductive process through various processes: by reducing egg numbers and size or inducing deformation of embryos; absence of spermatocytes; loss of organization in testes; and decrease or retardation in the spawning or increase of atresic eggs. In this manner, contaminants, such as heavy metals and pesticides, greatly impact reproduction, with severe population consequences. They can also interfere with the hormonal reproductive system of fish, causing effects such as sex change or arrest of reproduction.

Nutrition and food availability and quality are important in determining reproductive performance in fish. Insufficient nutrients may compromise reproductive success, as does the absence or the deficiency of certain diet components. For instance, lipid and fatty acid deficiency is associated with low fecundity and low-quality egg and sperm in fish under culture. Restriction of food resources and of specific components may either affect the energetic balance, preventing full reproduction or impairing hormonal equipment.

Pathogens (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Molecular Fish Pathology) and parasites, by inducing stress depending on the degree of infection and duration of exposure, also affect reproduction since the endocrine and the immune systems interact during stress. Pathogens induce apoptosis in the ovary or changes in the maturation state, thus decreasing gamete quality and egg production. This effect may be mediated by pathogen-induced cytokines such as tumor necrosis factor alpha (TNFα). Similarly, parasites may prevent gonadal development and reproductive performance depending on their infestation degree.

Most fish depend on temperature and photoperiod to determine the main traits of their reproductive clock. Thus, sex determination, while genetically based, may suffer if alterations to temperature and photoperiod are severe.

Effects on the Reproductive Behavior

Stressors may affect reproductive behavior (**see also Reproduction**: The Diversity of Fish Reproduction: An Introduction), especially in species such as cichlids in which behavior is an important part of reproductive performance. Stressors can affect reproductive behavior in a number of different ways. First, handling stressors can prevent fish from performing reproductive activities, such as nest building, courtship, or migration. Second, the increase of circulating hormones after stress may interfere with the social status, thus reducing reproductive competence, and even affecting structures of the hypothalamus–pituitary–gonadal axis (HPG axis). Third, reproductive behavior may be a highly energy-demanding process that may not eventually be completed since the resources available are used to cope with the stressors.

Stressors causing social alterations may also be a reason for reduced reproductive performance, especially in hermaphroditic species. Some species, such as wrasse (fish from the family Labridae) or clown fishes (family Pomacentridae), change sex depending on factors, such as size and population density. Husbandry stressors affecting these factors or the related environmental conditions may alter reproductive abilities in these species (**see also Hormonal Control of Reproduction and Growth**: Endocrine Control of Sex Differentiation in Fish).

Effects on the Progeny

The effects of stressors may be deleterious not only for the progenitors but also for the progeny either in gamete quality and/or quantity. Fish with stress-induced low-levels of gonadal steroids have lower fecundity. The quality of the rearing phase of fish can affect the timing of successive reproductive events at later stages. The incidence of stress depends on the resources available, mainly on the nutritional input and quality; also, other factors related to the life quality may improve reproductive success. The effects of chemical stressors or contaminants on the progeny appear to be more severe, resulting in both egg reduction and malformations in embryos, and further reduction in the number of viable juveniles.

Overall, the stressor effects observed in the progeny of various fish species suggest that there are two general strategies for managing the stress. On the one hand, there is the strategy of preserving the health of the breeder and thus reducing the number of eggs, since fewer resources are available due to stressors. On the other hand, egg size and quality are maintained in the presence of the stress at a cost paid by somatic tissues. In the latter case, an increase in progeny cortisol levels is prevented by the progenitors (**Figure 3**). This could be the case of environmental challenges affecting reproduction in cultured fish. As an example, short-term, low-severity stressors associated with hatchery practices do not affect gamete quality of sturgeons.

Alterations of Reproductive Hormones

In all vertebrates, reproduction is a process basically controlled by hormones released at three different levels along the reproductive endocrine (HPG) axis – the hypothalamus, releasing the gonadotropin-releasing hormone (GnRH), the pituitary, releasing gonadotropins (GtH), and the gonads, producing gonadal steroids (progesterone, androgens, and estrogens). Given that the

Breeder self-protection.

- The breeder health is maintained after stress and cortisol treatment
- body weight is maintained and the production of eggs is readjusted
- The development of the ovary is compromised during vitellogenesis.

Progeny protection.

- gg size and quality are not affected when stress occurs during late vitellogenesis.
- Eggs are maintained and the cost is paid by somatic tissues.
- The rise/excess in cortisol levels in the progeny is prevented by the progenitors.

Protection mechanisms:

- Mature females show an atenuated response to cortisol.
- Cortisol-binding proteins prevent tissue receptor binding.
- Faster enzymatic action in follicles converting cortisol to cortisone.

Figure 3 Protection strategies for reproduction in fish under stress.

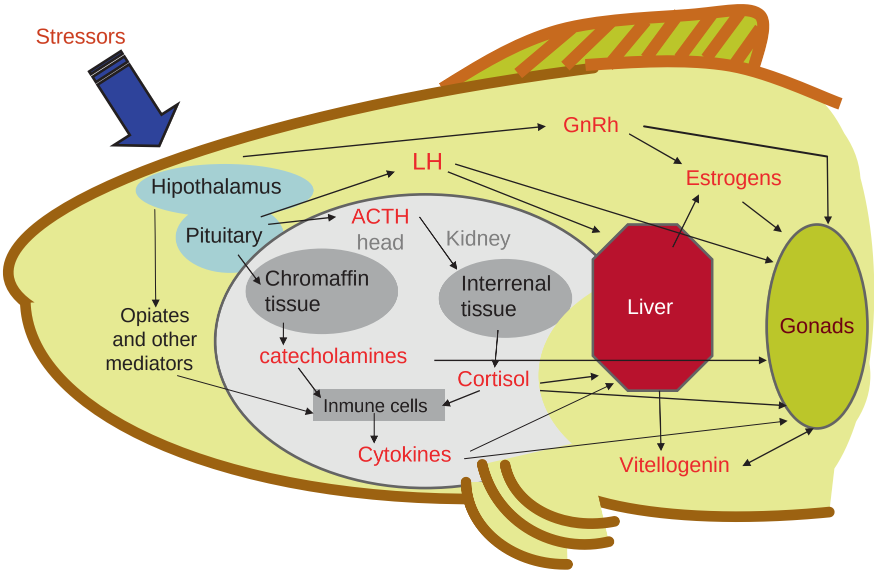

Figure 4 Scheme of the organs (hypothalamus, pituitary, head kidney, liver, and gonads) and messengers involved in stress, reproduction, and immunity.

stress response is also driven by another endocrine axis (hypothalamus–pituitary–interrenal (HPI); **see also The Pituitary**: Development of the Hypothalamus-Pituitary-Interrenal Axis), involving the same neuroendocrine structures, and that the final hormone of the HPIaxis is cortisol (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids), a steroid hormone, it is apparent that the influence or interference of these messengers on both systems may exist during stress episodes (**Figure 4**).

Little is known about the direct effects of stressors on the release of GnRH and its effect on the gonadotrope cells of the pituitary. Acute confinement of male brown trout (*Salmo trutta)* induces an increase of plasma GtH, whereas in the white sucker (*Catostomus commersoni*) GtH is reduced 24 h after capture. Cortisol-mediated impairment of stress on reproduction does not appear to be mediated through inhibition of GtH secretion in rainbow trout (*Oncorhynchus mykiss*). Nevertheless, it is difficult to differentiate the effects of stress from that of cortisol on fish reproduction under stressful situations (**see also Hormonal Responses to Stress**: Stress Effect on Growth and Metabolism).

Regarding gonadal hormones, reduction in testosterone and 11-ketotestosterone (11KT) levels (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction) corresponds with an increase in cortisol, including after chronic confinement. Thus, higher population density reduces 11KT in males, as well as 17β-estradiol and testosterone concentrations in females. Brown trout subjected to crowding elevated plasma adrenocorticotropin hormone (ACTH) and cortisol levels and decreased testosterone and 11KT levels, despite elevated gonadotropin levels. In non salmonids, depression of most gonadal steroids with a concurrent increase of cortisol occurs after capture, transport, or hypoxia and also up to 5 days after confinement.

The Interaction between Reproductive Hormones and Stress Hormones

As mentioned before, the structure of hormones from both the gonadal axis and stress axis is similar, belonging to the family of cholesterol-derived steroids (**Figure 5**). Thus, variations in cortisol, or its precursors corticotropin-releasing factor (CRF) and ACTH, may influence the concentrations of gonadal steroids. Arginine vasotocin also appears to be part of the stress response of fish affecting reproduction. Urotensin-I is also corticotropic and it is involved in regulating cortisol during reproduction.

The diversity in hormone levels among species, particularly cortisol, makes it difficult to predict such interactions. For instance, plasma cortisol levels reported in immature female trout range from 0.5 to 20 ng mL^{-1} and up to 90 ng mL^{-1} in some species of salmon (*Oncorhynchus masou*), whereas levels in immature males range from 1 to 4 ng mL^{-1} in most fish species and up to 70 ng mL^{-1} in *O. masou*. In mature fish, the levels increase significantly. Thus, levels of mature females rise from 15 to 80 ng mL^{-1} in trout up to 180 ng mL^{-1} in *Oncorhynchus nerka* or 400 ng mL^{-1} in *O. masou*, and in males from 5 to 20 ng mL^{-1} in trout up to 80 ng mL^{-1} in other species or 350 ng mL^{-1} in *O. masou* or *O. tshawytscha*. Therefore, since the plasma cortisol levels of stressed fish may oscillate between 50 and 100–400 ng mL^{-1} or more,

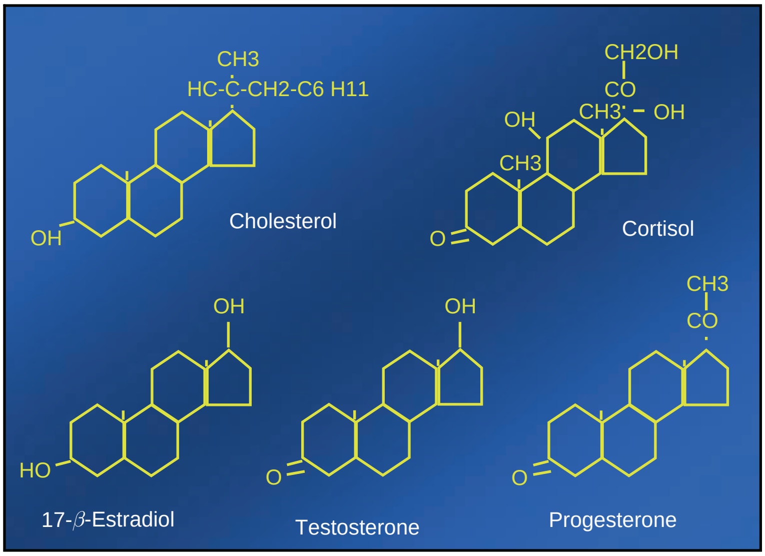

Figure 5 Chemical structure of the hormonal steroids.

cross-interactions between the sex and stress hormone axes will be seen in fish during the reproductive period, especially when a stressor is present. Thus, it is difficult to tease apart the effects of cortisol on reproduction versus the consequences due to the activation of stress-coping mechanisms in response to a stressor.

The effects of cortisol on reproductive hormones (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction) are diverse. A negative correlation between GtH and cortisol after stress exists. Cortisol administration decreases plasma estradiol and vitellogenin levels and reduces gonadal size. Inhibiting effects of exogenous cortisol administration on androgens exist, but are not seen if plasma cortisol concentration increases as a result of a natural increase due to the spawning period. Exogenously administered cortisol resulted in retarded oocyte growth, reduced condition factor, and lowered serum testosterone, and 17β-estradiol in tilapia (*Oreochromis* sp.). However, studies in goldfish (*Carassius auratus*), carp (*Cyprinus carpio*), and one sparid (*Pagrus auratus*) reveal that cortisol does not affect testosterone and 17β-estradiol production at the level of ovarian steroidogenesis. Other *in vitro* studies show inconsistent results. In some studies, cortisol did not inhibit steroidogenesis or had deleterious effects on oocyte maturation in rainbow trout. In other studies, cortisol blocked the production and metabolism of hydroxyprogesterone in rainbow trout, thereby reducing the levels of estradiol and testosterone, but this was not seen in *Salvelinus* (**Figure 6**).

Inhibitory Mechanisms

Several hypotheses have been formulated to explain the alterations observed in the reproductive process in a stressed fish. They involve alterations in the endocrine axes and the mechanisms related to the processing of circulating steroids (**Figure 7**).

One interaction mechanism induces a lower intensity of response at the initial levels of the axes that would

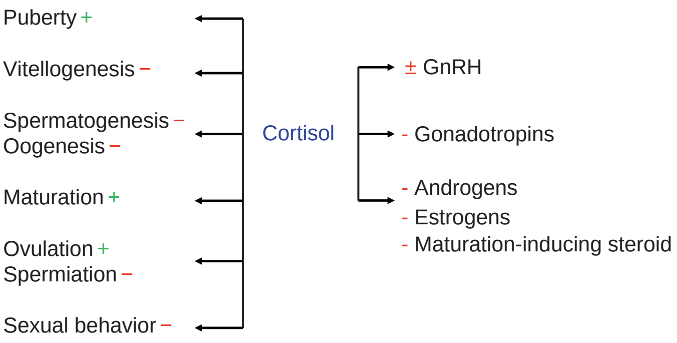

Figure 6 Stimulatory (+) or inhibitory (–) actions of cortisol on reproduction.

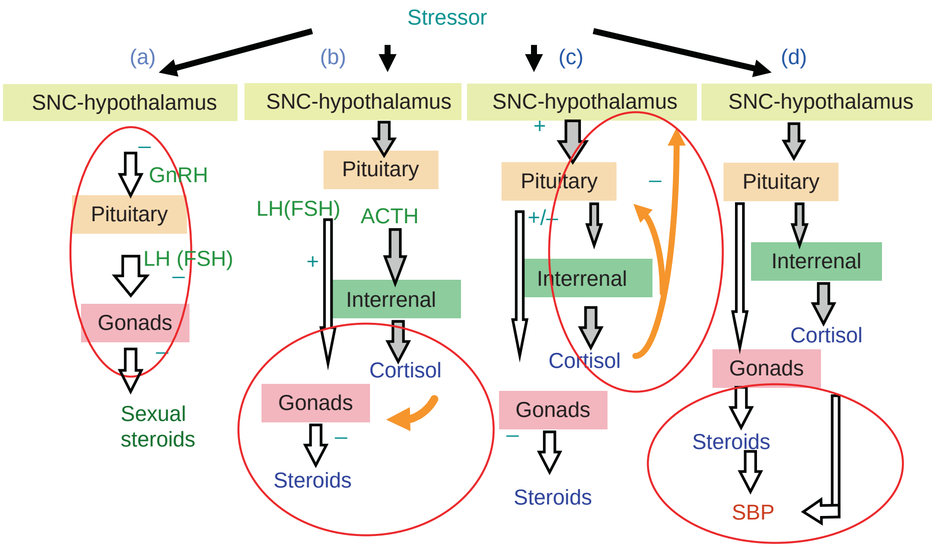

Figure 7 Possible mechanisms by which stress may affect the hormonal reproductive performance in fish. The red circle indicates the main point of action: (a) effects on SNC; (b) cortisol on gonads; (c) feedback; and (d) effects on circulating steroids.

reduce the full reproductive capacity. Under these circumstances, the hypothalamic and pituitary activation of gonads become less effective. The second mechanism involves cortisol altering gonadal efficiency by altering the production of the gonadal steroids and/or the production or quality of gametes. With this mechanism of steroidogenic inhibition, the effect of cortisol is exerted on the signal transduction of GtH, rather than at the pituitary level. A third mechanism consists of a feedback action of cortisol at the upper levels of the axis by blocking the synthesis or the secretion of gonadotropins or modulating the efficacy of such mechanisms. The fourth mechanism focuses on the steroid-binding protein (SBP). Estimations of the binding of the SBP indicate that the cortisol concentrations in plasma are over 100 times more than estradiol, which could displace the binding E2-SBP to cortisol-SBP. This would result in a higher rate of estradiol clearance, thereby affecting E2 efficacy in the activation and control of the reproductive activity.

Overall, the effects of stress on the reproductive ability of fish are mostly deleterious, but the effects will mostly depend on the duration and intensity of the stressor (see **Figure 8**). Regarding cortisol, its role may be as a modulator, rather than as a suppressor, since the deleterious effects are seen mostly in the early periods of reproduction and not at the later stages.

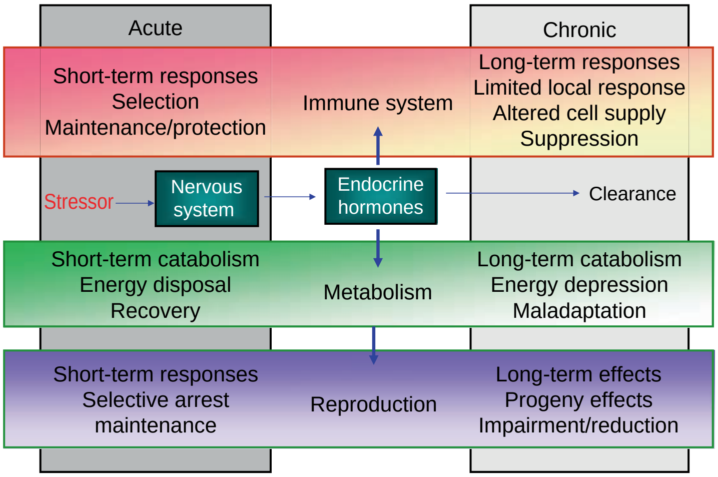

Figure 8 Comparison of short-term and long-term effects of stressors on the reproductive, metabolic, or immune performances.

Impact of Stress on Health

Fish, as in other vertebrates, maintain their integrity against infection by environmental pathogens (**see also** Cellular, **Molecular, Genomics, and Biomedical Approaches**: Molecular Fish Pathology) by activating the immune system, which is a complex network of specialized cells and molecules that are supported by other physiological systems (i.e., the other regulatory systems, neural and endocrine, and the energetic and metabolic system supplying resources for these functions). Stress, as a challenge to homeostatic equilibrium, may eventually modify such a balance and compromise the efficiency of the immune system.

The Neuro-Immuno-Endocrine Network

Similar to reproduction and growth (**see also Energy Utilization in Growth**: Energetics of Growth), the immune system and other defense processes are energetically demanding. In the event of an alarm situation, the stress response is by nature, an integrated response, thus affecting all physiological compartments. This means that the three main regulatory systems (i.e., neural, endocrine, and immune system) will be involved. Indeed, certain molecules of the neuroendocrine and immune networks belong to the same superfamilies and their functions are evolutionarily conserved.

Such molecules have been identified in higher vertebrates and some in zebrafish (*Danio rerio)*. Molecules such as heat shock proteins, acute phase proteins, or metallothioneins are present in most animals and have common generic functions involved in processes such as cell integrity, protection against oxidative processes, or cell regulation. Similarly, the influence of autonomic neurotransmitters is present in most fish. It has also been shown that the immune system can be regulated by specific peptides derived from the preopiomelanocortin (POMC) protein, the precursor of the pituitary hormones ACTH or alpha melanocyte-stimulating hormone (α-MSH), as some of these molecules are synthesized by immune cells.

Regarding the specific bidirectional connection between the immune system and the endocrine system, it has been shown that the recombinant Interleukin 1-β produce an increase of plasma cortisol or that cortisol inhibits the expression of TNFα. The receptor for interleukin (IL)1-β is present in both pars distalis and pars intermedia of the pituitary (**see also Brain and Nervous System**: Functional Morphology of the Brains of Ray-Finned Fishes) and that this cytokine stimulates the release of α-MSH and β-endorphin. At the same time, α-MSH modulates the production of cytokines by monocytes and macrophages. The corticosteroids affect phagocyte processes and modulate leukocyte responses. Some other hormones such as the GH and other interleukins may act directly on blood cells and stimulate their immune activity (see **Figure 9**).

In terms of the activation of responses at the endocrine and immune systems, such a connection is relevant since most often antigen recognition and stimulation share common stress response pathways that are also activated by physical or chemical stressors. For instance, warning mechanisms (acute phase proteins, heat shock proteins, cytokines, and neuropeptides) can be activated due to either pathogens or other stressors, thus modulating the hormone release and the involvement of metabolic–energetic responses, the cell protection systems, and the cellular and humoral immune responses (**Figure 10**).

The Role of the Head Kidney

In fish, another key organ in organizing the stress response is the head kidney (**see also Role of the Kidneys**: Histology of the Kidney), particularly concerning the activation of immune mechanisms driven by endocrine mediators. The head kidney is a key player in the endocrine response to stress (releasing cortisol (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids) and catecholamines (**see also Hormonal Responses to Stress**: Catecholamines) to the blood) and the hematopoietic response, producing different blood cell lines, including producing and maturing white blood cells for the immune defense and red blood cells for oxygen transport and delivery to the tissues (see **Figure 4**). Therefore, other than the neuroendocrine centers, this organ facilitates the stress response and the messenger molecules, such as neuropeptides, hormones, or cytokines, may play the role of the mediator between all the involved organs, not only through endocrine connections but also through direct paracrine action among the different cells present in the head kidney.

Stress and Immune Suppression

The overall effect of stressors often results in immune suppression. Yet, the effects on immune function depend on the type of stressor, its duration, and intensity; are varied; and even can be opposite; suppression may not always be observed. Thus, general rules on the effects of stressors on the immune system are lacking.

Stress normally compromises immunocompetence by diverting energy from immune function to the processes directly associated with coping with the stress (see **Figure 8**). Some of these changes are transient and without long-lasting immune suppression. Some initial or fast responses are stimulatory, at least at initial stages (see **Figure 10**). However, immune suppression is typically observed if the stressor persists, that is, it is chronic as opposed to acute.

Effects of Stressors on the Immune Function: Acute and Chronic Stressors

Overall, acute stressors may activate some immune responses and suppress others, whereas chronic stress normally results in immune suppression (see **Figure 8**).

An acute handling stress may induce a mitotic or proliferative response on the immune cells in the head kidney, spleen, or thymus. Handling stress can increase the number of glucocorticoid receptors in splenic and pronephric leukocytes, while handling and hypoxia produce an immediate increase of lysozyme and C3 complement proteins. All these responses should stimulate the immune system. By contrast, transport or high-density stress may suppress mitosis of head kidney leukocytes (**see also Blood**: Cellular Composition of the Blood).

Under chronic stress, fish experience immune suppression. Repeated chasing stress decreases the activity of the complement proteins. High fish density induces a decrease in the agglutinating capacity of blood and a reduction in the capacity of cytotoxicity and immune-related chemiluminescence. Dietary deficiencies depress nonspecific immune indicators. Pesticides, metals, or organic compounds may chronically induce immunosuppression, although phagocytic capacity can increase.

Genomic Assessment

Genomic analysis (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Global Gene Expression Profiling in Fish) confirms that the stress response is complex, involving most tissues, physiological compartments, and regulatory systems. Gene expression of the main metabolic and energetic pathways is upregulated. Genes involved in the cell protection mechanisms and energetic-demanding pathways, including metal-ion-binding proteins, glycolytic enzymes, and motor proteins, are transiently and rapidly induced. However, genes involved in immune response, cell proliferation and growth, signal transduction, apoptosis, protein biosynthesis, and folding increase more gradually and at later stages preparing the system for the phase of resistance. Therefore, the persistence of the stressor affects this second phase of gene expression, leading to immune suppression. Lipopolysaccharide (LPS)-stimulated fish macrophages show an expected increase of genes related to response to stress, humoral immunity, and apoptosis; administration of cortisol plus LPS suppresses this response. Nevertheless, the range of effects is more complex than simply the antagonism of LPS-induced transcriptional responses.

Immune Regulatory Hormones. The Role of Cortisol

Cortisol (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids) is a key mediator of immune suppression, as illustrated in numerous studies (**Figure 11**). For instance, macrophage respiration is suppressed after cortisol treatment, as is splenic nitric oxide and leukocyte production. Similarly, the mitogenic response to LPS is altered after incubation of leukocytes with cortisol. Head kidney monocyte-macrophage cell treatment with cortisol reduces the adherent capacity of such immune cells and increases the apoptotic index of lymphocytes and undifferentiated immune cells, suggesting cortisol-induced modulation of the hematopoietic potential of the fish (**see also Blood**: Cellular Composition of the Blood).

On the other hand, cortisol may activate an increase of leukocyte numbers in thymus and head kidney or myeloid and granulocyte numbers. In addition, a diversity of responses ranges from suppressive to activating, which is immune cell specific and dependent on cortisol concentration. Thus, cortisol may reduce B cells but increase the neutrophils, or may inhibit the lymphocyte proliferation and induce apoptosis, but not change their phagocytic competence.

Cortisol effects in peripheral tissues are equally varied. Cortisol does not consistently affect the phagocytic capacity or apoptosis of macrophages. Yet, cortisol clearly reduces pro-inflammatory cytokine expression in LPS-stimulated macrophages. The dual peripheral action of cortisol may be related to its two glucocorticoid receptors (GRs) found in most fish species. GR1 would be sensitive to high levels of cortisol (acute stress) and mediate the inhibition of LPS-induced cytokine production (TNFα, IL-12, or IFN). GR2 signaling-mediated modulation of humoral immunity would occur at lower cortisol levels. Current work on GRs should help to clarify their role in the physiological responses to stressors.

In summary, cortisol clearly modulates the immune response, rather than being a direct immunosuppressive agent. This modulatory role of cortisol fits with the role of other hormones of the HPI axis, which collectively ensure adequate supply of energetic and metabolic resources to cope with a stressor. This metabolic hypothesis allows some essential responses to be maintained, that is, phagocytosis in the tissues, while reducing other immune functions such as cell proliferation, which can be delayed until the recovery phase from the stress episode and refueling of resources.

Stress and Pathologies

Stress may result in pathologies. Stress is often the initial condition under which pathogens invade a host

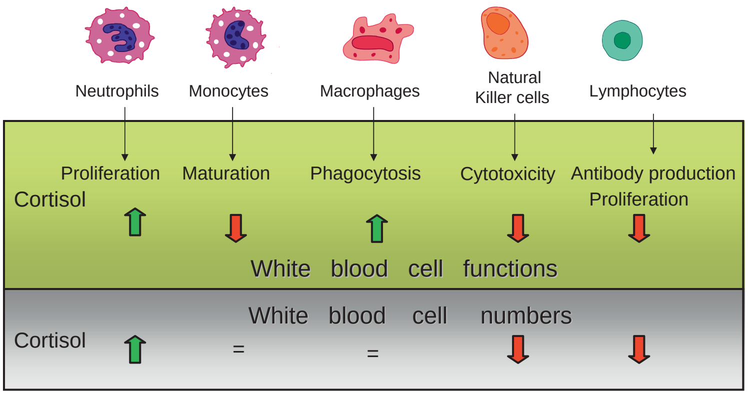

Figure 11 Reported effects of cortisol on the white blood cell numbers and function.

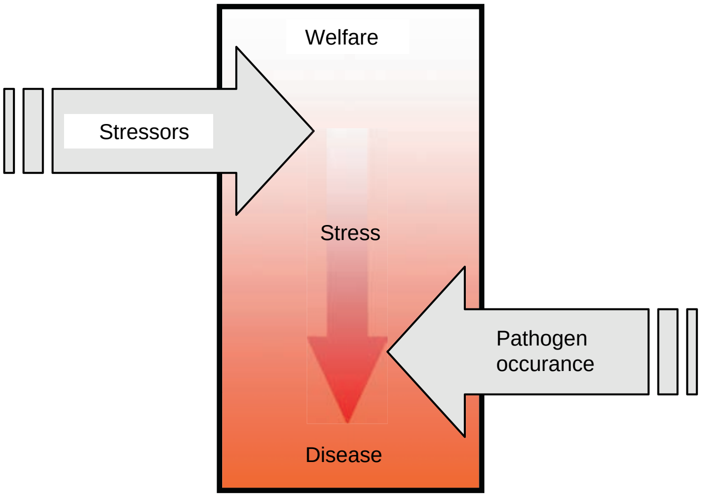

Figure 12 Stress affects facilitating pathogen infection and disease.

(**Figure 12**). Thus, pollution, contamination (**see also Toxicology**: The Toxicology of Metals in Fishes and The Toxicology of Organics in Fishes), and stress have been associated to both disease episodes or husbandry-related pathologies. For instance, cortisol increases cell death in fish previously contaminated with chemicals or high levels of cortisol increase the susceptibility of some fish to *Ichthyopthirius*. Thus, fish under compromised conditions (i.e., contaminated waters, presence of parasites (**see also Behavioral Responses to the Environment**: Manipulation of Fish Phenotype by Parasites), or sudden reductions of water temperature) show the classic hormone and metabolic response as in the chronic stress, as well as an increase in the susceptibility to pathogens, resulting in a heavy decrease of the immune competence and increased mortality.

The Integrated Immune Response to Stressors. Activation–Suppression–Modulation

The stress response may be modified by four factors: the species, the type of stressor, stress intensity, and stress duration. In addition, the response will depend on when response is monitored. Neural and HPI-axis responses occur in seconds to minutes, whereas metabolic and energetic responses take minutes to hours and days.

Stress duration and intensity may significantly change the immune status of the fish. Under acute stressors, the cost is short: high levels of circulating hormones are recorded but the energetic and metabolic consequences are limited. In these circumstances, an activating response is common but less so is suppression. Thus, an increase of cytokine production, an increase of other relevant proteins such as C3 or lysozyme, or the activation of enzymatic cascades such as the complement system may be observed.

However, the costs of chronic or repeated stressors are higher at medium term. Thus, the resources are diverted from other physiological processes, including the immune system, to cope with the stressor. The synthesis of new proteins, the production of immune cells in the head kidney, or the induction of inflammatory responses, which are costly processes, may be blocked until recovery. Therefore, responses based on these proteins or cells are compromised: a reduction of antibody synthesis, a reduction or arrest of monocyte maturation, and therefore loss of phagocytic potential.

In summary, indicators of immune suppression after stress are classified as innate, acquired, molecular, or cellular. However, none by themself is a reliable indicator, since each one changes depending on the conditions. A combination of indicators and/or a challenge test on disease resistance may be a better choice. A good immune indicator should ideally respond consistently to a wide range of stimuli, show a repetitive dynamics in terms of time and intensity for each stimulus, and reflect changes in both the innate and the adaptive response. Often, stress has two phases, initial activation and then suppression, each of which is reflected in several specific variables of the immune system changing (serum lysozyme, serum complement, number of lymphocytes, plasma immunoglobulins, white cell number and distribution, and nitric oxide production).

Glossary

Androgen Any natural or synthetic steroid hormone that is principally involved in growth, development, and maintenance of the male reproductive system and secondary sexual characteristics. The major endogenous fish androgen is 11-ketotestosterone.

Electro-olfactogram (EOG) recording Measures olfactory sensitivity using extracellular recording of odor-induced changes in transepithelial voltage via an electrode placed near the surface of the olfactory epithelium and is thought to measure generator potentials of olfactory receptor neurons.

Estrogen Any natural or synthetic steroid hormone that controls female sexual development, secondary sexual characteristics, and stimulates egg production. The endogenous fish estrogen is 17-estradiol and together with progesterone (another steroid hormone), it regulates the development and function of sex organs.

Gonadotropin Hormone produced in the pituitary gland that regulates the reproductive process in vertebrates. The main gonadotropins are the follicle-stimulating hormone and the luteinizing hormone.

Hormonal pheromone A pheromone that contains at least one compound that is a hormone, a hormone precursor, or a hormone metabolite.

Luteinizing hormone (LH) A dimeric glycoprotein hormone released from the anterior pituitary gland that acts through gonadal membrane receptors to stimulate steroidogenesis and gametogenesis. LH is a gonadotropin.

Maturation-inducing steroid (MIS) A steroid produced by ovarian follicular cells to promote final oocyte maturation: 4-pregnen-17,20β-diol-3-one (17,20β-P) appears to be the MIS in the majority of fishes.

Odor A mixture of odorants that is both detectable and distinguishable by the olfactory system.

Odorant A chemical that binds to and stimulates an olfactory receptor.

Olfactory receptor A protein located in membranes of olfactory receptor neurons that binds odorants.

Olfactory receptor neuron (ORN) A neuron in the olfactory epithelium that contains olfactory receptors.

Pheromone A chemical, or mixture of chemicals, that is released to the environment by an individual and that evokes a specific and adaptive response in conspecifics: the term pheromone is used in many ways – our definition follows the original and is broad.

Pheromone active space The space (volume of water) in which a pheromone can be detected.

Prostaglandin Any member of a group of lipid compounds that are 20-carbon fatty acid derivatives containing a five-carbon ring. They mediate a wide range of physiological functions in fish, such as ovulation (follicular rupture), female sexual behavior, and also act as pheromones in some species.

Steroid Lipid compound consisting of a four-ring carbon skeleton and attached chemical groups. Some steroids act as hormones (e.g., 17β-estradiol and 11-ketotestosterone) but others do not (e.g., cholesterol).

Introduction

Imagine the benefits of being able to walk through a dark and crowded room and, with just a subtle sniff, determine not only the gender, but also the reproductive status of anyone you pass. Although beyond our chemosensory abilities, similar acts of chemically mediated social snooping are commonplace in fishes that have evolved the ability to smell and respond to extremely low concentrations of hormones and related chemicals released by conspecifics (other members of the same species). We refer to this group of odorants as hormonal pheromones, although only some are unmodified hormones, and the majority in fact might be hormonal precursors or metabolites. In this brief overview, we examine hormonal pheromone function primarily from the perspective of the common goldfish (*Carassius auratus*), because only in this species are we beginning to understand how hormonal pheromones are released and detected, how they exert their effects, and how their biological responses affect reproductive success. Nonetheless, there is growing evidence that hormonal pheromone systems are common, if not ubiquitous, among fishes.

Fish have evolved in a physical–perceptual world that differs from ours in several key characteristics. Particularly in large lakes and oceans, the three-dimensional, featureless, and often dimly lit living spaces of fish pose unique challenges to establishing social interactions and achieving reproductive synchrony. This is particularly obvious when we consider that the majority of fish engages in external fertilization using gametes that are short-lived in water. Along with the limitations that the aquatic medium places on several sensory modalities, it does confer one remarkable advantage: it enables the myriad of information-rich chemicals that fish inevitably release to the water to be readily transported to the olfactory organs of conspecifics, thereby facilitating the evolutionary origin of pheromone function.

Although it has been known for many years that fish have evolved sex pheromones to synchronize both gamete maturity (a primer effect) and behavioral interactions between individuals (releaser effects), the chemical nature of these pheromones has only recently become apparent. The idea that at least some fish pheromones might be endogenous hormones released into the external environment was first proposed by Kjell Døving (Oslo, Norway) in the 1970s, and received support from Lorenzo Colombo (Padua, Italy), who found that the male black goby (*Gobius niger*) releases a conjugated steroid, etiocholanolone glucuronide, to attract ovulated females to his nest for spawning. Since then, waterborne hormonal compounds (steroids, prostaglandins, and their precursors and metabolites) have been found to have biological effects in a variety of fishes. In addition, electro-olfactogram (EOG) recordings, which can quickly screen putative odorants for their olfactory activity (**see also Smell, Taste, and Chemical Sensing**: Neurophysiology of Olfaction and **Toxicology**: The Effects of Toxicants on Olfaction in Fishes), have shown that several hundred fish species from at least eight orders can detect hormonal compounds at the nanomolar-to-picomolar concentrations that would be expected of pheromones derived from hormones that already are at low concentrations in the bloodstream before they are released into the environment and further diluted.

These findings do not imply that all fish pheromones are exclusively derived from hormones. For example, sea lamprey (*Petromyzon marinus*) use bile steroids as a migratory pheromone (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development and Lampreys: Environmental Physiology) and masu salmon (*Oncorhynchus masou*) use an amino acid as a female sex pheromone (**see also Smell, Taste, and Chemical Sensing**: Chemosensory Behavior), while other recent studies indicate that hormonal and nonhormonal odorants can function as a pheromonal mixture. Nonetheless, hormonal compounds are implicated in the great majority of teleost fishes where there is any indication of pheromone identity. Unfortunately, little, if any, attention has been paid to pheromones in the cartilaginous fishes (sharks, rays, and chimaeras), the lobe-finned fishes (lungfishes), or even the nonteleost ray-finned fishes (sturgeons, gars, and bichirs), with the result that the broader evolutionary significance of hormonal pheromones within the aquatic vertebrates is a mystery.

Goldfish and Related Carps

Carp is a common term for several dozen species in the family Cyprinidae that live in tropical and temperate freshwater lakes, streams, and rivers. Particularly well known are the common carp (*Cyprinus carpio*), the crucian carp (*Carassius carassius*), and the goldfish. Except for tubercles that form on the males' opercula and fins during the breeding season, these carps lack sexual dimorphism, spend their lives in apparently unstructured, mixed-sex aggregations, and employ a promiscuous mating system involving intense sperm competition among males. EOG studies show that goldfish, crucian carp, and common carp detect a remarkably similar suite of hormonal compounds, providing a possible explanation for the fact that they will occasionally hybridize under natural conditions. Carp hormonal pheromones are best understood in the goldfish, the only species for which a complete picture of hormonal pheromone function is beginning to emerge.

As with crucian and common carp, goldfish undergo yolk production (**see also The Reproductive Organs and Processes**: Vitellogenesis in Fishes) and oocyte growth in winter and early spring, and ovulate large numbers of oocytes several times over a protracted spring–summer spawning season. Laboratory studies and field observations indicate that local groups of females are triggered to begin ovulation by two key environmental cues: rising water temperature and the appearance of aquatic vegetation onto which the adhesive eggs are released. However, females that begin ovulation quickly release a steroidal pheromone that induces neighboring females to ovulate. These mechanisms, likely intended to promote reproductive synchrony, presumably have evolved because the release of large numbers of eggs swamps the ability of predators to eat the undefended eggs and young.

The environmental and social cues that trigger ovulation exert their effects very indirectly, by causing the pituitary gland to release a dramatic 12-h surge of luteinizing hormone (LH), which in turn acts on the ovarian follicles to stimulate synthesis of a maturation-inducing steroid (MIS) that prepares the oocytes to ovulate (**Figure 1**). During this preovulatory LH surge, males

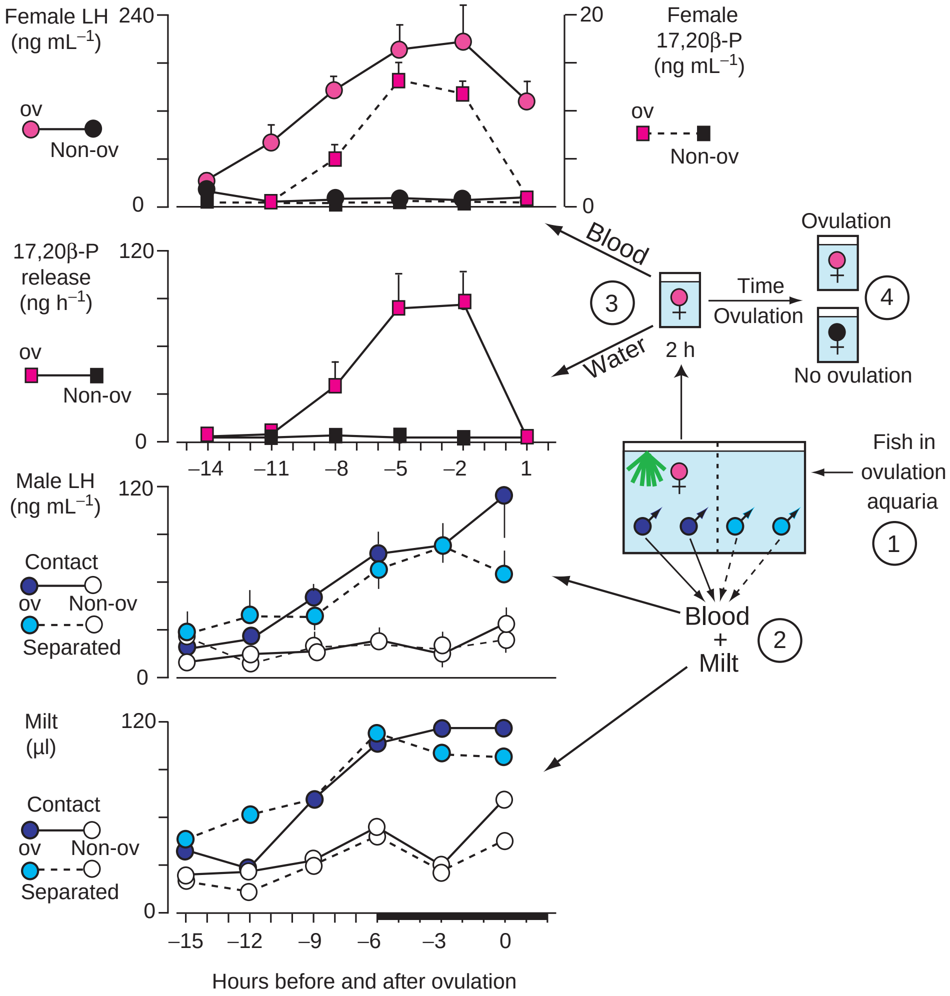

Figure 1 Male goldfish increase their blood LH concentrations and milt volumes if they are held with ovulating females, or separated from them by a perforated barrier. The right-hand side illustrates the experimental procedure. (1) Male and female goldfish were held overnight in warm water with aquatic vegetation, conditions that induced ovulation in half of the females. Half of the males were held behind a perforated barrier (separated) while the other half were in direct contact with females. (2) Males were removed from the experimental aquaria and immediately sampled for LH and milt. (3) Females were removed from the experimental aquaria, held for 2 h to obtain holding water for 17,20β-P determination, and then bled to measure blood concentrations of LH and 17,20β-P. (4) Females were checked frequently to determine if and when they ovulated. Graphs on the left-hand side of the figure illustrate the parameters measured. Adapted from Stacey NE and Sorensen PW (2006) Reproductive pheromones. In Sloman KA, Wilson RW, and Balshine S (eds.) *Behaviour and Physiology of Fish*, vol. 24, pp. 359–412. San Diego, CA: Elsevier; Stacey NE and Sorensen PW (1991) Function and evolution of fish hormonal pheromones. In: Hochachka PW and Mommsen TP (eds.) *Biochemistry and Molecular Biology of Fishes: Vol 1. Phylogenetic and Biochemical Perspectives*, pp. 109–135. New York, NY: Elsevier; and Stacey NE, Sorensen PW, Van Der Kraak GJ, and Dulka JG (1989) Direct evidence that 17α,20β-dihydroxy-4-pregnen-3-one functions as a goldfish primer pheromone: Preovulatory release is closely associated with male endocrine responses. *General and Comparative Endocrinology* 75: 62–70.

begin to follow and contact females, but the intensity of their behaviors increases dramatically when the females ovulate. At this point, and for the following hour or so, small and changing groups of males continuously chase a female, vigorously competing for position as she repeatedly enters vegetation, and then engaging in intense sperm competition as she quickly oviposits her eggs. In such a mating system, reproductive success of males will depend on the quantity and quality of sperm they are able to release, and on doing so, in proximity to released eggs. Although casual observation might suggest that these spawning behaviors are chaotic and rather unspecialized, they belie a surprisingly complex suite of pheromone-driven physiological and behavioral processes that begin soon after the surge in female LH and end when spawning ceases approximately 15 h later. During this brief time, hormonal pheromones function in three social contexts: between females, between males, and from female to male. The latter situation is best understood. Females first release steroid odors in the preovulatory period when the LH surge is stimulating final oocyte maturation, and then release prostaglandin odors during spawning.

Female Preovulatory Steroid Pheromone

If male goldfish or carp are held with females undergoing a preovulatory LH surge, or exposed to their odor, their blood LH concentration quickly increases, their social behaviors change, and within several hours they will have larger volumes of milt (sperm and seminal fluid) in their sperm ducts (**Figure 1**). In anosmic males (where the sense of smell is removed), these effects are completely blocked. The effects of preovulatory female odor are mediated by at least three specific and sensitive (picomolar threshold) olfactory receptors tuned to three key steroid odorants: the goldfish MIS (17,20β-dihydroxy-4-pregnen-3-one; 17,20β-P), a 20β-sulfated MIS metabolite (17,20β-P-su), and androstenedione (AD), an immediate precursor of testosterone. When added as single compounds to aquaria containing groups of male goldfish, both 17,20β-P and 17,20β-P-su rapidly increase male blood LH concentrations, whereas AD does not. However, all three odorants affect behavior, AD-inducing agonistic behavior between males, 17,20β-P-inducing weak chasing behavior, and 17,20β-P-su-inducing more intense but brief chasing bouts.

Although the female releases 17,20β-P, 17,20β-P-su, and AD simultaneously throughout the preovulatory period, there are two major reasons for believing that the male perceives these three steroids as a series of changing odors, rather than as a single odor mixture. First, each of the three key steroid odorants reaches a peak rate of release at a different time prior to ovulation – AD during the early surge, and 17,20β-P and 17,20β-P-su during the mid- and late surge, respectively. In both their endocrine and behavioral responses, males demonstrate the ability to discriminate mixtures differing in ratio, indicating they have the ability to discriminate among females at different stages in the preovulatory period. Second, and perhaps most importantly, the three key steroid odors are not released together: AD and 17,20β-P are released across the gills in an apparently continuous and passive manner, whereas 17,20β-P-su is released in pulses of urine. Based on release rates and EOG detection thresholds, it is estimated that males should detect the AD:17,20β-P mixture within only a few body lengths behind a moving female, whereas they should be able to detect 17,20β-P-su in urine patches at a much greater distance.

The primer and releaser effects of the preovulatory pheromone act in concert to increase male reproductive success (**Figure 2**). Microsatellite paternity studies show that if a male goldfish is exposed overnight to 17,20β-P (as would occur in the presence of an ovulatory female), and then allowed to spawn in competition with a control male, he sires the great majority of the offspring. This reproductive benefit of pheromone exposure is likely due to both behavioral and physiological factors. Pheromone-exposed males not only perform more spawning acts than control males, but also are more aggressive, a behavioral tactic strongly correlated with paternity. Furthermore, pheromone-exposed males not only ejaculate at least 10 times more sperm than control males, but their sperm are more motile as well, likely due to the action of LH-induced 17,20β-P synthesis in the testes. This increased motility apparently contributes to pheromone-enhanced paternity because, if sperm from 17,20β-P-exposed males are mixed with roughly equal numbers of control sperm and then allowed to compete for fertilization *in vitro*, they fertilize the majority of the eggs.

Female Postovulatory Prostaglandin Pheromone

Within minutes of ovulating, female carp cease releasing the preovulatory steroid pheromone, become sexually active, and begin to release an entirely different hormonal pheromone. Movement of ovulated eggs into the ovisac stimulates synthesis of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), which in turn rapidly exerts two critical and almost simultaneous effects. First, $PGF_{2\alpha}$ enters the blood and then acts hormonally in the brain to stimulate female spawning behavior. This is easily demonstrated by injecting $PGF_{2\alpha}$ into nonovulated females, which soon perform spawning behaviors that are normal in all aspects except that no eggs are released. Second, $PGF_{2\alpha}$ and a key metabolite, 15-keto-prostaglandin $PGF_{2\alpha}$ (15K-$PGF_{2\alpha}$), are released as a postovulatory pheromone that not only triggers intense chasing and related courtship behaviors in males,

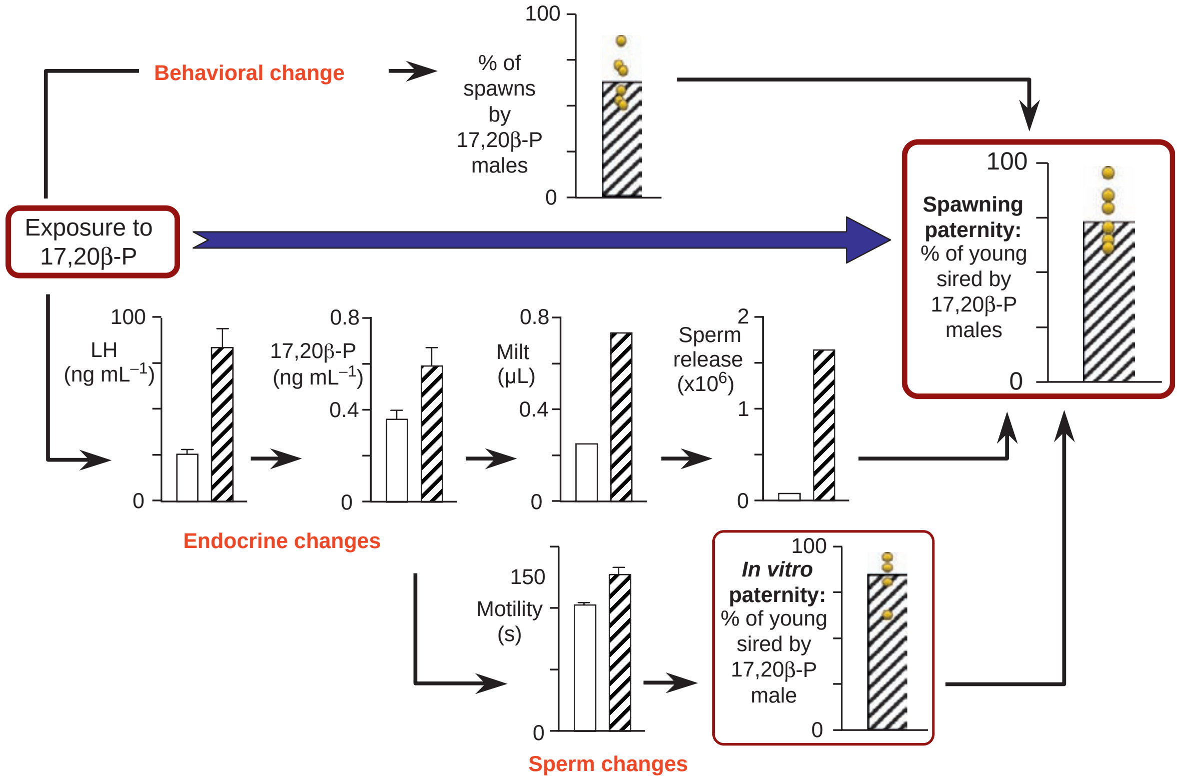

Figure 2 In each of six paired spawning competitions, DNA paternity studies showed that a male exposed overnight to pheromonal 17,20β-P sired a significantly greater percentage of the offspring than did his control male competitor (box at right). Each circle represents the percentage of paternity acquired by each 17,20β-P-exposed individual and the hatched bar represents the mean %. This effect on paternity likely is mediated by both behavioral and physiological changes. For example, in each of the six, paired competitions (top), 17,20β-P-exposed males performed a greater proportion of the total male spawning acts than did control males (again each circle represents one 17,20β-P-exposed individual). Moreover, these pheromone-exposed males (hatched bars) underwent rapid endocrine changes that enabled them to release dramatically more sperm than control males (open bars; middle and bottom graphs). Finally, it is likely that pheromone-induced 17,20β-P synthesis by the testis increases indices of sperm quality such as sperm motility. Such pheromone-induced sperm changes may account for the finding that in four, paired *in vitro* competitions, sperm from 17,20β-P-exposed males fertilized a greater percentage of the eggs than did sperm from control males. Adapted from Dulka JG, Stacey NE, Sorensen PW, and Van Der Kraak GJ (1987) A sex steroid pheromone synchronizes male–female spawning readiness in goldfish. *Nature* 325: 251–253; Hoysak DJ and Stacey NE (2008) Large and persistent effect of a female steroid pheromone on ejaculate size in goldfish. *Journal of Fish Biology* 73: 1573–1584; and Zheng W, Strobeck C, and Stacey NE (1997) The steroid pheromone 17α,20β-dihydroxy-4-pregnen-3-one increases fertility and paternity in goldfish. *Journal of Experimental Biology* 200: 2833–2840.

but also increases male LH concentration and milt volume, likely to maintain milt stores during spawning.

Although PGF$_{2\alpha}$ and 15K-PGF$_{2\alpha}$ appear to induce the same behavioral responses in males, EOG studies show that males have distinct olfactory receptors for these prostaglandins and are more sensitive to 15K-PGF$_{2\alpha}$ than to PGF$_{2\alpha}$. Whereas both PGF$_{2\alpha}$ and 15K-PGF$_{2\alpha}$ are released in urine (and therefore will be encountered as an odor mixture), only PGF$_{2\alpha}$ is released across the gills. From what is known of olfactory detection thresholds and the rates and routes of release, it appears that the urinary prostaglandin odor is able to inform males that an ovulated female is nearby, whereas PGF$_{2\alpha}$ released across the gills is detectable only in the female's immediate vicinity, and thus may identify her in a spawning group. Unlike the situation with the preovulatory steroid pheromone, which females appear to release in an unspecialized manner, female goldfish increase their urination rates just as they are selecting a spawning site in floating vegetation, suggesting that they release the postovulatory prostaglandin pheromone in controlled urinary pulses (**Figure 3**).

Mechanisms of Pheromone Action

The mechanisms mediating the actions of hormonal pheromones have been studied at several levels, from the olfactory sensory neurons, to the olfactory bulbs and tracts, and finally to brain centers through which olfactory input can affect behavior and pituitary function (**see also Smell, Taste, and Chemical Sensing**: Morphology of the Olfactory (Smell) System in Fishes).

Fish possess at least three morphologically distinct olfactory receptor neurons (ORNs) (**see also**

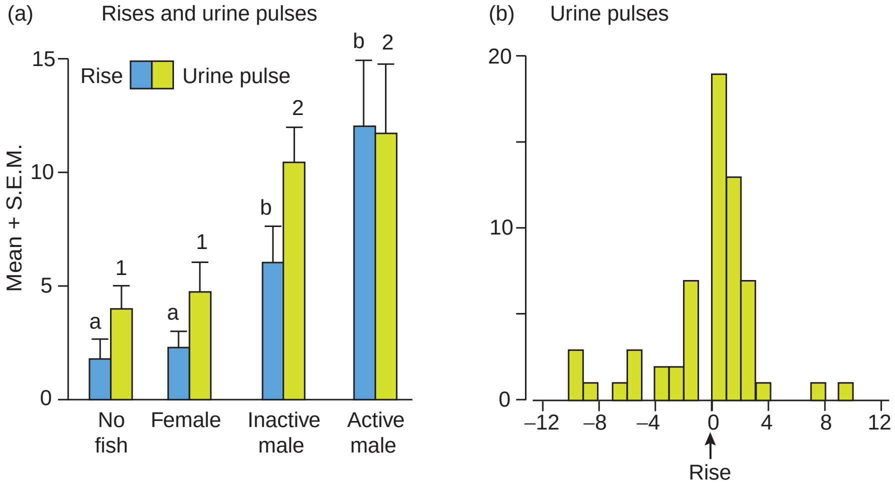

Figure 3 Female goldfish are specialized for signaling with the postovulatory prostaglandin pheromone by altering their urination frequency. (a) Immediately before each spawning act, females rise into floating spawning substrate. During a 60-min test, both rising and urine pulses increased in the presence of an inactive or active male, but not in the presence of a female. Letters (rise) and numbers (urine pulse) denote significant differences between treatments where bars sharing the same letter or number are not significantly different.
(b) Females urinate more frequently in the few seconds just preceding and following rising behavior. Bars indicate the total number of urine pulses released by eight females tested individually in the presence of sexually active males during a 60-min test. Adapted from Appelt CW and Sorensen PW (2007) Female goldfish signal spawning readiness by altering when and where they release a urinary pheromone. *Animal Behaviour* 74: 1329–1338; Stacey NE and Sorensen PW (2009) Fish hormonal pheromones. In: Pfaff DW, Arnold AP, Etgen AM, Fahrbach SE, and Rubin RT (eds.) *Hormones, Brain, and Behavior*, 2nd edn., vol. 2, pp. 639–681. San Diego, CA: Elsevier.

Smell, Taste, and Chemical Sensing: Morphology of the Olfactory (Smell) System in Fishes and Neurophysiology of Olfaction); current evidence suggests that it is the ciliated ORNs that detect pheromones. EOG recording studies reveal that, in addition to typically extreme sensitivity and specificity for their hormonal ligands, pheromone-sensitive ORNs in carps and other cyprinids display a consistent pattern of sexual dimorphism (**Figure 4**). For example, EOG responses to steroid odorants are not sexually dimorphic, but are equivalent in males, females, and prepubertal juveniles. In contrast, females and juveniles are much less sensitive to prostaglandins than mature males but, in response to androgen treatment, will develop male-typical EOG sensitivity within several weeks. This is one of the few clear vertebrate examples where sex steroids modulate the function of sensory neurons.

ORNs in the epithelium of the olfactory organs send their axons through the olfactory nerves to the olfactory bulbs, where ORNs with common receptor types converge in glomeruli, complex synaptic connections with the mitral cells, which in turn send their axons in the olfactory tracts to synapse in several brain areas (**see also Smell, Taste, and Chemical Sensing**: Morphology of the Olfactory (Smell) System in Fishes). Relatively little is known about how the brain transduces hormonal pheromone input into biological response (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction). However, despite the fact that male goldfish respond to the female's preovulatory and postovulatory pheromones with an apparently similar effect (increased LH concentration and milt volume), it is clear that distinct mechanisms mediate this response to female preovulatory and postovulatory pheromones (**Figure 5**). For example, the preovulatory odorant 17,20β-P increases LH and milt by activating a simple neuroendocrine reflex, because it is effective both in males held in groups and in males isolated from all social stimuli. In contrast, the postovulatory prostaglandin odorants do not increase LH and milt in isolated males, but are effective only when males are grouped or spawning with PGF$_{2\alpha}$-injected females, suggesting that these postovulatory odorants induce their endocrine effects indirectly through the sociosexual behaviors they trigger among conspecifics.

Another key difference between the responses to preovulatory and postovulatory pheromones involves the brain mechanisms that link pheromone detection to LH release from the pituitary, and the role of LH itself (**Figure 5**). Even though both preovulatory and postovulatory female pheromones increase blood LH concentrations in males within 20 min, the milt increase induced by pheromonal 17,20β-P occurs in 3–6 h, whereas that induced by the postovulatory pheromone occurs in less than 1 h and, unlike the 17,20β-P-induced milt increase, is not delayed if the experiment is run in colder water. Pheromonal 17,20β-P increases milt only by stimulating LH secretion, whereas pheromonal prostaglandins trigger at least one additional mechanism. For example, if the goldfish pituitary gland is removed to eliminate the endogenous source of LH, male

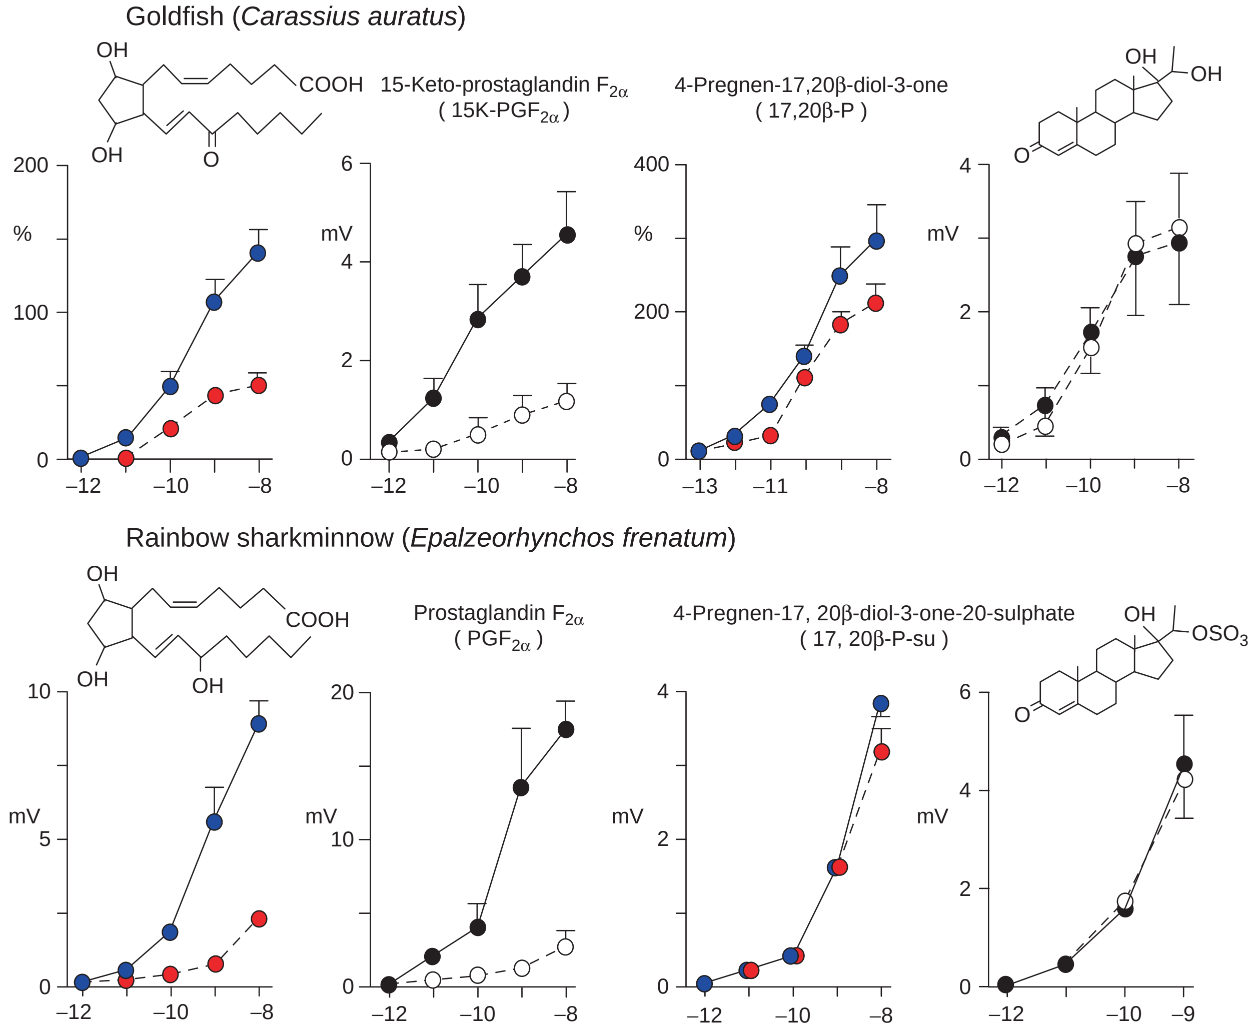

Figure 4 In cyprinid fishes, olfactory sensory responses to pheromonal prostaglandins are sexually dimorphic. EOG studies show that adult males (blue) are more sensitive to prostaglandins than are females (red), whereas males and females are equally responsive to pheromonal steroids. This adult difference likely is induced by male androgenic steroid hormones; because prepubertal juveniles treated with androgen (black circles) are more sensitive to prostaglandins than are untreated juveniles (white circles). Adapted from Belanger RM, Paszkowski MD, and Stacey NE (2009) Methyltestosterone-induced changes in electro-olfactogram responses and courtship behaviors of cyprinids. *Chemical Senses* 35: 65–74; Stacey NE and Sorensen PW (2009) Fish hormonal pheromones. In: Pfaff DW, Arnold AP, Etgen AM, Fahrbach SE, and Rubin RT (eds.) *Hormones, Brain, and Behavior*, 2nd edn., vol. 2, pp. 639–681. San Diego, CA: Elsevier; Stacey NE (2009) Pheromones and reproduction. In: Jamieson BGM (ed.) *Reproductive Biology and Phylogeny of Fish* (*Agnatha and Osteichthyes*), pp. 94–137. Enfield, NH: Science Publishers; Stacey NE and Sorensen PW (2006) Reproductive pheromones. In: Sloman KA, Wilson RW, and Balshine S (eds.) *Behaviour and Physiology of Fish*, vol. 24, pp. 359–412. San Diego, CA; and Stacey NE, Chojnacki A, Narayanan A, Cole TB, and Murphy CA (2003) Hormonally-derived sex pheromones in fish: Exogenous cues and signals from gonad to brain. *Canadian Journal of Phhsiology and Pharmacology* 81: 329–341.

goldfish still are able to increase milt volume when spawning with $PGF_{2\alpha}$-injected females but not when they are exposed to 17,20β-P, demonstrating that even though the postovulatory pheromone normally increases LH in intact males, it can also induce a milt response solely through an as-yet unknown extra-pituitary pathway.

The female goldfish's preovulatory and postovulatory pheromones also induce male LH release from the pituitary through distinct mechanisms (**Figure 5**). Under normal conditions, LH release from the goldfish pituitary is constantly inhibited by dopamine-containing neurons in the brain that make direct synaptic contact with pituitary LH cells (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction). The preovulatory pheromone 17,20β-P appears to increase LH release by removing this dopamine inhibition because, if male goldfish are first injected with a dopamine receptor agonist to maintain dopamine inhibition, the effect of 17,20β-P on LH is blocked; in contrast, dopamine receptor agonists do not prevent LH increase in males spawning with $PGF_{2\alpha}$-injected females.

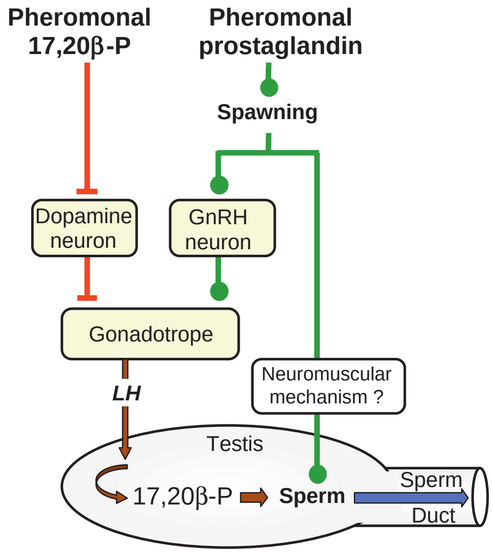

Figure 5 The preovulatory steroid pheromone and postovulatory prostaglandin pheromone of goldfish increase releasable sperm through different mechanisms. Pheromonal 17,20β-P appears to act only by inhibiting hypothalamic dopamine neurons that inhibit release of LH from pituitary gonadotropes. In contrast, pheromonal prostaglandin increases releasable sperm through at least two mechanisms. Pheromonal prostaglandin increases sperm by GnRH-induced LH increase, and also acts through a nonpituitary mechanism that has yet to be characterized. Adapted from Zheng W and Stacey NE (1997) A steroidal pheromone and spawning stimuli act via different neuroendocrine mechanisms to increase gonadotropin and milt volume in male goldfish (*Carassius auratus*). *General and Comparative Endocrinology* 105: 228–235; Stacey NE and Sorensen PW (2009) Fish hormonal pheromones. In: Pfaff DW, Arnold AP, Etgen AM, Fahrbach SE, and Rubin RT (eds.) *Hormones, Brain, and Behavior*, 2nd edn., vol. 2, pp. 639–681. San Diego, CA: Elsevier; and Zheng W and Stacey NE (1996) Two mechanisms for increasing milt volume in male goldfish. *Journal of Experimental Zoology* 276: 287–295.

Male-Derived Hormonal Pheromones

Given that their mating systems do not involve defense of a territory, mates, or offspring, it is perhaps not surprising that male carps have evolved complex mechanisms not only to anticipate ovulation and locate ovulated females, but also to increase their success in sperm competition. As discussed in the following section, interactions among male goldfish have dramatic and complex effects on testes and sperm that clearly appear to be adaptive tactics for sperm competition, although it is not yet clear if all these effects are mediated by hormonal pheromones. Nonetheless, two key findings suggest that interactions among males involve a pheromonal role for the steroid odorant AD. First, mature males release very large quantities of AD ($\sim$50 ng h^{-1}), and this release increases more than 10-fold when males begin to spawn. Based on release rates and EOG detection thresholds, spawning males have been estimated to produce an AD active space of $\sim$250 l h^{-1}; by comparison, it is estimated that the female's peak preovulatory release of AD ($\sim$100 ng h^{-1}) and 17,20β-P ($\sim$5 ng h^{-1}) generate active spaces of only 30 L h^{-1}. Second, aquarium studies demonstrate that AD released by dominant, sexually active males, mediates male–male interactions, stimulating agonistic interactions and inhibiting the milt increase that is normally induced by female pheromonal 17,20β-P. A key question, of course, is whether these effects might normally be exerted by AD released from males, or females, or both. Nevertheless, it is clear that AD serves as a hormonal sex pheromone in this species (and likely other carps) and that activity is linked with pheromone composition.

A Goldfish Chemical Network?

The preceding discussion is inevitably distorted by the fact that virtually all our understanding of goldfish hormonal pheromones pertains to female effects on males, and because it is convenient to discuss these effects in terms of an individual female sender and individual male receiver. However, hormonal pheromone effects are not only restricted to female effects on males, but also include intrasexual effects within each gender. Moreover, from the size of their pheromonal active spaces, and the proximity of goldfish in social groups, it is likely that these odorants operate to synchronize the final reproductive processes of many individuals within the local aggregations that form in early spring in typically turbid waters.

Male–male interactions affecting gonads and gametes are as dramatic as those between female goldfish, but evidently more complex, because males can either increase or decrease their milt production in response to the reproductive status of their male competitors. For example, if one male in a group is induced to increase milt stores by gonadotropin injection or exposure to 17,20β-P, his untreated tank mates will also increase their milt. On the other hand, males increase their milt volume when isolated from a group, and decrease their milt volume when returned. Finally, males that have been induced to increase milt volume (through either isolation or exposure to 17,20β-P) in turn stimulate milt production in additional males. These male–male effects might not be exclusively mediated by hormonal pheromones, and nothing is known about the underlying mechanisms, except that they do not involve a change in LH. Nonetheless, it is clear that males adaptively adjust milt production to the perceived level of sperm competition through cues provided by both males and females.

Putting all of this together, it appears that, prior to the occurrence of a female preovulatory LH surge, the male goldfish is both a source and a receiver of unknown cues that suppress sperm stores by maintaining basal concentrations of LH and testicular steroids, such as 17,20β-P

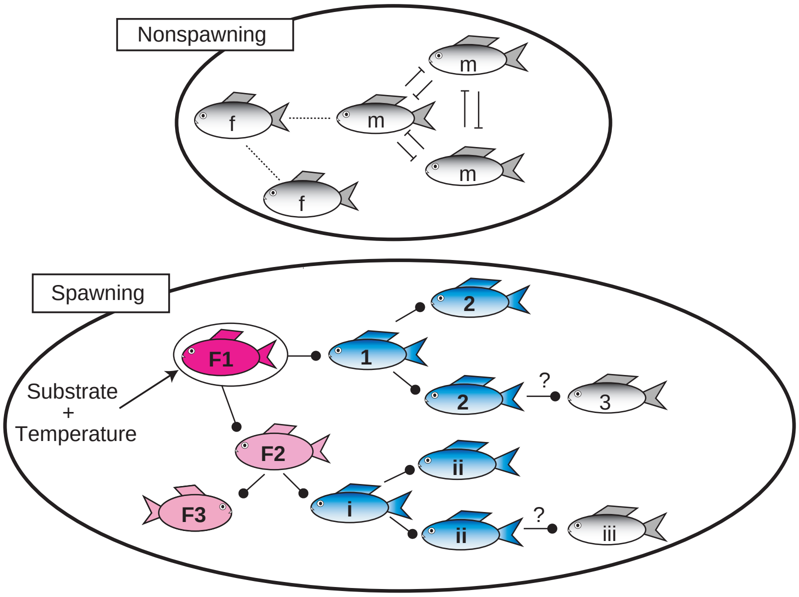

Figure 6 Proposed mechanism for pheromone-mediated synchronous ovulation and mass spawning in goldfish. In the nonspawning condition of early spring, when water temperature is low and aquatic vegetation (spawning substrate) has not begun to grow, males (m) are in a basal endocrine state and release unknown cues that suppress milt volume in other males. Laboratory experiments suggest that the transition to the spawning condition can occur when increasing water temperature and appearance of aquatic vegetation trigger an ovulatory LH surge in a single female (F1), releasing a preovulatory steroid pheromone that in turn triggers ovulatory LH surges in additional females (F2 and F3). The preovulatory pheromone also directly increases releasable sperm in males (1 and i) by increasing LH, and indirectly increases sperm in additional males (2 and ii) through an unknown mechanism; it is not known whether such indirectly stimulated males can increase releasable sperm in additional males (3 and iii). Adapted from Stacey NE (2003) Hormones, pheromones and reproductive behavior. *Fish Physiology and Biochemistry* 28: 229–235; Wisenden BD and Stacey NE (2005) Fish semiochemicals and the evolution of communication networks. In: McGregor PK (ed.) *Animal Communication Networks*, pp. 540–567. London: Cambridge University Press; Stacey NE and Sorensen PW (2009) Fish hormonal pheromones. In: Pfaff DW, Arnold AP, Etgen AM, Fahrbach SE, and Rubin RT (eds.) *Hormones, Brain, and Behavior*, 2nd edn., vol. 2, pp. 639–681. San Diego, CA: Elsevier.

(**Figure 6**). However, when exogenous stimuli such as warm temperature and aquatic vegetation trigger a preovulatory LH surge in at least one female, this stable, negative-feedback interaction among males is rapidly perturbed. Males and females encountering the preovulatory pheromone in turn increase their LH, thereby amplifying and disseminating the original stimulus and promoting synchronous final maturation (ovulation and increased sperm stores) of individuals within the local chemical network. Although it is difficult to exclude the possibility that these pheromone-mediated elements of goldfish reproductive physiology have been influenced by domestication, EOG and other studies both in the laboratory and in the field indicate that remarkably similar hormonal pheromone systems are used by the goldfish and the closely related crucian and common carps.

Hormonal Pheromones and Species Specificity

In general, the evolution of species recognition systems that enable reproductive interactions to be restricted to conspecifics is assumed to be a prerequisite for successful reproduction. Numerous studies have shown that many fish will behaviorally discriminate between the odor of conspecifics and the odor of another, even closely related, species. However, there are two key reasons why these observations might be difficult to reconcile with the fact that the use of hormonal compounds as pheromones appears to be widespread among the fishes: (1) sex steroids and prostaglandins are highly conserved throughout the vertebrates, making them poor candidates for species-specific odorants and (2) although EOG recordings have shown that distantly related taxa typically detect different steroid and prostaglandin odorants, they also show that the hormonal odorants detected by closely related species, such as the carps, can be remarkably similar. Our current understanding of hormonal pheromones does not allow us to reconcile these observations in the context of species specificity, because it is based almost entirely on simple laboratory experiments using single synthetic odorants, whereas insight into species specificity will require studies of the effects of whole body odors under natural conditions. Because pheromonal species specificity is a remarkably complex issue that is very poorly understood in fish, we end our brief review with several comments intended to stimulate further research in this area.

First, species specificity does not mean that all pheromones are unique, but simply distinct from those of historically encountered heterospecifics. Selection for specificity should be expected only where the fitness of a species is reduced by entering the pheromonal active space of heterospecifics. From this perspective, we predict that many fishes never experience such intimate reproductive sympatry, simply because they and neighboring species create only small pheromonal active spaces.

Second, although fish androgen (11-ketotestosterone), estrogen (17β-estradiol), and MISs (17,20β-P and 17,20β,21-P) have no ability to encode species specificity, this is not the case for their precursors and metabolites. EOG studies show that the MIS-related steroids in particular are highly diverse odorants in fishes because they can be synthesized and metabolized in many ways, making the number of MIS-related metabolites released by fish potentially enormous. Unfortunately, it is not known if fish have taken advantage of this potential for species-specific steroid odorants, because steroid metabolism and release is not an active area of research at this time.

Third, the olfactory receptors for hormonal pheromones are highly specific, such that a single enzymatic change to a potent steroid or prostaglandin odorant can make it undetectable at physiological concentrations. This characteristic of hormonal pheromone function is highly relevant to the issue of species specificity, because it means that even subtle changes in hormone metabolism can have drastic effects on the pattern of intimate reproductive sympatry.

Fourth, and perhaps most importantly, studies of hormonal pheromones have yet to test the possibility that hormonal pheromones might not be single compounds, but rather mixtures that could contain both hormonal and nonhormonal odorants. Indeed, the use of complex odor mixtures is perhaps to be expected, given that all insect and mammalian pheromones that have been fully characterized and then tested in field conditions are mixtures of two to seven compounds.

Finally, although responses to pheromones are generally assumed to be innate or unlearned, this need not be the case, particularly in long-lived species such as the carps that mate in large groups many times in their life and that would have numerous opportunities to associate hormonal and nonhormonal odorants with reproductive events.

In conclusion, two things are clear: many fishes detect hormonal odorants and many fishes discriminate between conspecific and heterospecific odors. A thoughtful consideration of the implications should lead to some very exciting research.

EDITORS' BIOGRAPHIES

Editor-in-Chief

Anthony P. Farrell, Department of Zoology, University of British Columbia, Vancouver, BC, Canada

Tony Farrell is a graduate of Bath University, where he was fortunate to study with Peter Lutz. His fortunes grew further when he moved in 1974 to Canada and the Zoology Department at the University of British Columbia (UBC) to complete his PhD degree under the excellent tutelage of Dave Randall. In 2004, Tony returned to UBC when he accepted an endowed research chair in sustainable aquaculture. In between these positions at UBC, Tony was employed at the University of Southern California (PDF), the University of New Brunswick (sessional lecturer), Mount Allison University (first real job), and Simon Fraser University (moving through the ranks to a full professor). In addition to highly controlled laboratory experiments on fish cardiorespiratory physiology, Tony is committed to working on animals in their own environment. Therefore, his research on fish physiology has taken him on an *Alpha Helix* expedition to the Amazon, the University of Gothenburg and the Kristineberg Marine Research Station in Sweden, the Portobello Marine Biological Station in New Zealand, the University of Christchurch and Massey University in New Zealand, the Bamfield Marine Science Station and the Huntsman Marine Station in Canada, the University of Aarhus in Denmark, the University of Adelaide Charles and Darwin University in Australia, and to the Danish Arctic Marine Station on Disco Island in Greenland. These travels have allowed him to work with many superb collaborators wordwide, as well as study the physiology of over 70 different species of fish. Tony has received a number of awards for his scientific contributions: an honorary degree from the University of Gothenburg in Sweden; Awards of Excellence from the American Fisheries Society for Fish Physiology, Conservation and Management; the Fry Medal from the Canadian Society of Zoologists; and the Beverton Medal from the Fisheries Society of the British Isles.

Associate Editor

Joseph J. Cech, Jr., Department of Wildlife, Fish, and Conservation Biology, University of California, Davis, CA, USA

Joe Cech grew up in northern Illinois <1 km from the Salt Creek Preserve, where he spent many hours as a boy. Summer trips to northern Wisconsin, northern Minnesota, and southern Ontario increased his interest in aquatic habitats and their fishes. He graduated from the University of Wisconsin (UW, Madison), where he was fortunate to study oceanography under Robert Ragotzkie and fish biology under Art Hasler and Fran Henderson in the UW Laboratory of Limnology. Before completing his BS degree in zoology, he was fortunate to serve as the resident zoologist aboard the R/V *Dante Deo*, for a year, as it crossed the Caribbean Sea and the South Pacific Ocean. Completing his degree upon his return, he was hired as a research assistant at the University of Texas' Marine Science Institute (UTMSI), where he earned his MA and PhD degrees in zoology, under the supervision of Curly Wohschlag. During his graduate education in Austin (Texas), he studied fish biology under Clark Hubbs and physiology under Jack Myers and Jim Larimer. After a 2-year postdoctoral position in Maine, he was hired as a fish physiological ecologist faculty member at the University of California (UC), Davis, in the Department of Wildlife, Fish, and Conservation Biology.

During his 32 years as an active faculty member at UC Davis, his research on the physiological ecology of fishes took him to Canada (University of British Columbia, Bamfield Marine Station), Finland (University of Helsinki), and to other laboratories in the USA (University of Tennessee, Scripps Institution of Oceanography, R/V *David Starr Jordan* in the North Pacific Ocean, UTMSI, Oregon Institute of Marine Biology, and the UC Bodega Marine Laboratory) where he collaborated with many excellent scientists. During this period, he taught courses in physiology of fishes, physiological ecology, and field studies in fish biology; he supervised 25 graduate students (10 MS and

15 PhD) in the disciplinary areas of ecology, physiology, zoology, and pharmacology/toxicology at UC Davis. He is a fellow of the AIFRB and AAAS, and he received Awards of Excellence from the American Fisheries Society (Physiology Section, and California-Nevada Chapter) and the UC Davis Prize for Undergraduate Teaching and Scholarly Achievement. Finally, he co-authored a popular ichthyology textbook, with Peter Moyle, and he published more than 160 peer-reviewed publications on the physiological ecology of fishes. He is currently Professor Emeritus of Fish Biology at the University of California Davis.

Associate Editor

Jeffrey G. Richards, Department of Zoology, University of British Columbia, Vancouver, BC, Canada

Jeffrey Richards is an associate professor in the Department of Zoology at the University of British Columbia, Canada. He started his academic career in the Department of Biology at Wilfrid Laurier University obtaining a BSc in 1995. He then went on to do an MSc at the University of Waterloo under the guidance of the late Prof. Richard Playle. With Prof. Playle, he studied environmental physiology and toxicology in fish. Following his MSc, he entered the laboratory of Prof. Chris Wood at McMaster University and focused his research on energy metabolism in swimming fish. He completed his PhD in 2002 and took up a postdoctoral fellowship at the University of British Columbia with Prof. Patricia Schulte. After a 2-year postdoctoral work, he started at the University of British Columbia as an assistant professor in 2004. His lab studies the relationship between plasticity and adaptive variation in the mechanisms that initiate, maintain, and coordinate metabolic energy balance in animals during exposure to environmental stress. He is particularly interested in the adaptations to low oxygen (hypoxia) in fish and other lower vertebrates. He prefers, whenever possible, to study animals in their natural habitat; thus, he travels extensively to unique and challenging environments, including the Amazon and the Tibetan plateau.

Associate Editor

E. Don Stevens, Department of Biomedical Sciences, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, PE, Canada

Don Stevens did an MSc with the late Edgar Black on the effects of severe exercise on metabolites in trout in the Physiology Department at UBC after an undergraduate degree in mathematics and zoology at the University of Victoria. He then moved across the street to do a PhD on effects of moderate exercise on respiration and circulation in trout with Dave Randall, who just had been hired in the Zoology Department at UBC (summarized in a JEB classics article, *Journal of Experimental Biology* 211: 1521). His first position was at the Zoology Department at the University of Hawaii where he discovered that there was more to the fish world than trout, and that there was no such thing as the physiology of fish, rather there was a physiology of fishes. In Hawaii, he worked mostly on the biology of tropical tunas with a focus on their warm-bodiedness, in particular how they achieved higher than ambient body temperatures and the adaptive advantage of them. He then joined the Zoology Department at the University of Guelph working in the general area of comparative physiology with a focus on exercise effects until he retired in 2004. He now has an adjunct position at the Atlantic Veterinary College and continues to do research in fish physiology.

P-P Hwang
Academia Sinica, Taipei, Taiwan, China

JM Jørgensen
University of Aarhus, Aarhus, Denmark

WR Jeffery
University of Maryland, College Park, MD, USA

E Jönsson
University of Gothenburg, Gothenburg, Sweden

M Jobling
University of Tromsø, Tromsø, Norway

DR Jones
University of British Columbia, Vancouver, BC, Canada

MG Jonz
University of Ottawa, Ottawa, ON, Canada

F Jutfelt
University of Gothenburg, Gothenburg, Sweden

IM Kaatz
Stamford, CT, USA

I Katsiadaki
Cefas Weymouth Laboratory, Weymouth, UK

A Kawano
University of Waterloo, Waterloo, ON, Canada

M Kawasaki
University of Virginia, Charlottesville, VA, USA

CJ Kennedy
Simon Fraser University, Burnaby, BC, Canada

P Kiilerich
Institut National de la Recherche Agronomique (INRA), Rennes, France

SS Killen
University of Glasgow, Glasgow, Scotland, UK

M Kinoshita
Kyoto University, Kyoto, Japan

F Kirschbaum
Humboldt-Universität zu Berlin, Berlin, Germany

CS Krahforst
East Carolina University, Greenville, NC, USA

Å Krogdahl
Norwegian School of Veterinary Science, Oslo, Norway

RHH Kröger
Lund University, Lund, Sweden

D Kültz
University of California, Davis, CA, USA

F Ladich
University of Vienna, Vienna, Austria

LEJ Lee
Wilfrid Laurier University, Waterloo, ON, Canada

B Levavi-Sivan
Hebrew University of Jerusalem, Rehovot, Israel

MW Levine
University of Illinois at Chicago, Chicago, IL, USA

D Liedtke
University of Würzburg, Würzburg, Germany

JH Long Jr.
Vassar College, Poughkeepsie, NY, USA

Z Lu
University of Miami, Coral Gables, FL, USA

JJ Luczkovich
East Carolina University, Greenville, NC, USA

WI Lutterschmidt
Sam Houston State University, Huntsville, TX, USA

P Machnik
University of Bayreuth, Bayreuth, Germany

N Maclean
University of Southampton, Southampton, UK

CP Madenjian
Great Lakes Science Center, Ann Arbor, MI, USA

H Malte
Aarhus University, Aarhus, Denmark

F Marino
University of Messina, Messina, Italy

NJ Marshall
The University of Queensland, Brisbane, QLD, Australia

GB McClelland
McMaster University, Hamilton, ON, Canada

CA McCormick
Oberlin College, Oberlin, OH, USA

SD McCormick
USGS, Conte Anadromous Fish Research Center, Turners Falls, MA, USA

DJ McKenzie
Université Montpellier 2, Montpellier, France

DB McMillan
University of Western Ontario, London, ON, Canada

M Megías
University of Vigo, Vigo, Spain

AF Mensinger
University of Minnesota Duluth, Duluth, MN, USA

JD Metcalfe
Centre for Environment, Fisheries and Aquaculture Science, Lowestoft, UK

WK Milsom
University of British Columbia, Vancouver, BC, Canada

CMR Le Moine
University of Ottawa, Ottawa, ON, Canada

JC Montgomery
University of Auckland, Auckland, New Zealand

TW Moon
University of Ottawa, Ottawa, ON, Canada

PC Morris
Heriot-Watt University, Edinburgh, UK

CD Moyes
Queen's University, Kingston, ON, Canada

CA Myrick
Colorado State University, Fort Collins, CO, USA

HOW TO USE THE ENCYCLOPEDIA

STRUCTURE OF THE ENCYCLOPEDIA

The material in the Encyclopedia is arranged as a series of articles within a certain topic.

There are three features to help you easily find the topic you're interested in: a contents list, cross-references to other relevant articles in the Encyclopedia, and a full subject index.

1. CONTENTS LIST

The contents list, which appears at the front of all volume, lists the entries in the order that they appear in the Encyclopedia. It includes both the volume number and the page number of each entry.

2. CROSS-REFERENCES

All of the entries in the Encyclopedia have been extensively cross-referenced. The cross-references which appear at the end of an entry, serve three different functions:

i. To indicate if a topic is discussed in greater detail elsewhere
ii. To draw the readers attention to parallel discussions in other entries
iii. To indicate material that broadens the discussion

Example

The following list of cross-references may appear in text and at the end of the entry
The Muscles|Cartilaginous Fishes Cranial Muscles

See also: **Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics. **Chondrichthyes**: Physiology of Sharks, Skates, and Rays. **Food Acquisition and Digestion**: Energetics of Prey Capture: From Foraging Theory to Functional Morphology. **The Muscles**: Bony Fish Cranial Muscles. **The Reproductive Organs and Processes**: Anatomy and Histology of Fish Testis. **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics.

3. INDEX

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4. CONTRIBUTORS

At the start of each volume there is list of the authors who contributed to the Encyclopedia.

This page intentionally left blank

CONTENTS

VOLUME 1 – THE SENSES, SUPPORTING TISSUES, REPRODUCTION, AND BEHAVIOR

SENSING THE ENVIRONMENT

BRAIN AND NERVOUS SYSTEM

Functional Morphology of the Nervous System: An Introduction *AB Butler* 1

Cranial and Spinal Nerves of Fishes: Evolution of the Craniate Pattern *B Fritzsch and DC de Caprona* 6

Functional Morphology of the Brains of Agnathans *MA Pombal and M Megías* 16

Functional Morphology of the Brains of Cartilaginous Fishes *I Rodríguez-Moldes* 26

Functional Morphology of the Brains of Ray-Finned Fishes *AB Butler* 37

Functional Morphology of the Brains of Sarcopterygian Fishes: Lungfishes and *Latimeria*
A González and RG Northcutt 46

Motor Control Systems of Fish *S Grillner* 56

Physiology of the Mauthner Cell: Discovery and Properties *AE Pereda and DS Faber* 66

Physiology of the Mauthner Cell: Function *DS Faber and AE Pereda* 73

Autonomic Nervous System of Fishes *S Nilsson* 80

Opioids and Opioid Receptors in Fishes *MJ Herrero-Turrión, FM Sánchez-Simón, and RE Rodríguez* 89

VISION

Vision in Fishes: An Introduction *H-J Wagner* 98

Physiological Optics in Fishes *RHH Kröger* 102

Photoreceptors and Visual Pigments *JK Bowmaker* 110

Adaptations of Photoreceptors and Visual Pigments *JK Bowmaker* 116

Inner Retina and Ganglion Cells *MW Levine* 123

Optic Tectum *D Northmore* 131

Behavioral Assessment of the Visual Capabilities of Fish *S Schuster, P Machnik, and W Schulze* 143

Color Vision and Color Communication in Reef Fish *J Marshall and K Cheney* 150

Extraretinal Photoreception *H-J Wagner* 159

Visual Adaptations to the Deep Sea *RH Douglas and JC Partridge* 166

see Communication Behavior: Visual Signals, Volume 1, p. 692
see Coloration and Chromatophores in Fishes, Volume 1, p. 489
see Bioluminescence in Fishes, Volume 1, p. 497

SMELL, TASTE, AND CHEMICAL SENSING

Chemoreception (Smell and Taste): An Introduction *TJ Hara* 183
Morphology of the Gustatory (Taste) System in Fishes *TJ Hara* 187
Morphology of the Olfactory (Smell) System in Fishes *TJ Hara* 194
Neurophysiology of Olfaction *TJ Hara* 208
Neurophysiology of Gustation *TJ Hara* 218
Chemosensory Behavior *TJ Hara* 227
see The Effects of Toxicants on Olfaction in Fishes, Volume 3, p. 2078
see Oxygen Sensing in Fish, Volume 2, p. 871

HEARING AND LATERAL LINE

Fish Bioacoustics: An Introduction *AN Popper and BM Casper* 236
Vestibular System Anatomy and Physiology *H Straka and R Baker* 244
Auditory System Morphology *AN Popper* 252
The Ear and Hearing in Sharks, Skates, and Rays *BM Casper* 262
Biomechanics of the Inner Ear in Fishes *MC Hastings* 270
Psychoacoustics: What Fish Hear *RR Fay* 276
Auditory/Lateral Line CNS: Anatomy *CA McCormick* 283
Physiology of the Ear and Brain: How Fish Hear *Z Lu* 292
Sound Source Localization and Directional Hearing in Fishes *DG Zeddies, RR Fay, and JA Sisneros* 298
Effects of Human-Generated Sound on Fish *AD Hawkins* 304
Acoustic Behavior *J Luczkovich, MW Sprague, and CS Krahforst* 311
Vocal Behavior of Fishes: Anatomy and Physiology *F Ladich and AH Bass* 321
Lateral Line Neuroethology *JC Montgomery and S Coombs* 329
Lateral Line Structure *J Webb* 336
see How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling, Volume 1, p. 684

DETECTION AND GENERATION OF ELECTRIC SIGNALS

Detection and Generation of Electric Signals in Fishes: An Introduction *BA Carlson* 347
Morphology of Electroreceptive Sensory Organs *JM Jørgensen* 350
Physiology of Ampullary Electrosensory Systems *MH Hofmann* 359
Physiology of Tuberous Electrosensory Systems *ES Fortune and MJ Chacron* 366
Active Electrolocation *G von der Emde and J Engelmann* 375
Electric Organs *AA Caputi* 387
Generation of Electric Signals *M Kawasaki* 398

Development of Electroreceptors and Electric Organs *F Kirschbaum and J-P Denizot* 409
see Shocking Comments: Electrocommunication in Teleost Fish, Volume 1, p. 699

MUSCLES, SKELETON, SKIN, AND MOVEMENT

Functional Anatomy of Bones, Muscle, and Skin: An Introduction *ED Stevens* 416

THE SKELETON

Cartilaginous Fish Skeletal Anatomy *KM Claeson and MN Dean* 419
Cartilaginous Fish Skeletal Tissues *MN Dean* 428
Bony Fish Skeleton *EJ Hilton* 434

THE MUSCLES

Cartilaginous Fishes Cranial Muscles *DR Huber, MC Soares, and MR de Carvalho* 449
Bony Fish Cranial Muscles *LA Ferry and L Hernandez* 463

THE SKIN

The Many Functions of Fish Integument *DG Elliott* 471
Functional Morphology of the Integumentary System in Fishes *DG Elliott* 476
Coloration and Chromatophores in Fishes *D Burton* 489
Bioluminescence in Fishes *AF Mensinger* 497
Hagfish Slime *DS Fudge, JE Herr, and TM Winegard* 504

BUOYANCY, LOCOMOTION, AND MOVEMENT IN FISHES

Buoyancy, Locomotion, and Movement in Fishes: An Introduction *ED Stevens* 516
Buoyancy in Fishes *RMcN Alexander* 520
Swimbladder Function and Buoyancy Control in Fishes *B Pelster* 526
Experimental Hydrodynamics *ED Tytell* 535
Undulatory Swimming *DJ Ellerby* 547
Functional Properties of Skeletal Muscle: Work Loops *DA Syme* 555
Paired Fin Swimming *EM Standen* 564
Maneuverability *PW Webb* 575
Stability and Turbulence *PW Webb and AJ Cotel* 581
Fast Start *P Domenici* 587
Feeding Mechanics *TE Higham* 597
Biomimetics: Robotics Based on Fish Swimming *JH Long Jr.* 603
see Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems, Volume 2, p. 935
see Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder, Volume 2, p. 929
see The Retia, Volume 2, p. 1119
see Deep-Sea Fishes, Volume 3, p. 1953

see Applied Aspects of Fish Swimming Performance, Volume 3, p. 1652
see Integrated Cardiovascular Responses of Fish to Swimming, Volume 2, p. 1215
see The Effect of Exercise on Respiration, Volume 2, p. 812

REPRODUCTION

The Diversity of Fish Reproduction: An Introduction *KA Sloman* 613

THE REPRODUCTIVE ORGANS AND PROCESSES

Anatomy and Histology of Fish Testis *RW Schulz and RH Nóbrega* 616
Regulation of Spermatogenesis *RW Schulz and RH Nóbrega* 627
Vitellogenesis in Fishes *BJ Reading and CV Sullivan* 635
see Parental Care in Fishes, Volume 1, p. 670
see Endocrine Regulation of Fish Reproduction, Volume 2, p. 1500
see Socially Controlled Sex Change in Fishes, Volume 1, p. 662
see Nutritional Provision During Parental Care, Volume 1, p. 678
see Sexual Behavior in Fish, Volume 1, p. 656

BEHAVIOR AND PHYSIOLOGY

Linking Fish Behavior and Physiology: An Introduction *KA Sloman* 647

SOCIAL AND REPRODUCTIVE BEHAVIORS

Dominance Behaviors *KA Sloman* 649
Sexual Behavior in Fish *I Katsiadaki and M Sebire* 656
Socially Controlled Sex Change in Fishes *J Godwin* 662
Parental Care in Fishes *S Balshine and KA Sloman* 670
Nutritional Provision During Parental Care *KA Sloman and J Buckley* 678
see Hormonal Pheromones, Volume 2, p. 1553
see The Diversity of Fish Reproduction: An Introduction, Volume 1, p. 613

SENSORY SYSTEMS, PERCEPTION, AND LEARNING

How Fishes Use Sound: Quiet to Loud and Simple to Complex Signalling *IM Kaatz* 684
Communication Behavior: Visual Signals *GG Rosenthal and NJ Marshall* 692
Shocking Comments: Electrocommunication in Teleost Fish *K Pappas and K Dunlap* 699
Fish Learning and Memory *VA Braithwaite* 707
Nociception or Pain in Fish *LU Sneddon* 713
Spatial Orientation: How do Fish Find their Way Around? *T Burt de Perera* 720
Magnetic Sense in Fishes *MM Walker* 726
Circadian Rhythms in Fish *SG Reebs* 736
see Bioluminescence in Fishes, Volume 1, p. 497

see Acoustic Behavior, Volume 1, p. 311
see Behavioral Assessment of the Visual Capabilities of Fish, Volume 1, p. 143
see Chemosensory Behavior, Volume 1, p. 227

BEHAVIORAL RESPONSES TO THE ENVIRONMENT

A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food *MV Abrahams* 744
Effects of Compensatory Growth on Fish Behavior *D Álvarez* 752
Temperature Preference: Behavioral Responses to Temperature in Fishes *LI Crawshaw and JE Podrabsky* 758
Behavioral Responses to Hypoxia *KA Sloman* 765
Sleep in Fish *IV Zhdanova* 772
Manipulation of Fish Phenotype by Parasites *O Seppälä* 777
Anthropogenic Influences on Fish Behavior *KA Sloman* 783
see The Biology of Fish Migration, Volume 3, p. 1921

VOLUME 2 – GAS EXCHANGE, INTERNAL HOMEOSTATIS, AND FOOD UPTAKE

GAS EXCHANGE

Respiration: An Introduction *JJ Cech Jr. and CJ Brauner* 791

VENTILATION AND ANIMAL RESPIRATION

Plasticity in Gill Morphology *GE Nilsson* 796
Gill Respiratory Morphometrics *NC Wegner* 803
The Effect of Exercise on Respiration *H Thorarensen* 812
Efficiency of Gas Exchange Organs *H Malte* 820
Respiratory Gas Exchange During Development: Models and Mechanisms *PJ Rombough* 829
Respiratory Gas Exchange During Development: Respiratory Transitions *PJ Rombough* 838
Techniques in Whole Animal Respiratory Physiology *JJ Cech Jr. and CJ Brauner* 846
see Branchial Anatomy, Volume 2, p. 1095

CONTROL OF RESPIRATION

Generation of the Respiratory Rhythm in Fish *EW Taylor* 854
The Ventilatory Response to CO_2/H^+ *WK Milsom* 865
Oxygen Sensing in Fish *MG Jonz* 871

TRANSPORT AND EXCHANGE OF RESPIRATORY GASES IN THE BLOOD

Red Blood Cell Function *M Nikinmaa* 879
Hemoglobin *M Nikinmaa* 887
O_2 Uptake and Transport: The Optimal P_{50} *T Wang and H Malte* 893
Carbonic Anhydrase in Gas Transport and Exchange *KM Gilmour* 899

Carbon Dioxide Transport and Excretion *D Randall* 909
Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange *CJ Brauner and JL Rummer* 916
Evolution of the Bohr Effect *M Berenbrink* 921
Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder *W Waser* 929
Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems *M Berenbrink* 935
Hemoglobin Differentiation in Fishes *C Verde, D Giordano, R Russo, and G di Prisco* 944
see Cellular Composition of the Blood, Volume 2, p. 984

TISSUE RESPIRATION

Cellular Respiration *GB McClelland* 951
Mitochondrial Respiration *CD Moyes and CMR Le Moine* 959
Specializations in Mitochondrial Respiration of Fish *CD Moyes and CMR Le Moine* 966

CIRCULATION

The Circulatory System: An Introduction *AP Farrell* 973
Circulatory System Design: Roles and Principles *KR Olson* 977

BLOOD

Cellular Composition of the Blood *AP Farrell* 984
Erythropoiesis in Fishes *C Verde, D Giordano, R Russo, and G di Prisco* 992
see Hemoglobin Differentiation in Fishes, Volume 2, p. 944
see Red Blood Cell Function, Volume 2, p. 879
see Hemoglobin, Volume 2, p. 887

DESIGN AND PHYSIOLOGY OF THE HEART

Cardiac Anatomy in Fishes *AP Farrell and S Pieperhoff* 998
Cellular Ultrastructure of Cardiac Cells in Fishes *GLJ Galli* 1006
The Outflow Tract from the Heart *DR Jones and MH Braun* 1015
Physiology of Cardiac Pumping *AP Farrell* 1030
Action Potential of the Fish Heart *M Vornanen* 1038
Cardiac Excitation–Contraction Coupling: Routes of Cellular Calcium Flux *HA Shiels* 1045
Cardiac Excitation–Contraction Coupling: Calcium and the Contractile Element *TE Gillis* 1054
Cardiac Cellular Length–Tension Relationship *HA Shiels* 1060
Intracardiac Neurons and Neurotransmitters in Fish *G Zaccone, A Mauceri, and D Zaccone* 1067
Accessory Hearts in Fishes *AP Farrell* 1073
The Coronary Circulation *AP Farrell* 1077

DESIGN AND PHYSIOLOGY OF ARTERIES AND VEINS

Anatomical Pathways and Patterns *KR Olson* 1085
Branchial Anatomy *KR Olson* 1095
Physiology of Resistance Vessels *KR Olson* 1104

Physiology of Capacitance Vessels *KR Olson* 1111

The Retia *ED Stevens* 1119

The Gastrointestinal Circulation *M Axelsson and H Seth* 1132

see Secondary Circulation and Lymphatic Anatomy, Volume 2, p. 1161
see The Coronary Circulation, Volume 2, p. 1077

DESIGN AND PHYSIOLOGY OF CAPILLARIES AND SECONDARY CIRCULATION

Capillaries, Capillarity, and Angiogenesis *S Egginton and F Syeda* 1142

Circulatory Fluid Balance and Transcapillary Exchange *KR Olson* 1154

Secondary Circulation and Lymphatic Anatomy *KR Olson and AP Farrell* 1161

INTEGRATED CONTROL AND RESPONSE OF THE CIRCULATORY SYSTEM

Integrated Control of the Circulatory System *KR Olson* 1169

Central Control of Cardiorespiratory Interactions in Fish *EW Taylor* 1178

Hormone Metabolism in the Circulation *KR Olson* 1190

Integrated Responses of the Circulatory System to Temperature *AK Gamperl* 1197

Integrated Responses of the Circulatory System to Digestion *H Seth and M Axelsson* 1206

Integrated Cardiovascular Responses of Fish to Swimming *AP Farrell* 1215

Integrated Responses of the Circulatory System to Hypoxia *AK Gamperl* 1221

see Hormone Metabolism in the Circulation, Volume 2, p. 1190
see Accessory Hearts in Fishes, Volume 2, p. 1073
see Respiratory Adaptations for Air-Breathing Fishes, Volume 3, p. 1861
see The Osmorespiratory Compromise, Volume 2, p. 1389

THE GUT

The Gastrointestinal Tract: An Introduction *C Olsson and S Holmgren* 1229
Appendix A 1232

GUT ANATOMY AND MORPHOLOGY

Gut Anatomy *C Olsson* 1268

Pancreas *MA Caruso and MA Sheridan* 1276

Development of Fish Gut *KN Wallace* 1284

see The Gastrointestinal Circulation, Volume 2, p. 1132

INTEGRATED FUNCTION AND CONTROL OF THE GUT

Gut Motility *A Gräns and C Olsson* 1292

Gut Secretion and Digestion *Å Krogdahl, A Sundby, and AM Bakke* 1301

Intestinal Absorption *KS Sundell I Rønnestad* 1311

Barrier Function of the Gut *F Jutfelt* 1322

Nervous System of the Gut *S Holmgren and C Olsson* 1332
Endocrine Systems of the Gut *E Jönsson and S Holmgren* 1341
see Integrated Responses of the Circulatory System to Digestion, Volume 2, p. 1206

OSMOTIC, IONIC AND NITROGENOUS-WASTE BALANCE

Osmoregulation in Fishes: An Introduction *DH Evans* 1348
Mechanisms of Gill Salt Secretion in Marine Teleosts *DH Evans* 1354
Mechanisms of Ion Transport in Freshwater Fishes *P-P Hwang* 1359
Water Balance and Aquaporin *CP Cutler* 1366
Osmosensing *D Kültz* 1373

ROLE OF THE GILLS

Morphology of Branchial Ionocytes *JM Wilson* 1381
The Osmorespiratory Compromise *RJ Gonzalez* 1389

ROLE OF THE KIDNEYS

Histology of the Kidney *DB McMillan* 1395
The Kidney *SF Perry* 1411

ROLE OF THE GUT

Gut Ion, Osmotic and Acid-Base Regulation *RW Wilson* 1419
Dogfish Rectal Gland *WW Dowd* 1429
see The Hormonal Control of Osmoregulation in Teleost Fish, Volume 2, p. 1466
see Barrier Function of the Gut, Volume 2, p. 1322
see Endocrine Systems of the Gut, Volume 2, p. 1341
see Intestinal Absorption, Volume 2, p. 1311

NITROGENOUS-WASTE BALANCE

Excretion of Ammonia *D Randall* 1437
Ureotelism *PA Wright* 1444

HORMONAL CONTROLS

THE PITUITARY

Development of the Hypothalamus-Pituitary-Interrenal Axis *D Alsop and N Aluru* 1450
Pituitary Gland or Hypophysis *DB McMillan* 1457

HORMONAL CONTROL OF METABOLISM AND IONIC REGULATION

The Hormonal Control of Osmoregulation in Teleost Fish *SD McCormick* 1466
Corticosteroids *P Kiilerich and P Prunet* 1474

HORMONAL CONTROL OF REPRODUCTION AND GROWTH

Endocrinology of Fish Growth *MA Sheridan* 1483

Endocrine Control of Sex Differentiation in Fish *F Piferrer* 1490

Endocrine Regulation of Fish Reproduction *Z Yaron and B Levavi-Sivan* 1500

Control of Appetite in Fish *H Volkoff* 1509

HORMONAL RESPONSES TO STRESS

Hormone Response to Stress *SE Wendelaar Bonga* 1515

Catecholamines *SG Reid* 1524

Stress Effect on Growth and Metabolism *TW Moon* 1534

Impact of Stress in Health and Reproduction *L Tort* 1541

HORMONES IN COMMUNICATION

Hormonal Pheromones *N Stacey and P Sorensen* 1553

see Hormone Metabolism in the Circulation, Volume 2, p. 1190

see Integrated Control of the Circulatory System, Volume 2, p. 1169

VOLUME 3 – ENERGETICS, INTERACTIONS WITH THE ENVIRONMENT, LIFESTYLES, AND APPLICATIONS

ENERGETICS

Energetics: An Introduction *JA Nelson* 1563

General Energy Metabolism *JA Nelson and D Chabot* 1566

Physiological Functions that Scale to Body Mass in Fish *CR White and RS Seymour* 1573

FOOD ACQUISITION AND DIGESTION

Energetics of Prey Capture: From Foraging Theory to Functional Morphology *LA Ferry* 1583

Energetics of Foraging Decisions and Prey Handling *S Killen* 1588

Digestive Efficiency *DP German* 1596

Cost of Digestion and Assimilation *SM Secor* 1608

Dietary Requirements of Fish Under Culture Conditions *IP Forster* 1617

see A Survival Guide for Fishes: How to Obtain Food While Avoiding Being Food, Volume 1, p. 744

ENERGY UTILIZATION IN GROWTH

Energetics of Growth *RJ Wootton* 1623

Growth: Environmental Effects *RJ Wootton* 1629

INDEX 2091

PREFACE

The *Encyclopedia of Fish Physiology: From Genome to Environment* is the first of its kind. It follows in the strong tradition built by the book series *Fish Physiology* that was pioneered in the late 1960s by Bill Hoar and Dave Randall and is still ongoing; however, the Encyclopedia differs markedly from this book series in three important respects.

Foremost, the Encyclopedia targets a much broader audience, not just the research community. My hope is that the Encyclopedia will serve as a general educational tool for biologists, as well as being of general use as an information resource for those interested in fishes. After all, the Encyclopedia is replete with magnificent examples of how fishes are marvelously adapted to almost every water body on the Earth, no matter how deep, how hot, how cold, how salty, or, in some cases, how dry!

Second, the articles span well beyond just the physiology of fishes. The intent here is to connect physiological functions, environmental factors, behavior, and the genome. This is the case even though the main focus here is on physiology.

Third, and as a result, the breadth of topics covered by the Encyclopedia far exceeds that of any focused volume of the *Fish Physiology* book series. Thus, the Encyclopedia is ambitious in both its content and its target audience.

The Encyclopedia contains a very impressive array of entries, each in the form of a discrete, self-standing article that is typically 3000–4000 words in length, not counting the ancillary material contained in figures, glossary, further reading, etc. In total, there are 252 articles written by over 200 international experts from over 20 countries.

The articles are arranged thematically. The larger thematic sections have an introductory article, written by a section editor, who explains contributions in that theme and places them in a broader and often historical context. Tributes are deservedly given to those who made key scientific advances.

The electronic format of the Encyclopedia was deliberate and a crucial requirement before this project even started. I have to thank Andy Richford for garnering Elsevier's support of this idea, as well as initiating this project when he was an acquisition editor. The electronic format, through 'hot keys', provides an easy and almost instant access to the glossary and related articles. Each article is generously linked to many others in this manner, offering the reader easy digressions or more detailed information and explanations. The 'Further Reading' section associated with each article provides additional resources.

This ambitious opus could not have been possible without the dedication and commitment of a great number of individuals. I had an idea that I have steered to completion, but others did most of the hard work. I am especially indebted to my associate editors, Don Stevens, Joe Cech, and Jeffrey Richards. They embraced my dream early on and stayed with me until completion. Without their wisdom, breadth of knowledge, and hard work, the Encyclopedia could not have come to fruition. I think we worked well together, and, on my part, it was a distinct pleasure to have such enthusiastic support.

I am equally indebted to the section editors: Colin Brauner, Ann Butler, Bruce Carlson, Brandon M Casper, Greg Goss, Jeff Graham, Toshiaki Hara, Sue Holmgren, Norman Maclean, Jay Nelson, Ken Olson, Catharina Olsson, Arthur Popper, Trish Schulte, Bob Shadwick, Kath Sloman, Adam Summers, Matt Vijayan, and Hans-Joachim Wagner. They shaped their section and carried the core of the editorial responsibilities for the contributed articles during the many rounds of review and revisions.

Finally, and importantly, there are over 200 authors and their collaborators, who contributed the articles. My hope is that your rewards go well beyond the recompense, which is a pittance for the time that I know you devoted to generating such marvelous articles. You are thanked for your dedication and trust in the project, and are congratulated for your respective skills and knowledge.

There is another side to the production of this Encyclopedia, and that is the Elsevier team, with whom the editors and authors interacted. This team was headed by Kristi Gomez, the acquisitions editor in San Diego. Milo Perkins, the

development editor in the Oxford office, was our go-to-man after Esmond Collins had set the ball rolling. Milo endured the rough and the smooth, and his rapid responses, as well as his flexible deadlines, were greatly appreciated. Kate Mittell worked quietly and efficiently in the background supporting Milo and was responsible for keeping me on track with the enormous glossary of terms. Nicky Carter, our project manager, superbly rounded out the team. We relied on her for the professional appearance and content of the final copy.

As Editor-in-Chief, I am ultimately responsible for any errors contained herein. If you find any, please let me know so that they can be corrected; likewise, if you feel there are important omissions, please let me know of these. They might be incorporated in future updates.

Bringing this Encyclopedia to its conclusion means one thing for me personally: Miriam, Dustin, Naomi, Nicole and Natalie will all be seeing a lot more of me over the next while! Miriam, your patience throughout was astounding, although it was pushed to the limit at times.

Energy Use by Fish

Glossary

Entropy A thermodynamic property measuring the amount of disorder in the system. Greater disorder is energetically favorable; thus, entropy favors unfolding of proteins.

Specific dynamic action (SDA) The additional amount of oxygen or energy consumed above SMR as a result of feeding, measured during the period after feeding until metabolic rate returns to SMR; SDA represents the energetic cost of digestion, assimilation, and protein turnover.

Standard metabolic rate (SMR) The minimum metabolic rate of survival. Typically, SMR is measured on resting, unstressed adult animals in the post-absorptive state under normothermic conditions. For fish, normothermic is defined as a temperature well within the species tolerance limits for which the animals have had ample time to acclimate.

Energy Use by Fish

Metabolism is the word used to describe the totality of energy-consuming, manipulative, and storage chemical reactions undertaken by organisms. The second law of thermodynamics demands that all processes increase the amount of entropy (disorder) in the universe. Thus, a highly ordered entity like a fish requires a constant input of energy to remain ordered, even in the absence of growing. In the process of obtaining and assimilating that energy, the fish randomizes the rest of the universe more than the ordering of the fish itself. This results in a net increase in the disorder of the universe and the possibility of fish life, but only with this constant energy input. Therefore, a primary goal of fish existence is to obtain sufficient energy to offset this universal randomization process. This energy needs to be of two types, chemical bond energy and high-energy electrons (reducing power) which, along with some minerals and macromolecules that fish are unable to synthesize themselves, constitutes the daily dietary requirement for that fish species (**see also Food Acquisition and Digestion**: Digestive Efficiency). A subsequent, but equally essential goal of fish life is to obtain these components in sufficient excess to fuel growth and reproduction, leading to eventual evolutionary success. This excess fuel can also support locomotion or other work done on the environment. A bioenergetics flow chart, such as **Figure 1**, summarizes the energy inputs and outputs of a fish.

Of the energy consumed in food (*C*), only a certain fraction is actually absorbed across the intestinal epithelium into the fish (*A*), with the remainder being lost as feces (along with a small, not depicted, fraction of energy lost from the sloughing of gastrointestinal cells into the eventual feces). Fish tend to be very efficient at retaining the energy contained in their food. Of the absorbed energy (*A*), nitrogen in excess of the animal's requirements for protein and nucleic acid growth or turnover is not available to the organism and is excreted. The energy contained in this lost nitrogen as well as any energy lost in processing it, for

example, to urea, CN_2H_4O, is represented by the term U and is not available to the animal (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia and Ureotelism). The remaining energy (A') is available to the organism and can be used to support either maintenance functions (R), nonmaintenance activities (W), or the work of assimilating more food molecules (SDA) (**see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation). Excess energy is then available for storage or to support organismal growth (B) and gonad maturation (G) so that the animal can be successful from an evolutionary perspective and reproduce. This flow chart is often expressed in the form of an energy budget equation such as eqn (1) for modeling fish energy requirements:

$$C = (F + U) + (R + W + SDA) + (B + G) \qquad (1)$$

where, F is the fraction of ingested energy lost in the feces. This section of the encyclopedia focuses on this flow of energy through a fish. The section is divided into three main subsections: (1) energy acquisition, the energy cost to the fish to find, internalize, and extract the energy and other key molecules found in their food and how extrinsic and intrinsic factors influence that cost; (2) energy utilization, a detailed examination of the different ways that fish allocate the energy they procure from the environment and the effects of the variable aquatic environment on that allocation process; and (3) models and applications, where we explore how knowledge of the energy flow through fishes has led to advances in the management of exploited fish stocks and improvements in the aquaculture industry.

Energy acquisition encompasses the cost to the fish of finding food, successfully subduing it, manipulating it to the point that it can be swallowed, and then the cost of mechanically and chemically breaking down the macromolecules in food to a size that can be absorbed across the intestinal epithelium (digestion). Also included in this cost are the biochemical costs of manipulating the absorbed molecules into the proper forms to become self or storage compounds.

Lara Ferry-Graham opens this section with a consideration of how fish morphology matches up with the prey they consume, presumably minimizing energy acquisition costs, and how past evolutionary events may or may not have shaped these relationships. Shaun Killen continues with a discussion of the energetic costs of prey handling and ingestion, and how those costs may influence which prey items a fish actually attempts to consume. Donovan German then details what happens to the energy in food after it is ingested, that is, what factors determine the amount of energy extracted by a given fish on a given diet. Finally, Stephen Secor wraps up the 'energy acquisition' subsection with a detailed examination of the energetic costs associated with processing a meal.

The 'energy utilization' subsection deals with the main ways that fish can expend the energy they acquire with the exception of reproduction, which is dealt with in other areas of the encyclopedia (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction). The chapter by Jay A. Nelson and Denis Chabot focuses on just the standard metabolism (SMR) term R of eqn (1). This is the energy required by the organism just to stave off the forces of entropy and includes both extrinsic and intrinsic determinants of SMR. Resolving the terms of eqn (1) is essential if we are to predict growth and thus production in any fish species, which is the subject of Bob Wooton's first chapter. He then goes on to explore how environmental factors can change energy allocation to growth in a second contribution. Environmental effects on fish energy allocation are also the subject of Hans-Otto Pörtner's chapter, but his focus is on how the environment influences energy consumption or metabolic rate. Finally, David McKenzie details the energy cost of exercise in fish and how that integrates with the other parts of the bioenergetic budget because, of course, most fish need to move to procure food in the first place, or to avoid becoming food themselves!

The last subsection of the bioenergetics section, 'models and applications' deals with how this bioenergetic information is put to work solving real-world problems of fisheries management and aquaculture. Equation (1) needs to be resolved on an ecosystem level if we are to understand how changes in a species' numbers will influence energy flow in their ecosystem. Chuck Madenjian details the history of bioenergetics use in fisheries management and presents several case studies where bioenergetics models have been essential in making good fisheries-management decisions. Finally, Malcolm Jobling presents a cogent argument for why all food production is basically an exercise in bioenergetics and how the aquaculture industry is steadily improving the bioenergetic basis of how it operates.

Metabolic Rates of Fish
Conclusions
Further Reading

Glossary

Adenosine triphosphate (ATP) An almost universal carrier of chemical bond potential energy; fish use ATP made from catabolism of foodstuff or body reserve molecules to fuel energy-dependent processes.

Direct calorimetry The measurement of waste heat produced by metabolic processes to assess the rate of these processes.

Entropy A thermodynamic property measuring the amount of disorder in the system. Greater disorder is energetically favorable; thus, entropy favors unfolding of proteins.

Indirect calorimetry The measurement of O_2 or foodstuff molecules consumed or CO_2 produced to assess the rate of metabolic processes.

Mass exponent, β (also called allometric exponent) The power function exponent for the relationship of metabolic rate as a function of body size.

Metabolic scaling How metabolism changes as body size changes; typically summarized by the mass exponent.

$\dot{M}_{O_2}$ Mass of oxygen consumed by an organism. The SI unit is micromoles or millimoles per unit time, but often expressed as milligrams of oxygen per unit time. It can also be divided by the mass of the fish (e.g., mg-O_2 h^{-1} kg^{-1}) in which case, it is called 'mass-specific oxygen consumption'.

Quantile A value that divides a data set into parts. Where the division is made depends upon the parameter *q*. If $q = 0.5$, half the data are below the quantile and half above, which gives the median. If *q* is given as a percent instead of a proportion, the quantile can be called a percentile.

Standard metabolic rate (SMR) The minimum metabolic rate of survival. Typically, SMR is measured on resting, unstressed adult animals in the post-absorptive state under normothermic conditions. For fish, normothermic is defined as a temperature well within the species tolerance limits for which the animals have had ample time to acclimate.

Metabolic Rates of Fish

Measuring Metabolic Rate

Organismal energy use is thermodynamically inefficient, that is, about two-thirds of the potential energy of the reactants is lost as a less-useful form of energy known as heat during the execution of essential life processes. In addition, the catabolic reactions of the body that convert the energy in food to the adenosine triphosphate (ATP) required to fuel these process are themselves inefficient and generate heat. Thus, although the most useful indicator of total metabolic activity would be to measure the rate of total ATP turnover in an organism, in the absence of a convenient way to measure ATP turnover, accounting for the heat produced by these aggregate reactions is the best way to assess total metabolic activity, a process called 'direct calorimetry'. Unfortunately, the high heat capacity of water and the relatively low metabolic activity of fish result in a low 'signal:noise' ratio for direct calorimetry in aquatic studies. Therefore, we find limited measurements of metabolic rate by direct calorimetry available for the fishes; most studies instead rely upon a process called 'indirect calorimetry'.

Indirect calorimetry takes advantage of the fact that substances are consumed or produced during the catabolic conversion of foodstuffs to useful ATP energy. Eqn (2) depicts the complete aerobic respiration of an example foodstuff molecule, glucose:

$$\begin{aligned} &C_6H_{12}O_6 + 36\text{ADP} + 36\text{P}_i + 36\text{H}^+ + 6O_2 \\ &\quad \Rightarrow 6CO_2 + 36\text{ATP} + 42H_2O + \text{Heat} \end{aligned} \qquad (1)$$

Both oxygen (O_2) and carbon dioxide (CO_2) are gases at the range of temperatures and pressures encountered by fish; their stoichiometric consumption (O_2) or release (CO_2) can be monitored to gauge the rate of this reaction. Some studies also follow the decline in storage metabolites in starved fish as a way to monitor rates of respiration reactions. However, because starvation is a nonstandard physiological state, these types of experiments will not be discussed further here (**see also Gut Anatomy and Morphology**: Gut Anatomy). Because each foodstuff (protein, fat, or carbohydrate) produces different amounts of energy per amount of O_2 consumed or CO_2 emanated, accurate use of indirect calorimetry for bioenergetics requires a strict assessment of the substrate being respired. This is not a great challenge in laboratory situations, but may be impossible for most field studies because the exact composition of the diet is often unknown. Because measuring $[CO_2]$ in water is more challenging than measuring $[O_2]$, studies of fish metabolic rate over the past 30 years have relied upon measuring O_2 consumption almost exclusively, often without any attempt to relate the measurement back to energy usage. As such, oxygen consumption ($\dot{M}_{O_2}$) has actually become a measurement in its own right because without accounting for the substrate being oxidized or accounting for any anaerobic metabolism that occurs, it may be quite different from the actual metabolic rate. Recent careful comparisons of metabolic rate in endotherms using both direct and indirect calorimetry on the same animals suggest that the use of indirect calorimetry incurs routine errors of the order of 20%, with isolated cases as high as 35%.

Standard Metabolic Rate and its Measurement

$$C = (F + U) + (R + W + SDA) + (B + G) \qquad (2)$$

In eqn (2), a standard bioenergetics equation, (**see also Energetics**: Energetics: An Introduction) '*R*' represents the minimum rate of energy expenditure needed to keep a fish alive. It involves three broad classes of processes, the first of which is biosynthesis of macromolecules. Even when a fish is not growing, there is a constant, energy-requiring renewal of the macromolecules that make up the fish with molecules from the diet. The second class of processes concerns the chemical work of moving ions and molecules against concentration gradients or moving polar compounds across nonpolar membranes. These energy-requiring processes are essential for osmoregulation, the maintenance of internal cellular integrity, cellular communication, intra-organismal communication (e.g., action potentials or hormone release), and the transport of food molecules. The third class of processes concerns the internal mechanical work required to preserve organismal integrity (e.g., work done by the heart to accelerate blood).

R is often called basal metabolic rate (BMR) in endotherms and standard metabolic rate (SMR) in ectotherms. *R* allows for no activity, digestion, or reproduction, and care needs to be taken to exclude other sources of energy expenditure when measuring it. Measurement methodologies for BMR in endotherms are well established. In humans, for example, BMR is measured in subjects who are awake, supine, fasted for 12 h, motionless, after a 20–30-min period of rest, and isolated from external stimuli in a thermoneutral dark environment. Even so, BMR is not without criticism because metabolic rate can decrease further during sleep. Nevertheless, the stringent measurement conditions facilitate comparisons between studies and can also be applied to many nonhuman mammals.

By contrast, the conditions in which SMR is measured in aquatic ectotherms are more loosely defined. SMR is typically observed in postabsorptive (but not starving), resting organisms after acclimation to the experimental temperature and apparatus, isolated from outside stimuli (including sensory stimuli from potential predators and possibly conspecifics), during the part of the circadian activity cycle when $\dot{M}_{O_2}$ is lowest. Strictly speaking, SMR should be measured only in animals that are in a steady state (no growth or reproduction). However, the minimum metabolic rate of juvenile fish is often called SMR and the growth of many fish species is indeterminate, so the no-growth criterion is often not met. SMR of adult fish should be measured outside of the reproductive season, although in practice, the reproductive status of fish used in SMR determinations is not always known. Because there is usually some activity during measurements of metabolic rate, or because activity has not been monitored, many authors refrain from using the term SMR and instead use resting, fasting, or most commonly resting routine metabolic rate. However, this may be unduly restrictive and the term SMR should be allowed when activity level is measured and known to be at the minimum possible for the species.

Handling stress has undoubtedly inflated many published estimates of SMR in fishes. Human contact and air exposure need to be minimized before measuring SMR. Visual contact with humans or laboratory noises can elevate metabolic rate considerably even in the absence of movement. An acclimation period is required before $\dot{M}_{O_2}$ measurements can be used to estimate SMR. Handling stress and the novelty of the experimental setup may elevate $\dot{M}_{O_2}$ in fish for hours or even days. Sufficient acclimation can be verified by measuring $\dot{M}_{O_2}$ during the acclimation period to confirm that the fish has reached a state where repeatable measurements of minimum metabolic rate can be made. Striking a balance between ensuring that an animal is only postabsorptive and not starving with adequate acclimation may prove to be difficult. In social species, isolating fish to measure SMR may produce stress and increase $\dot{M}_{O_2}$. It may be necessary to determine SMR for groups of fish, after examination of the relationship between $\dot{M}_{O_2}$ and group size.

Spontaneous activity is extremely difficult to control or even measure in fish, yet activity can increase metabolic rate by an order of magnitude (**see also Ventilation and Animal Respiration**: The Effect of Exercise on Respiration). One approach has been to circumvent the problem by measuring $\dot{M}_{O_2}$ during forced activity at different speeds, and then by extrapolating the relationship between $\dot{M}_{O_2}$ and swimming speed back to zero swimming speed. However, fish can engage in spontaneous locomotor activity, have additional maneuvering costs at high speed, or be subject to stress, in addition to the sustained swimming at low speeds, thereby elevating $\dot{M}_{O_2}$ and the predicted $\dot{M}_{O_2}$ at zero speed. Because of this, $\dot{M}_{O_2}$measured at low swimming speed is generally less repeatable than at higher speeds, so if this method is employed, relatively high, but still aerobic, swimming speeds should be used. Another concern is that the routine metabolism of some organ systems (e.g., the gut) can be turned down with swimming activity, which, if left unaccounted, could lead to an underestimate of SMR.

An alternative method is to measure the level of spontaneous activity in a static respirometer, relate $\dot{M}_{O_2}$ to activity level (i.e., through regression analysis), and use the intercept (i.e., at zero activity) of this relationship as SMR. Yet another method is simply to estimate SMR only on measurements obtained when activity is zero. Some authors have employed anesthesia to eliminate activity from SMR measurements, but this method is not recommended because the anesthetic may interfere with other functions, including those responsible for SMR. However, for very active, dangerous or obligate ram-ventilating species, this may be the only tractable method available, in which case, the minimum dose to eliminate swimming activity should be used.

There is more uncertainty in estimating SMR when activity is not accounted for in static respirometry. Unless the period of minimum spontaneous activity is known for the species, $\dot{M}_{O_2}$ must be measured over at least 24 h; longer experiments increase confidence in estimated SMR by verifying that similar low levels of $\dot{M}_{O_2}$ are observed for the circadian minimum on multiple days. Long records of $\dot{M}_{O_2}$ can be obtained using two different respirometry techniques: open-flow respirometry and intermittent-flow respirometry. However, there is no standardized method to estimate SMR from these records. It may be nonadvisable to use the lowest value of $\dot{M}_{O_2}$ because it could be the result of measurement error. Often, an arbitrary number of the lowest values of $\dot{M}_{O_2}$ observed after the fish is deemed acclimated are averaged to obtain SMR, sometimes after removing 'outliers' that are arbitrarily also identified.

Another approach is to fit a mixture of normal distributions to the frequency distribution of $\dot{M}_{O_2}$ values. The mode with the lowest $\dot{M}_{O_2}$ can be interpreted as SMR; it constitutes the lowest value of $\dot{M}_{O_2}$ that is most frequently observed (**Figure 1**). This approach has two main advantages: (1) estimation of SMR is based on a large number of observations, and (2) it is unnecessary to manually select which measurements are used to estimate SMR. It turns out that this method does not work when there are many measurements with moderate activity or stress. It becomes impossible to discriminate the normal distribution corresponding to SMR from the distribution(s) corresponding to the moderately active or stressed fish and estimated SMR resembles routine metabolic rate (i.e., the metabolic rate of a moderately active fish, **Figure 2**).

Removing the 'noisy' part of the signal may improve the estimation of SMR by this approach, but the second advantage (see above) is negated (**Table 1**)

Yet another approach is to define SMR as a quantile: a proportion q (e.g., 0.05–0.25) of the measurements are assumed to be below SMR and the remaining $1 - q$ of the values above SMR. Models suggest that values of 0.10–0.15 result in small errors in estimating SMR across a broad range of activity and stress levels and could be used even in situations when fitting normal distributions (**Table 1**). However, the quantile approach has not yet been adopted widely to estimate SMR.

The postabsorptive state is also loosely defined in SMR studies on fish. Only rarely is gut-passage time measured for the same species under the same conditions; most studies rely on postabsorptive times from the literature that may not account for temperature or dietary differences (e.g., gut passage being significantly longer in herbivorous fishes (**see also Food Acquisition and Digestion**: Digestive Efficiency) or scaling effects (e.g., using published values based on fish of a different size; **see also Energetics**: Physiological Functions that Scale to Body Mass in Fish).

Body Size and SMR

Of the factors that contribute to differences in SMR, body size has to be considered the most pervasive. An animal's metabolic rate changes with body size in a nonproportional manner such that tissues of larger animals consume less energy per unit tissue than those of smaller animals (**see also Energetics**: Physiological Functions that Scale to Body Mass in Fish). The original mammal-centric literature on the subject dating to the nineteenth century considered this as a consequence of heat dissipation requirements by endothermic organisms and concluded that SMR scaled as the surface area to volume ratio or as body mass (M_b) to the two-thirds power:

$$\mathrm{MR} = CM_b{}^{0.67}$$

often expressed in the logarithmic form:

$$\log \mathrm{MR} = \log C + 0.67 \log M_b$$

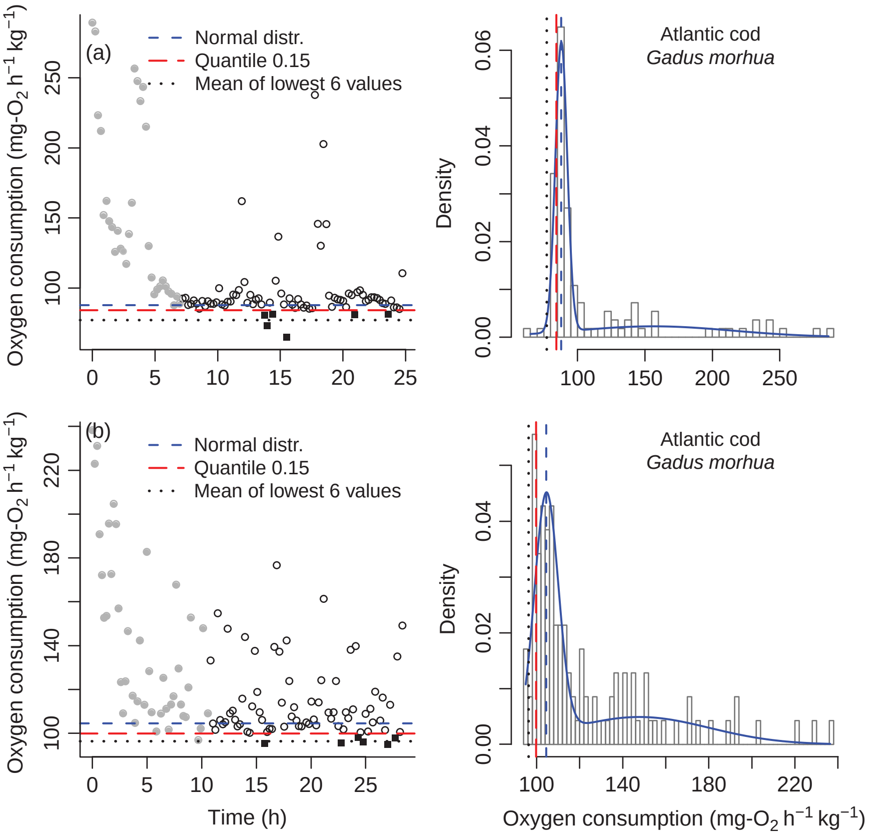

Figure 1 Oxygen consumption ($\dot{M}_{O_2}$) as a function of time in the respirometer (left), and frequency distribution of $\dot{M}_{O_2}$ values (right). (a) Juvenile Atlantic cod (*Gadus morhua*) with steady low levels of $\dot{M}_{O_2}$ and (b) juvenile cod with more variable $\dot{M}_{O_2}$ after acclimation. Gray circles and open circles represent values recorded during or after the acclimation period, respectively. The black squares are the six lowest values recorded after the acclimation period. Three estimates of SMR are shown: the average of the six lowest observations of $\dot{M}_{O_2}$, the lowest mode from fitting a mixture of normal distributions to the frequency distribution of $\dot{M}_{O_2}$ values shown in the right panels, and the quantile 0.15. The last two estimates were obtained using all available data, including the acclimation period.

where, MR is the metabolic rate, M_b the body mass, C the proportionality coefficient or MR at unit body mass, and 0.67 is β, the slope or power exponent describing the rate of change of metabolic rate with increasing body size. Subsequent empirical measurements throughout the twentieth century often arrived at a general interspecific 0.75 scaling coefficient for the metabolic rate of both ecto- and endotherms (i.e., $M_b^{0.75}$), but without a generally accepted physiological mechanism to account for it. Throughout the latter part of the twentieth century, measurements on fish generally returned a wide range of scaling coefficients. Knut Schmidt-Nielsen, in his seminal 1984 book on scaling, decried the huge variation in intraspecific β values for fish (0.37–1.1) and settled on a value of about 0.8 as the best. As the twentieth century was drawing to a close, several major new theories were advanced to either explain or discount the 0.75 scaling coefficient. These new theories created renewed interest in the field and stimulated many scientists to examine old data sets or undertake new measurements. To date, evidence has accumulated that metabolic scaling in fish may be higher than 0.75 (**see also Energetics**: Physiological Functions that Scale to Body Mass in Fish), especially if larval fishes are included. Scaling of metabolic rate under active conditions (**see also Swimming and Other Activities**: Energetics of Fish Swimming) appears to approach 1 for fish. Overall, SMR change with size is not proportional in juvenile through adult life stages in fish, and the exact scaling coefficients may be species specific. Certainly, the best way to correct for body-size differences, within a species, is to either find a carefully collected data set or construct one's own scaling factor, using specimens across a wide body-size range. Another way is to use an analysis of covariance (ANCOVA) to analyze data, using body mass as the covariate.

Sources of Variation in SMR

After correcting for body size, there still remains substantial inter-specific and intra-specific variability in SMR. Perusal of the literature can return values that vary by more than 70-fold for fish of similar lifestyles corrected

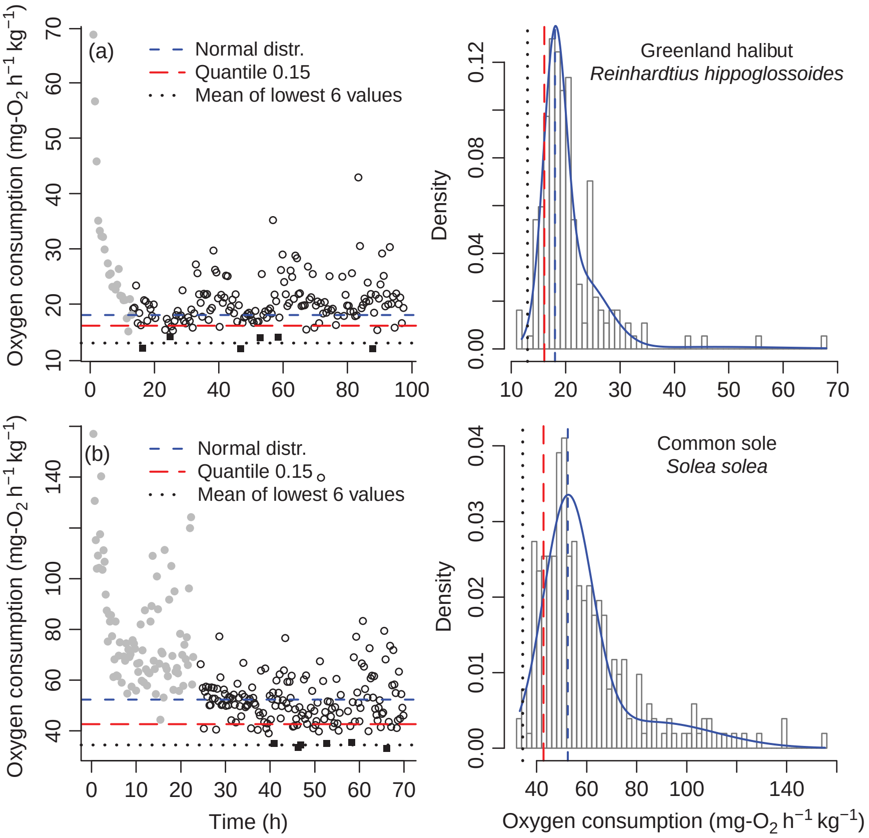

Figure 2 Oxygen consumption ($\dot{M}_{O_2}$) as a function of time in the respirometer (left), and frequency distribution of $\dot{M}_{O_2}$ values (right). (a) Mature female Greenland halibut (*Reinhardtius hippoglossoides*) and (b) juvenile common sole (*Solea solea*), both with high variability in $\dot{M}_{O_2}$ after the acclimation period. Symbols and lines are as in **Figure 1**.

Table 1 SMR estimated for the four fish shown in **Figures 2** and **3** using five different methods on four individuals from three species: averaging the six lowest values observed after the acclimation period, fitting a mixture of normal distributions to the frequency distribution of $\dot{M}_{O_2}$ measurements and selecting the leftmost mode, and taking the quantile 0.15, the latter two both with and without the acclimation period

			Normal distributions		*Quantile$_{0.15}$*	
Species	*Figure*	*Average of Six lowest values*	*All data*	*Excluding acclim. period*	*All data*	*Excluding acclim. period*
Atlantic cod	2A	77.1	87.6	87.2	84.2	83.1
Atlantic cod	2B	96.4	104.6	103.4	99.8	98.9
Greenland halibut	3A	13.0	18.1	18	16.1	16.1
Common sole	3B	34.4	52.7	47.9	42.7	41.1

for size and temperature. Much of this variation is due to experimental differences between laboratories, starting with how SMR was calculated. Many studies of standard or resting routine metabolic rate in fishes did not adequately control for human presence or elapsed time from human contact or transfer to the respirometer (see above). Thus, many of these values are inflated beyond standard or even resting routine levels. Another factor contributing to the large variance in standard metabolism estimates between species and studies are differences in water chemistry. Because of the constraints of Fick's first law of diffusion (eqn (3))

$$\mathcal{J}_{\mathrm{net}} = DA\Delta P_{\mathrm{gas}/\Delta d} \tag{3}$$

(where J_{net} is the net diffusional flux between two compartments, A the area over which the flux is occurring, ΔP the difference in partial pressure of the gas between the two compartments, Δd the distance separating the two compartments and D a constant), and the need for fish to extract O_2 and release CO_2, respiratory surfaces such as the skin or gills need to be large surface-area structures with a short diffusion distance to the external environment. These characteristics present an opportunity for the salt and water of the environment to also equilibrate across electrochemical gradients in water-breathing fish (**see also Role of the Gills**: The Osmorespiratory Compromise). Fish need to counteract these movements through active, energy-requiring processes. This fundamental conflict between the need to exchange respiratory gases and the relative cost of osmoregulation in water-breathing fish has been termed the 'osmorespiratory compromise'. Active osmoregulatory and acid–base processes will contribute to the animal's SMR, accounting for some of the variance between studies performed under different water chemistries. There is a fairly extensive literature attempting to define the cost of osmoregulation, that is theoretically at a minimum in environments iso-osmotic to body tissues, in fishes. Anadromous fishes and euryhaline fishes from primarily freshwater groups tend to conform to this theoretical prediction; however, euryhaline fish from primarily marine groups seem to generally have their lowest SMR's in full-strength seawater.

Even intraspecific, SMR measurements made within the same laboratory may vary as much as 10-fold between individuals of the same size at the same temperature. What accounts for this degree of variation in oxygen consumption? Studies of fish eggs have shown substantial genetic variation in SMR even before hatching. Studies of clonal fishes have also shown substantial environmentally induced variance in metabolic rate even in laboratory-reared fish, suggesting both genetic and environmental involvement. Respiratory rates of mitochondria corrected for temperature do not vary at the same magnitude as do whole animal metabolic rates among individuals of the same species or even across different species. Thus, differences in organismal metabolic rates corrected for body size and temperature differences come from different densities of mitochondria or differential patterns of either mitochondrial or whole tissue activation.

Some of the interspecific differences in SMR may arise from differential species-level activity patterns. The more aerobically active a species is, the more mitochondria they need to fuel those periods of activity. If the mitochondria can only be throttled down to a certain level, higher rates of standard metabolism are inevitable. It has been known for some time that active fish generally have a larger gill surface area and a higher muscle–mitochondrial density than less active fish. Thus, a more active species will have a relatively greater cost of osmo- and acid–base regulation and will have to maintain more metabolically expensive tissue like gills with high protein-turnover and ion-transport rates. A general linkage of SMR with activity metabolism has been found in many taxa and formed the basis of the activity metabolism hypothesis that was proposed to explain the evolution of endothermy in birds and mammals. Extrapolating this argument to the intraspecific level in fish, differential temporal selection regimes for either efficiency in standard metabolism or aerobic activity could account for the large variance in SMR that is apparent in extant populations. However, some studies have found that exercise training in fish can simultaneously increase muscle–mitochondrial density and decrease whole-animal SMR.

There is also some evidence that population-level differences account for some of the observed intraspecific variance in SMR. Regional differences in natural selection for SMR or traits linked to SMR could produce populations that differ significantly in SMR. There is some evidence that energetically expensive morphological traits that facilitate high rates of aerobic metabolism such as a high density of mitochondria (**see also Temperature**: Mitochondria and Temperature), large hearts (**see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes), and higher capillary densities (**see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis) may be outcomes of natural selection for fast recovery from exercise and not for exercise performance *per se*, because the highest rates of performance in fish are fueled anaerobically, and fish with higher resting metabolic rates recover faster from exhaustive exercise. This could result in a bimodal composition of some fish populations, one mode composed of cruising specialists (e.g., with higher SMR, higher aerobic performance, quick recovery from strenuous swimming, but low maximum-burst speeds) and a second mode composed of sprinting specialists (e.g., with higher maximum-burst speeds, but lower SMR, lower aerobic performance, and slow recovery from strenuous swimming), both maintained through disruptive (or diversifying) selection in the wild.

Temporal and geographic factors may also influence SMR, independent of the controlling factors of temperature and sexual maturation (**see also Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism). Certainly, the evidence is better for the former. Several studies have shown seasonal cycles of SMR in sexually immature fish kept at constant temperature. Krogh suggested, as early as 1915, that polar ectotherms might compensate for the effects of temperature on reaction rate by elevating temperature corrected SMR ('idling the engine faster'). This was eventually termed the metabolic cold adaptation (MCA) hypothesis and found enough early support that it was generally accepted. However, recent studies have failed to find any difference in SMR of polar fish compared with SMR extrapolated to the same temperatures for temperate and tropical species. Therefore, early measurements of $\dot{M}_{O_2}$ in polar species may have overestimated SMR, because polar fish measured in cold water require longer acclimation periods (just to recover from handling stress) and longer periods to become post-absorptive (**see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation).

Conclusions

Despite a century of concerted effort, we have to conclude that the measurement of fish SMR is in its infancy. The lack of standardized methods and uncertainty regarding stress level or human contact in a given study leaves much of the published literature uninterpretable. The situation is far better for swimming metabolism (**see also Swimming and Other Activities**: Energetics of Fish Swimming), although repeat measurements on the same fish are rarely made to verify results. Similarly, published scaling coefficients for SMR in fish span an incredible range, with many near 0.85 for adults and juveniles and 1 for larvae. Considering the current uncertainty in fish SMR values and how they change with body size, parameterization of bioenergetic models for real-world applications can contain many uncertainties. SMR corrected for temperature and body size is quite variable both between species and within species. Much current research is focusing on the relationship between these intrinsic differences in SMR and factors that are directly related to fitness such as dominance hierarchies or aerobic scope.

Glossary

Allometric Not proportional to body mass ($b <> 1$).

Critical partial pressure of oxygen The lowest partial pressure of oxygen at which a given physiological process can be maintained.

Interspecific Between different species.

Intraspecific Between individuals of the same species.

Isometric Proportional to body mass ($b = 1$).

Metabolic rate The rate at which an organism uses energy, often measured as rate of oxygen consumption.

Scaling exponent (*b*) A biological variable proportional to body mass^b.

Scaling Study of the relationship between biological variables and body mass.

Introduction

Body size affects practically every aspect of the biology of organisms. Among fish, the effects can be enormous, because the size range of adult fish spans 7.9 mm long and about 3 mg in a member of the carp family, *Paedocypris*, to 12.65 m and 21.5 tonnes in a whale shark, *Rhincodon*. The smallest fish is smaller than any other vertebrate animal, and the largest fossil fish, *Leedsichthys*, is said to equal the largest vertebrate, a blue whale. Thus, the size range in fish spans nearly 10 orders of magnitude, making the largest living fish about 10 billion times larger than the smallest. If one includes embryonic and larval stages, perhaps another order of magnitude can be added.

Changes in body size affect nearly all aspects of an animal's biology, including not only its morphology and physiology, but also the ecology, behavior, and life history. In most cases, measures of these aspects are not linearly related to body size, but are curved. The study of how they are related to body size is called 'scaling': variables that vary in direct proportion to body mass are said to scale isometrically, whereas those that do not are said to scale allometrically, meaning by another measure.

Curves of selected variables plotted on body mass are generally fit with a power equation of the form

$$Y = aM^b \tag{1}$$

where Y is the variable of interest, a the scaling factor (which defines the elevation or height of the curve), M the body mass (in defined units, usually grams as in this presentation), and b is the power or scaling exponent of the equation (which defines the shape and direction of the curve). In order to estimate the b value, it is generally required to obtain data spanning at least an order of magnitude range in M. The b value can be estimated over smaller ranges of M, but precision is reduced. Over very large ranges of M encompassing larval and adult fish, the b value often changes and fitting only a single exponent to the data may be inappropriate.

Sometimes data are expressed in mass-specific units, in a mistaken attempt to account for the effect of body mass, for example, metabolic rate (MR) per unit of body mass. In these cases, the a value is unchanged, but the mass-specific b value ($b_{m\text{-}s}$) is the negative complement of the whole-body one ($b_{m\text{-}s} = b - 1$). This shows that taking mass-specific values does not remove the allometric effect of body mass, except under the unique situation of isometric scaling ($b = 1$). Even if the mass range is small, say only twofold, the error would be 16% or 20% if b is 0.75 or 0.67, respectively.

The importance of allometry is the realization that most variables are far from being proportional to body size. This presentation can include only selected examples of scaling in fish. However, the most common one is the relationship between MR and body size, because MR affects many of the animal's other characteristics. Unlike some vertebrate animals that reach adulthood within a narrow range of body sizes, many fish species continue to grow throughout life. The study of scaling can be approached during ontogeny with intraspecific analyses; however, it is also interesting to compare fishes phylogenetically with interspecific analyses of adults. This presentation includes both approaches.

Scaling in Embryonic Fish

The largest fish egg is from the Coelacanth (*Latimeria chalumnae*) weighing as much as 325 g, although the egg capsules of sharks can exceed this. In these cases, the maternal delivery system supplies oxygen or the well-developed juvenile ventilates its capsule in later development. However, the free-living eggs of oviparous teleost fish are surrounded by a capsule that impedes diffusion of oxygen to the embryo. The eggs of these fish are limited to less than about 5 mm capsule size, for example, in the seawolf (*Anarhichas lupus*) or the Australian lungfish (*Neoceratodus forsteri*). It is apparent that the limitation in egg size is related to the difficulty for diffusion to supply adequate oxygen across the capsule. One line of evidence is that many fish parents tend their eggs and ventilate them to renew the oxygen around them (**see also Social and Reproductive Behaviors**: Parental Care in Fishes, Sexual Behavior in Fish, and **Reproduction**: The Diversity of Fish Reproduction: An Introduction). Diffusion through the capsule is slower than through pure water, which itself occurs some 250 000 times slower than through air. The gelatinous capsules of amphibian eggs are also known to limit oxygen diffusion, keeping them relatively small as well. By comparison, the eggs of reptiles, birds, and mammals are orders of magnitude larger than fish and amphibians, because the oxygen diffuses largely in the gas phase.

There are essentially three barriers in the way of oxygen uptake by fish embryos: the capsule, the perivitelline fluid around the embryo, and the embryo's tissue itself. Before the embryo's circulatory system is developed, it is possible to calculate the maximum size that an embryo can be and still be oxygenated by diffusion through its tissues. This depends on temperature and MR. At 20 °C, the carp (*Cyprinus carpio*) embryo is near the limit at about 0.5 mg. Embryos that are larger have higher respiration rates (**Figure 1**), and require circulatory systems and respiratory exchange organs. The capsule is the other major barrier to gas exchange that persists until hatching. Embryonic movements and ciliated epithelium circulate the

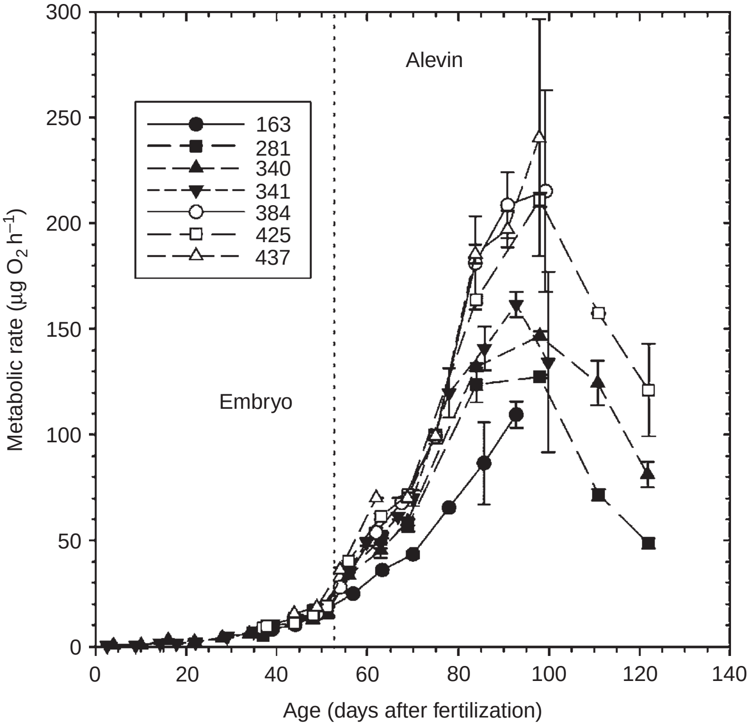

Figure 1 Metabolic rate of Chinook salmon (*Oncorhynchus tshawytscha*) embryos and alevins from eggs of seven selected sizes (163–437 mg). The vertical dashed line is the time of hatching. The effect of egg size is clear for the alevins – eggs with more resources produce larger larvae with higher rates of oxygen consumption. Reproduced from figure 1 of Rombough PJ (2007) Oxygen as a constraining factor in egg size evolution in salmonids. *Canadian Journal of Fisheries and Aquatic Sciences* 64: 692–699.

perivitelline fluid sufficiently to deliver oxygen from inside the capsule to the respiratory surface.

Because fish eggs are generally round, it is relatively easy to measure the capsule surface areas, and relate them to the respiratory demand of the embryos. A study of Chinook salmon (*Oncorhynchus tshawytscha*) eggs of different sizes (163–437 mg) indicated that the surface area of the capsule, which scaled with egg size with $b = 0.67$, increased in larger eggs faster than respiratory demand, which scaled with $b = 0.30$. In a similar study on Atlantic salmon (*Salmo salar*), oxygen consumption was measured in eggs ranging in size of about 100–210 mg, yielding $b = 0.44$, which was again less than the exponent of egg surface area. A conclusion of the studies was that oxygen uptake is not limited by egg size. However, such scaling analyses can be misleading. The egg mass range was less than about 0.4 orders of magnitude, reducing the confidence in the value of *b*. The values are much less than scaling of early embryos and larvae of other species that are nearly isometric ($b = 1$), as discussed subsequently. In addition, the thickness of the capsule is assumed to be constant and independent of egg mass. It is not known whether capsule thickness is a constant in fish, or whether it increases with egg size. Because oxygen conductance is proportional to surface area divided by thickness, the gas conductance may scale with an exponent considerably less than that for surface area. In eggs of 11 species of amphibians, capsule thickness increases with egg size to the 0.84 power and effective surface area (the geometric mean surface area of the capsule wall) scales to the 0.52 power; conductance, therefore, scales with mass to the –0.35 power. It is evident that increasing metabolic demand in larger amphibian eggs is not matched by increasing conductance; in fact, conductance decreases. Therefore, the size of amphibian eggs is certainly limited by diffusion. It would be surprising if fish differed.

The role of the capsule in limiting oxygen uptake is apparent in the sensitivity of oxygen uptake to external partial pressure of oxygen (P_{O_2}). This is often measured by the critical P_{O_2}, above which oxygen uptake is not limited by diffusion, but below which it is. In Chinook salmon, the critical P_{O_2} increases with development until just before hatching, when critical P_{O_2} is nearly atmospheric (**Figure 2**). This illustrates that if the embryo did

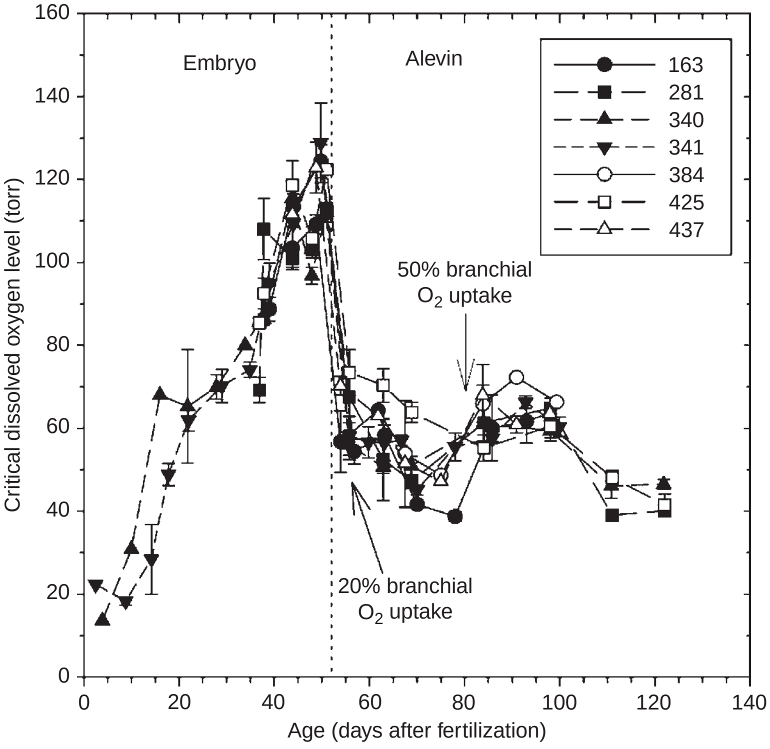

Figure 2 Critical partial pressures ($P_{O_{2c}}$) of Chinook salmon (*Oncorhynchus tshawytscha*) embryos and alevins from eggs of seven selected sizes (163–437 mg). The $P_{O_{2c}}$ is the value of external aquatic P_{O_2} below which the rate of oxygen uptake declines and above which uptake is independent of P_{O_2}. Because the capsule of embryos restricts diffusion, as the respiration rate of the embryo increases, it takes a greater external P_{O_2} to drive it into the capsule. Eventually, the $P_{O_{2c}}$ approaches atmospheric levels (~150 torr) just before hatching. After the capsule is removed at hatching, the diffusion barrier is removed, and the $P_{O_{2c}}$ drops. As the alevins grow, their increasing oxygen demand is met by increasing respiratory surface areas, so the values remain stable. Reproduced from figure 2 of Rombough PJ (2007) Oxygen as a constraining factor in egg size evolution in salmonids. *Canadian Journal of Fisheries and Aquatic Sciences* 64: 692–699.

not hatch, increasing oxygen demand would become diffusion limited. After hatching, low critical P_{O_2} indicates that the barrier of the capsule has been removed and the gills and skin are capable of supplying sufficient oxygen (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Models and Mechanisms and Respiratory Gas Exchange During Development: Respiratory Transitions).

It is significant that the scaling of MR in hatching-stage fish is somewhat low. The same situation also occurs among amphibians ($b = 0.52$ at 30 °C and $b = 0.62$ at 15 °C) in relation to egg size. This is interpreted as an adaptation to diffusion limitation by the capsule in large eggs, because the value is low compared to respiration rates in other vertebrates and because the exponent increases at cooler temperatures that reduce oxygen demand. The price that the larger embryos pay for a relatively low respiration rate is a longer incubation time, because the rate of development depends closely on the rate of oxygen uptake. Consequently, larger amphibian eggs are incubated at lower temperatures and for a longer time. Such evolutionary trade-offs may well occur in embryonic fish. Therefore, rather than concluding that fish eggs are not diffusion limited because of a low exponent for metabolism, the exponent may in fact result from depression of MR due to the capsule, either proximately by a direct effect on respiration, or ultimately (through evolution) by an inherently low MR matched to the oxygen delivery capacity of the capsule.

Ontogenetic Changes in Standard Metabolic Rate after Hatching

There are many studies of MRs of individual species of fish over some mass range during their lives. Examples of mass-specific standard MR from 31 fish species are shown in **Figure 3**. Although the variability in the elevations of the data may be due to differences in temperature, activity levels, accuracy of measurement, and inherent differences between species, the exponents in each study should represent each species over the range of mass. Of course, the wider the mass range, the more confidence can be placed in the value of *b*. Most of the studies encompass mass ranges of about two orders of magnitude (a 100-fold difference), but some are less than one order. Even over similar mass ranges, the exponents are obviously quite variable, so there is little general information to be gained, other than to note that mass-specific respiration rate tends to decrease with increasing size, but not always.

The problems of narrow ranges of body mass have been recently overcome in several studies of standard MR in fish throughout their post-hatching life, ranging up to seven orders of magnitude in body size. Several species exhibit conspicuous breakpoints in allometric plots in which the exponents are high in the early larval stages but decrease abruptly in later stages. For example, carp with masses up to about 0.3 g show almost isometric scaling of MR ($b = 0.95$), but above this mass, the exponent is 0.82. Rainbow trout (*Oncorhynchus mykiss*) and sea bream (*Pagrus major*) also show distinct breaks during ontogeny, as do ocean pout (*Macrozoarces americanus*), lumpfish (*Cyclopterus lumpus*), and shorthorn sculpin (*Myoxocephalus scorpius*; **Figure 4**). The positions of the breakpoints and the values of *b* before and after the break vary greatly. There seems to be little correlation with metamorphosis or depletion of yolk, and the mass at the breakpoint can vary over two orders of magnitude between species. Whether a breakpoint actually exists or is a result of statistically forcing two allometric curves to fit the data is a moot point. To illustrate the problem, several analyses have been undertaken with the same data set for developing yellowtail kingfish (*Seriola lalandi*; **Figure 5**). Both a biphasic model and a quadratic model fit the data with high precision.

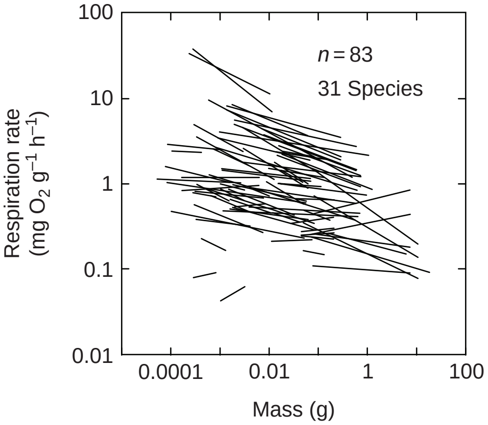

Figure 3 Meta-analysis of 81 selected studies of metabolic rate during growth in 31 species of fish. Each tick on the axes represents one order of magnitude. Reproduced from figure 2 of Post JR and Lee JA (1996) Metabolic ontogeny of teleost fishes. *Canadian Journal of Fisheries and Aquatic Sciences* 53: 910–923.

Hypotheses to explain declining allometric exponents or breaks during ontogeny include changes in respiratory structures, differences in swimming ability, shifts in the proportions that different organs add to the total demand, and changes in water content. The first explanation implies that routine oxygen uptake is limited by diffusion in the respiratory gas exchangers, which is probably not true, at least because respiration rate can increase when the fish becomes active and gill perfusion increases (**see also Integrated Control and Response of the Circulatory System**: Central Control of Cardiorespiratory Interactions in Fish, **Integrated Response of the Circulatory System**:

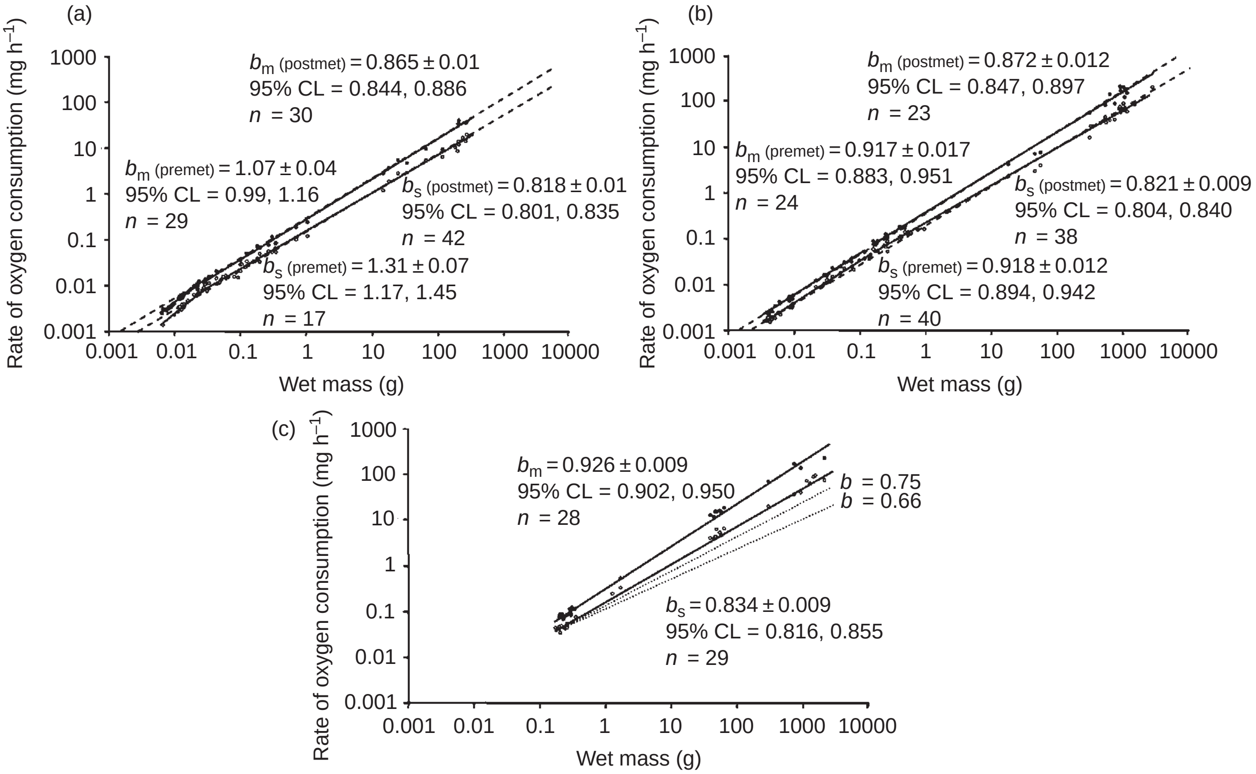

Figure 4 Rates of oxygen consumption during post-hatching development in (a) ocean pout (*Macrozoarces americanus*), (b) lumpfish (*Cyclopterus lumpus*), and (c) shorthorn sculpin (*Myoxocephalus scorpius*). Reproduced from figure 1 of Killen SS, Costa I, Brown JA, and Gamperl AK (2007) Little left in the tank: Metabolic scaling in marine teleosts and its implications for aerobic scope. *Proceedings of the Royal Society B: Biological Sciences* 274: 431–438.

Integrated Cardiovascular Responses of Fish to Swimming, Integrated Responses of the Circulatory System to Hypoxia, and **Control of Respiration**: The Ventilatory Response to CO_2/H^+). Even if there is a relationship between MR and gill area, it is likely that the demand for oxygen is the independent variable that ultimately influences gill development, not the reverse.

The second explanation concerns a shift in swimming ability, as fish pass through larval stages and finally reach adulthood. The argument is basically that swimming becomes more energetically efficient because there are shifts in swimming action and the fish becomes more hydrodynamically shaped. Greater efficiency would reduce MR at the same speed. This is consistent with the results from most fish, whether they are deemed to have a breakpoint in a biphasic allometry or a gradually decreasing *b*. On the other hand, the ability to increase aerobic MR above the standard metabolic rate (SMR) increases during ontogeny. This is measured as a factorial metabolic scope, which is the ratio of maximum metabolic rate (MMR) and SMR. Factorial scope increases from nearly 1 at hatching to about 6 at later stages in some species (**Figure 6**). A greater MMR, however, is not reflected in greater SMR, because the exponents differ, and the exponent for MMR is higher (**Figure 4**). Evidence from the literature suggests that athletic species, such as salmonids, have essentially isometric scaling of MMR ($b = 1$), while more sedentary benthic species show *b* values between 0.87 and 0.93. Thus, there is little basis for assuming that scaling of SMR is related to aerobic swimming performance.

The third explanation is that the decreasing value of *b* with ontogeny is possibly due to disproportionately high involvement of organs with high respiratory rate early in development. For example, the brains and kidneys are generally relatively larger in smaller fish, but decrease in relative size during ontogeny. This would also create a decreasing value of *b* with growth. Because it is difficult to assign MRs of specific organs to the whole animal, however, assessing the validity of this hypothesis may be difficult.

A fourth explanation relates to the water content of developing fish. Because the water content decreases during development in vertebrates in general, and most allometric studies measure wet mass, the energetic intensity of yolk-free younger fish may be figuratively diluted by higher water content. The result is that gradually decreasing water content causes allometric exponents to decrease. However, the extent of this effect has not been studied in fish.

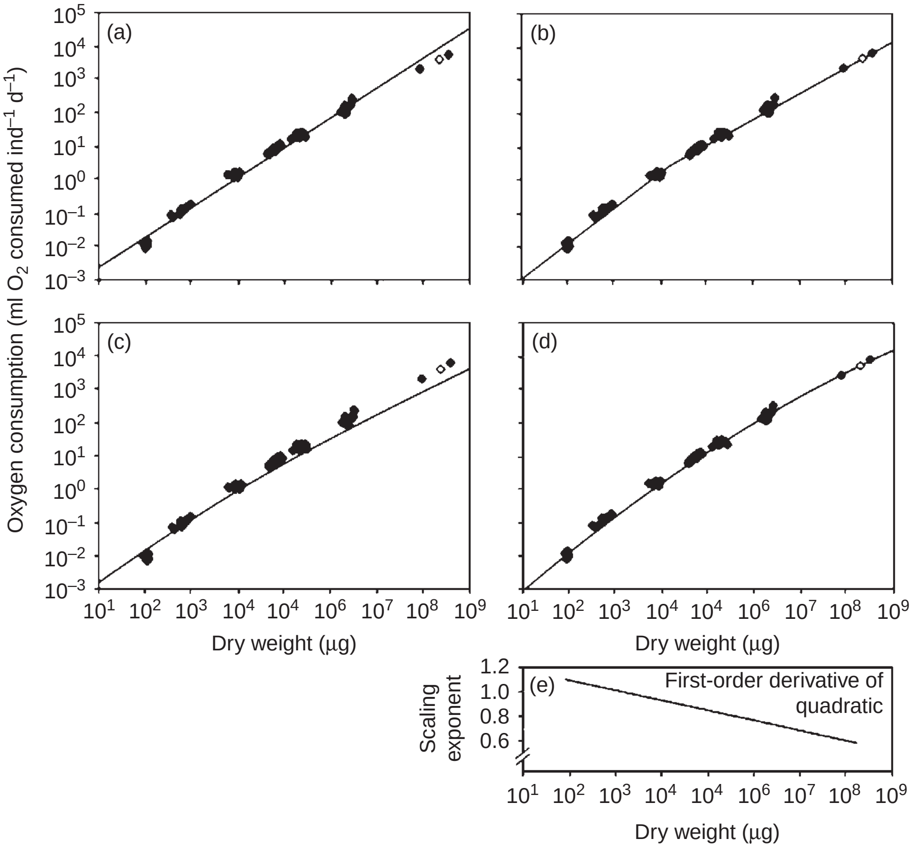

Figure 5 Oxygen consumption of yellowtail kingfish (*Seriola lalandi*) during ontogeny. Four functions were used to model the data: (a) LS linear regression; (b) LS segmented regression; (c) Bochdansky and Leggett model; and (d) LS quadratic regression. (e) Represents the first-order derivative of the quadratic regression ($y = 1.26 - 0.08x$) to illustrate the decreasing metabolic scaling exponent. Figure 6 Ontogenetic changes in factorial aerobic metabolic scope (= maximum aerobic MR/standard MR) in three teleosts. Reproduced from figure 2 of Killen SS, Costa I, Brown JA, and Gamperl AK (2007) Little left in the tank: Metabolic scaling in marine teleosts and its implications for aerobic scope. *Proceedings of the Royal Society B: Biological Sciences* 274: 431–438.

There have been a few studies that examined the respiratory gas exchange structures in post-hatching fish and analyzed them allometrically. In post-hatching salmon, for example, scaling of the respiratory surface area appears to have a two-phase pattern (**Figure 7**). In the latter phase, the exponent (b = 0.86) is not greatly different from the scaling of MR at the time. Earlier, however, total surface area exceeds apparent requirements. Thus, respiration in early post-hatching larvae is not limited by surface area. It is clear that oxygen delivery to support SMR is not limited by respiratory structures in later development either, because the gills and skin can increase delivery for higher aerobic demands during activity.

Comparison of ontogenetic changes in SMR between species demonstrate that b is influenced by a range of factors, including temperature, aerobic scope, swimming mode, and lifestyle. The value of b decreases with temperature and is related to lifestyle and metabolic scope such that it is lowest in active pelagic species ($b = 0.70$), intermediate in benthopelagic species ($b = 0.78$), and highest in relatively sedentary benthic ($b = 0.80$) and abyssal species ($b = 0.86$). Swimming mode influences b in a similar manner, such that b is lower in athletic thunniform

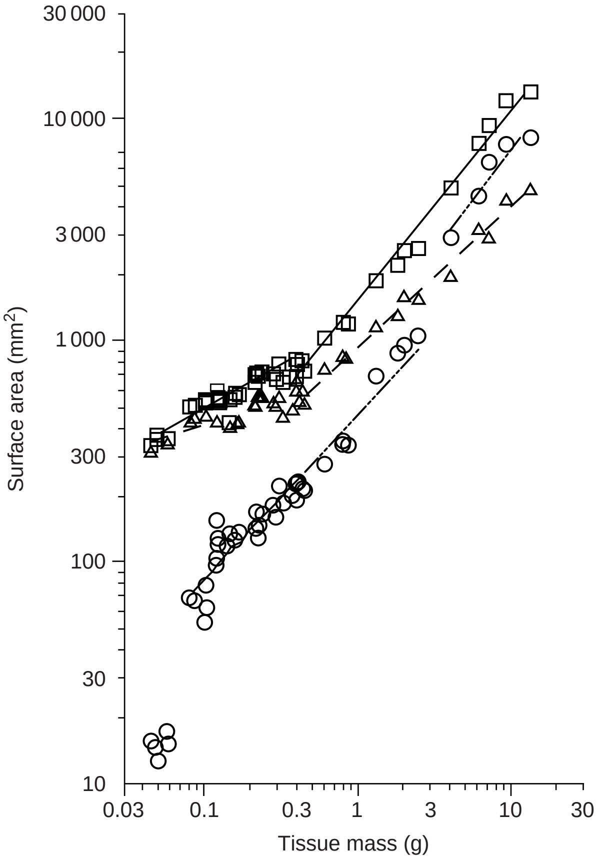

Figure 7 Relationship between the surface areas of the skin (△), the branchial structures (○), and the total (□) and body mass in chinook salmon (*Oncorhynchus tshawytscha*). swimmers (b = 0.56) than in carangiform (b = 0.74), subcarangiform (b = 0.83), or anguilliform swimmers (b = 0.78). This effect of lifestyle and metabolic scope on b has been proposed to occur as a result of varying investment in energetically expensive tissues associated with different capacities for swimming during predator–prey interactions, but the hypothesis remains to be tested.

Interspecific Scaling

An advantage of comparative analyses of the relationships between physiological functions and body mass across a range of species is that it is possible to examine how evolutionary (rather than ontogenetic) changes in body mass influence physiology, as well as to examine data spanning very wide ranges of mass. For example, data for SMR and swim speeds are available for species spanning around 100 000-fold in mass, the relationship between brain mass and body mass can be examined for species spanning a 4.3-million-fold range of mass, and gill surface areas are available for species spanning 40-million-fold. It is notable, however, that while data for gill surface area, brain mass, sustained swim speed, and burst swim speed are available for large species (1200, 430, 290, and 270 kg, respectively), measurements of MR are currently limited to individuals no larger than 10–20 kg (lingcod (*Ophiodon elongatus*) and three species of tuna: albacore (*Thunnus alalunga*), Pacific bluefin (*Thunnus orientalis*), and Southern bluefin (*Thunnus maccoyii*)). Given the logistical difficulties involved in measuring the MRs of large fish, it seems unlikely that this will change in the foreseeable future and caution must be exercised with extrapolating from the available measurements to make estimates of SMR for larger species.

The interspecific scaling exponent of gill surface area (b = 0.88, **Figure 8**(**a**)) is similar to that of SMR (b = 0.89, **Figure 8**(**b**)). This similarity of scaling exponents, however, is not sufficient to demonstrate that gill area and SMR are related, although it seems likely that they are. At any given size, species with high SMR tend to have large gill surface areas. This is exemplified by large tunas, which have the highest gill surface areas, and SMRs of all fish (unfilled symbols in **Figures 8**(**a**) and **8**(**b**)). It is important to note that although the relationship between mass and SMR appears tight, it nevertheless conceals a great deal of variation: the SMR of species of similar mass at the same body temperature can differ by over an order of magnitude. Some of this variation is associated with climate, such that when measured at the same body temperature, species from high latitudes tend to have higher SMR than species from lower latitudes. This pattern is commonly referred to as 'metabolic cold adaptation', because species from cold environments have relatively high SMRs, but it remains a controversial hypothesis.

Skeletal mass of fish scales approximately isometrically ($b \approx 1$), although data are available for relatively few species (**Figure 8**(**c**)). Skeletal mass also scales approximately isometrically in cetaceans, but the skeletal mass of terrestrial mammals scales allometrically ($b > 1$). The difference between aquatic and terrestrial vertebrates might arise because most of the weight of aquatic animals is supported by water, whereas the skeletal elements of large terrestrial species need to be relatively robust compared to small species to support their mass against gravity. This is because the weight of a bone varies in proportion to its volume ($b = 1$), but its strength varies in proportion to its cross-sectional area, which scales with $b = 0.67$. It can therefore be predicted that the skeletal mass of animals that must support their weight against

gravity should increase allometrically ($b > 1$), because the cross-sectional area, not the mass, of bones must increase in proportion to animal mass.

Unfortunately, it is difficult to evaluate this hypothesis with data for fish, because all of the species for which skeletal masses are available weigh less than 1.2 kg. For these relatively small fish, skeletal masses are similar to those of similarly small terrestrial mammals. Large fully aquatic mammals (cetaceans), on the other hand, have skeletons that are a smaller fraction of body mass than large terrestrial mammals (elephants). It therefore seems that the large aquatic vertebrates have lighter skeletons than large terrestrial ones; however, measurements of skeletal weight of large bony fish (e.g., ocean sunfish (*Mola mola*) that weigh up to 2300 kg or blue marlin (*Makaira nigricans*) that weigh up to 900 kg) would be valuable in resolving the issue.

In contrast to skeletal mass, the scaling exponent of brain mass is clearly allometric ($b = 0.65$, **Figure 8**(**c**)). This value is close to that predicted for the scaling exponent of body surface area ($b = 0.67$), and the relationship between brain mass and body mass has been thought to arise as a consequence of the scaling of surface area, because the body surface is the interface between an animal and its environment. However, this hypothesis was rejected following the observation that the scaling exponent of brain mass for mammals, reptiles, and birds is significantly greater than that of surface area, and more closely approximates that of MR. A link between brain size and MR has also proved to be unsatisfactory, since in fish the scaling exponents of SMR and brain mass are different and, for any given size, there is no association between SMR and brain mass (this is also true for birds, and the existence of a link is contentious for mammals). However, mormyrid fish have exceptionally large brains, in similar proportions as humans and, undoubtedly, associated with electro-sensation (**see also Detection and Generation of Electric Signals**: Detection and Generation of Electric Signals in Fishes:An Introduction). The MR of the brains of these fish can account for 60% of their SMR.

Burst swimming speed scales with an exponent higher than sustained swimming speed ($b = 0.21$ and 0.14, respectively), though not significantly so (**Figure 8**(**d**)). The scaling exponent of burst speed is not significantly different from that of sprint speed in mammals ($b = 0.17$). However, the relationships between log-transformed sprint speed and log-transformed body mass in mammals are curved with a peak at a body mass of 119 kg. When plotted on log–log axes, the relationship for fish shows no such curvature and burst swimming speed increases throughout the mass range of species that are available (up to 290 kg, **Figure 8**(**d**)). However, the available data for many of the largest fish are not appropriate for inclusion in **Figure 8**(**d**), because body masses are generally unknown. Many of the largest fish are generally regarded as somewhat sluggish (e.g., ocean sunfish, basking sharks (*Cetorhinus maximus*), and whale sharks), and do not attain the high speeds of smaller species. For example, whale sharks and megamouth sharks (*Megachasma pelagios*) generally swim slowly (around $0.5\ \mathrm{m\,s^{-1}}$), but whale sharks can maintain speeds of $2\ \mathrm{m\,s^{-1}}$ for at least 10 min and can reach speeds of almost $4\ \mathrm{m\,s^{-1}}$ for short periods. These speeds fall toward the lower range of values recorded for other species. The fastest fish are probably either black marlin (*Makaira indica*) that are estimated to reach speeds of $36\ \mathrm{m\,s^{-1}}$, or Indo-Pacific sailfish (*Istiophorus platypterus*) that may reach speeds of $30\ \mathrm{m\,s^{-1}}$ (masses up to 750 and 100 kg, respectively). Swordfish (*Xiphias gladius*) that reach 650 kg have been measured swimming at $25\ \mathrm{m\,s^{-1}}$, while yellowfin tuna (*Thunnus albacares*; up to 200 kg) and wahoo (*Acanthocybium solanderi*; up to 83 kg) reach $21\ \mathrm{m\,s^{-1}}$. These are all smaller than the largest fish, yet they reach higher speeds. This suggests that the largest fish are not the fastest ones, just as the largest terrestrial animals are also not the fastest.

When MR is measured in flume respirometers at different swim speeds, the relationship generally increases in an upwardly bending curve, because the resistance of the water (drag) increases at higher speeds. Many fishes have been shown to swim voluntarily at an optimal speed that minimizes the energy cost of

Figure 8 Interspecific scaling of (a) gill surface area, (b) standard metabolic rate, (c) brain and skeletal mass, (d) burst and sustained swim speeds (unfilled and filled symbols, respectively), (e) minimum gross cost of transport at optimal swimming speed, (f) critical partial pressure of oxygen (P_{O_2}) for standard metabolic rate, and (g) resting heart rate. One data point for the largest body mass available for each species is shown for standard metabolic rate and brain mass; data for smaller body masses were excluded for clarity. All available data are shown for gill surface area, skeletal mass, swim speeds, cost of transport, heart rate, and critical P_{O_2}. Data for standard metabolic rate and heart rate are normalized to a body temperature of 20 °C using mean Q_{10} values calculated from available data (2.3 and 2.1, respectively). Allometric relationships (aM^b, with b shown ±95% confidence interval) were calculated by linear regression of log–log transformed data, using only the single measurement with largest M for each species; nonsignificant relationships for critical P_{O_2} and heart rate are not shown. Data for large scombrids are shown as unfilled symbols in (a) and (b) and were not included in regression calculations for gill surface area and standard metabolic rate. Data were compiled from FishBase website http://www.fishbase.org and a range of literature sources.

locomotion. The gross energy cost of locomotion at the optimum speed, compared allometrically over about six orders of magnitude body mass, scales with $b = 0.70$. However, the cost of transport is more often expressed as a mass-specific value, which represents the cost of transporting 1 g of fish a unit distance. Here, $b = -0.30$, showing that larger fish are more economical at transporting a unit of body mass than small ones (**Figure 8**(**e**)). Swimming in fish is also far more economical than any other form of transport, including running and flying, because of their hydrodynamic shape, lack of gravity effects, and generally continuous, undulatory swimming action.

Not all physiological functions vary with body mass. Both critical P_{O_2} for SMR (**Figure 8**(**f**)) and heart rate (**Figure 8**(**g**)) are not significantly related to body mass (i.e., b is not significantly different from zero). In the case of critical P_{O_2}, this probably arises because gill surface area and SMR scale with similar exponents (**Figures 8**(**a**) and **8**(**b**)). The partial pressure gradient required to sustain diffusion across the gills is therefore independent of body mass, all other things being equal. It is surprising that heart rate scales with $b \approx 0$ for fish, because large birds and mammals have lower heart rates than small ones, and the scaling exponent for heart rate is around −0.25 in these groups. However, most species of fish for which heart rate data are available weigh between 50 g and 2 kg, and high variability may obscure a trend (**Figure 8**(**g**)). The available data for zebrafish (*Danio rerio*) suggest that heart rates are possibly higher in small fish than large ones, but measurements are clearly required from fish of a greater range of body size.

Glossary

Character displacement An idea linked fundamentally to the notion of competitive exclusion. Character displacement refers generally to changes in the morphology or behavior (any measurable character or trait) of a species in response to, or facilitating, the utilization of a new resource.

Competitive exclusion The process whereby two species diverge in their utilization of a limiting resource. Two species cannot utilize the same resource, if limiting, without competing and one ultimately excluding the other, to the extent that the resource is available.

Ecomorphological paradigm The structural or physical differences are a reflection of an organism's ecology.

Evolutionary stable strategy The strategy or behavior that offers an advantage compared with other strategies or behaviors. Such a strategy that, once fixed within a population, cannot be invaded by rare strategies.

Niche All the resources an organism utilizes in space and time.

Overview of Competition Theory and Relevance

In order to understand the role of competition in shaping diet and foraging patterns, it is necessary to first understand the concept of the niche. Many authors have attempted to define this, but perhaps the most popular definition is G. Evelyn Hutchinson's *n*-dimensional space that an organism occupies. This definition attempts to capture all the resources that an organism uses or interacts with in space and time. This utilization space defines the niche. Although this section focuses on diet, and therefore only a subset of the resources that an organism utilizes, this concept of niche is still useful. It is important to note that if resources are not limiting, competition will not occur, and other forces will be more important for shaping diet and foraging patterns.

Given that each organism, or set of organisms, has a niche, there exist several possible niche relationships. These are the included niche, unequal niches, equal niche breadth, and abutting or adjoining niches (**Figure 1**). In the case of the included niche, the niche

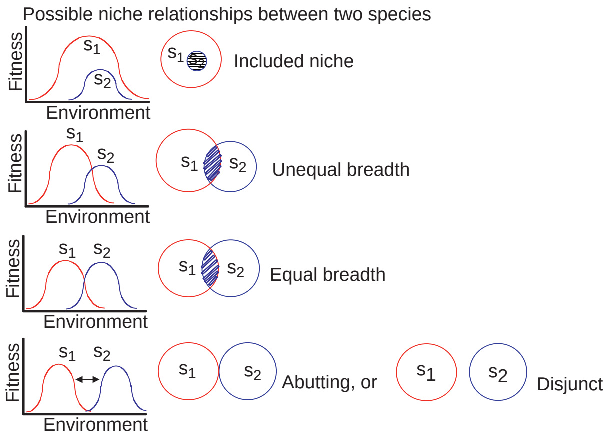

Figure 1 Graphical representation of various possible modes of niche interaction. Modified from Pianka ER (1983) *Evolutionary Ecology*, 3rd edn, 416pp. HarperCollins Publishers.

of species A is completely contained within species B. This scenario could arise when species B outcompetes A and limits it to a subset of the available resources. This scenario could also arise if resources were not limiting, and species A simply required a smaller quantity of the available resource. In the case of unequal niches, similar phenomena presumably lead to the area contained under the curve, but species A is also utilizing somewhat different resources than species B. Equal niches are produced when A and B are utilizing similar amounts of the available resources. Finally, in the case of abutting or adjoining niches, the resources utilized by species A and B do not overlap.

It is tempting, in the case of abutting or adjoining niches, to conclude that two species such as species A and B have gone through one or more of the possible relationships shown prior to exhibiting separate niches. We tend to assume that the two species progressed from a scenario wherein one suppressed the other to the point that their diets eventually diverged. Indeed, this sequence of events can take place and competition theory predicts that, when resources are limiting, they will be partitioned. Resource partitioning is achieved by what is known as limiting similarity, by making species A and B less similar. Dissimilarity is brought about by evolutionary character displacement and competitive exclusion. These interrelated ideas predict that as one species is excluded from a resource and forced to utilize another, selection will begin to favor different traits in the excluded species, and that the species will begin to adapt to the utilization of the new resource, showing traits more strongly favored for that resource or go extinct. Such selection requires that there be variation within the original source population, that these traits are heritable, and that suitable traits that confer differential fitness exist for selection to act upon. A word of caution is needed, however, when invoking this explanation for the observed distributions and patterns of resource distribution in the present-day populations. Indeed, Jim Connell treated this idea early on in the development of competition theory and its role in shaping ecological relationships with his famous paper 'Ghost of competition past'. However, demonstrating that competition occurred is possible, it is prevalent enough that many additional theories have been developed from the generalization that competition does occur and does shape resource utilization patterns, as well as the traits associated with the procurement of those resources.

The Ecomorphological Paradigm

Among these additional theories is the ecomorphological paradigm, popularized by noted functional morphologist Karel Liem. This paradigm states that structural or physical differences are a reflection of an organism's ecology (**Figure 2**). Therefore, the unstated underlying premise is

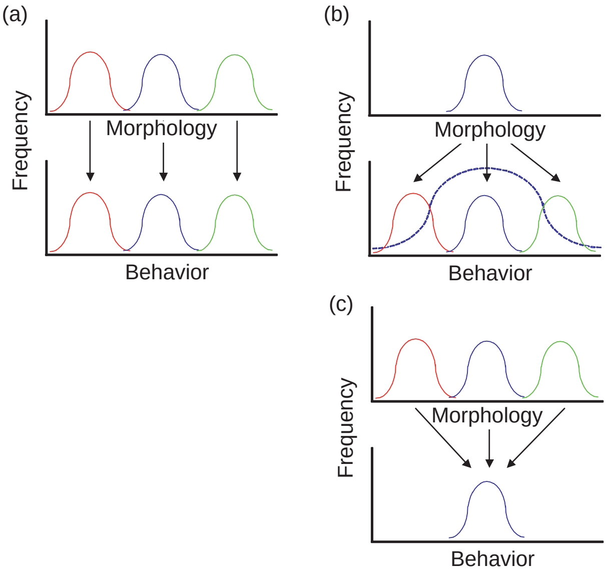

Figure 2 An expression of the ecomorphological paradigm, following from the style of niche representation in **Figure 1**. Panel (a) shows three different morphologies mapping onto three different behaviors, denoting one concept of specialization. Behavior in this sense is the action taken by an organism to utilize some aspect of the available resources. The behavior axis could just as easily be represented by a resource utilization axis. Panel (b) shows possible variations, where a species is more generalized and can perform all three behaviors with one morphology, perhaps through modulation. Modulation is the ability to choose a particular behavior from a repertoire of possible behaviors (the assumption is that the individual has the underlying ability to perform each). Another possible outcome is that the three behaviors are not distinct behaviors, but a continuum of behaviors, denoting another mechanism for generalization. Panel (c) describes a possible representation of Liem's paradox, where many different morphologies utilize one common behavior, in this case suction prey capture, and do not seem to map.

that the challenges associated with procuring resources are strong enough that they evoke change in the organism's phenotype. Competition is not necessarily required for such changes to evolve, but it is easy to see how such a force would drive change and subsequent diversification among organisms, all the more strongly. Indeed, this may serve to explain, at least in part, why we see the diversity of fish shapes that we do.

Mouth types have served as a prominent example in the literature of the ecomorphological paradigm. An example of a group of fishes that demonstrates the paradigm in a general sense is the wood-eating catfishes (**see also Food Acquisition and Digestion:** Digestive Efficiency). The wood-eating catfishes show differences in mouth shape, to some extent, as well as digestive morphology, associated with the amount of woody material in the diet. Similarly, suction-feeding fishes may show differences in the degree to which the jaws are protruded, or the heads expanded, for suction generation (**see also Buoyancy, Locomotion, and Movement in Fishes:** Feeding Mechanics). Jaw protrusion is thought to be one of the key evolutionary innovations in fishes and is evoked as one of the key reasons that fishes have diversified to the extent that they have. As it turns out, suction generation is actually quite energetically inexpensive, and therefore many fish use this as part of their prey-capture repertoire, not to mention gill ventilation. The trick, however, is in getting close enough to the prey for suction to be effective. Furthermore, differing contributions of swimming to the prey-capture event will change the energetic costs associated with feeding. This challenge for fish may be among the most important in shaping foraging behaviors.

An interesting challenge to the ecomorphological paradigm is Liem's paradox. The hallmark example of Liem's paradox is the cichlid fishes of the African rift lakes. The cichlid fishes exhibit a well-known diversity of mouth shapes often correlated, at least by authors describing the system, with incredibly novel diets and unique niches. It is often stated that these fishes underwent intense competition for resources within the rift-lake system, and therefore diverged sharply and partitioned the available resource space into many finely separated niches. It was curious, therefore, that studies of diet in these fishes sometimes showed that all of the species within the lakes were eating the same food source, zooplankton (**Figure 2(c)**). It was Beren Robinson and David Sloan Wilson, who put forth a logical explanation: when resources were seasonally abundant, all species ate the preferred food item, zooplankton, which was readily available and not limiting. When the lake levels dropped, and zooplankton became scarce, competition began and species began to utilize the food items that they appeared specialized for. That all fishes were able to perform a similar behavior (i.e., suction feed effectively on zooplankton) underscored the utility of suction feeding for aquatic prey capture and its prevalence, even with the odd changes to their morphology.

In other cases, the ecomorphological paradigm may fail entirely. While we still inherently believe that an organism's interaction with the environment shapes its morphology, there are many reasons the paradigm can fail. First, we may be studying a trait or morphological feature that we do not truly understand. Therefore, we, as scientists, fail to express the paradigm in a manner that is meaningful to the organism. For example, what is the role of the hammerhead cephalofoil on hammerhead sharks? Electrosensory? The cephalofoil is clearly covered with sensory ampullae, and the foil provides a larger surface than most other sharks would possess. Photosensory (i.e., visual)? The eyes are farther apart; therefore, the visual field may be enhanced. Hydrodynamic or locomotory? The foil may act like a wing, helping the shark to turn more easily. Furthermore, there are numerous casual observations of hammerheads using the cephalofoil to pin prey to the substrate. Are these advantages conferred by the foil, or merely ways to compensate for it? Which of these is the primary function? Which of these might merely be ways in which the foil is coopted? Why ultimately did it evolve? Similarly, the paradigm may fail because scientists attempt to ascribe function to a trait that actually has no functional value. Many morphological features also are not free to evolve in any manner and are subject to a variety of constraints. Traits may also be the product of developmental pathways, the convergence of growth zones, or inheritance of traits that long ago have lost any function.

Foraging and Prey Capture Behavior

The behaviors associated with the acquisition of food resources are shaped in part by the interactions among those organisms, including competition. This then begs the question: What is behavior? Behavior, in the most general sense, is the response of an organism to a stimulus. Behavior as a field within biology has a long and rich history. Prominent behavioral ecologist Niko Tinbergen suggested that there were four causes of behavior: (1) phylogenetic (historical) constraint; (2) mechanistic (physiological or morphological) constraint; (3) learned/experiential or ontogenetic constraint; and (4) adaptive significance. This suggests that, like morphological traits, behaviors are inherited, and can be shaped by evolution. However, also like morphological traits, they can be the mere product of constraints, particularly morphological constraints, and they may not always be functional or even beneficial.

This last point is important as it underlies the shift in the field from using optimal foraging theory (OFT) to predict or describe foraging behavior to the use of evolutionary stable strategies (ESSs) (**see also Food Acquisition and Digestion:** Energetics of Foraging Decisions and Prey Handling). It is not that OFT does not make accurate predictions. Indeed, it can be used quite effectively in many cases to model the parameters that shape individual foraging decisions or persistent population-level behaviors. However, the recognition that, in many cases, organisms represent a series of compromises, and that they often cannot make optimal decisions, has led to the use of ESS instead. ESS is that strategy or behavior that offers an advantage compared with other strategies or behaviors. They are those strategies that, just like genes or alleles, once fixed within a population, cannot be invaded by rare strategies. They are based on game theory, applied to biological concepts by John Maynard Smith, in which the outcome of an interaction depends upon the actions of the other players in the game.

There are broad categories of behavior associated with foraging that represent the steps between a hungry organism and a food item, which include (**Figure 3**): (1) encounter; (2) detection; (3) recognition; and (4) decision to ingest. So, in order for a particular food item to be found in the stomach of any given organism, that organism must encounter the organism, be able to detect it, recognize it as prey, and then make the decision to attack or otherwise ingest it. It must be noted that all of these categories have morphological bases, at least in part. For example, for an organism to encounter a particular mobile prey item, it must possess the appropriate locomotor ability to be in the general area of that prey item. However, for each category there is a strong behavioral aspect. Continuing from the same example, the moving organism above may tend to forage in particular parts of the water column, and this tendency may have been shaped by any of the four causes of behavior.

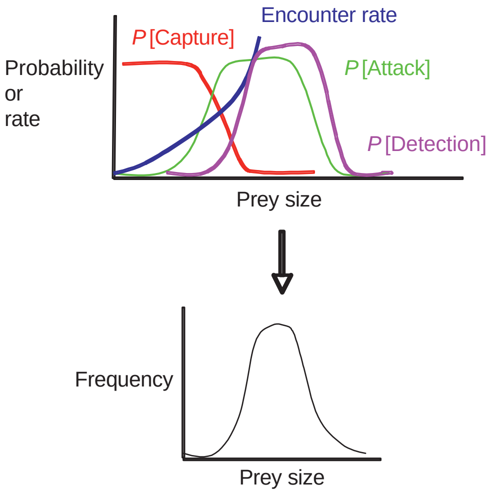

Figure 3 One possible graphical representation of the probabilities that affect what food items are ultimately taken by a foraging fish.

Of course, the tendency to be successful with that behavior is probably the ultimate cause for why it is observed. Each of the categories of behavior listed contains within it a probability distribution. There is a certain probability that our moving organism will encounter a prey item. This probability not only affects the act of encounter, but it interacts with the other steps in the chain of events as well. This means that the probability of encounter might easily then shape both the detection and recognition probabilities. This interaction can then move in both directions. The probability of successfully ingesting a prey item could easily influence the probability that an organism recognizes that item as a potential food item. If our organism has tremendous success with a particular type of zooplankter, it may begin to more readily recognize this as prey in the future.

Capture ability has both a behavioral component, such as applying the right trick at the right time, and a strong morphological component, such as having the right tools for the job. The line between behavior and morphology becomes quite blurred in terms of determining how and why certain items end up in the diet.

Performance Consequences

Changes to behavior or morphology will tend to have performance consequences. This means that a change will bring about an increase, or a decrease, in foraging success. This notion of performance consequences has been the driving force behind the study of the diversity of morphologies and behaviors exhibited within the polyphyletic group referred to as ‘fishes’. Fishes are the most taxonomically rich vertebrate group on the planet, and they inhabit nearly every realm including the terrestrial realm. The diversity in form and function associated with this richness is vast, and has spurred an entire field of research, often termed ecomorphology (or functional morphology) or ecophysiology.

It is easy to look at a typical filter-feeding fish, like a sardine, and see the long gill rakers, and immediately understand how they must function to sieve prey from the water, or, we look at a predatory fish, like a barracuda, and see the elongate jaws and sharp teeth and to understand that this is an active, highly piscivorous species. We look at the ilicium and esca on the head of a deep-sea angler fish and assume that this must be to lure prey closer to the mouth in the vast, deep sea (**see also Deep-Sea Fishes**). The ecomorphological paradigm, as detailed above, often holds true at these very general levels (though our assumptions also often go untested because we are willing to assume that what makes the most sense to us must be true). However, the interesting aspect to this research lies more in the exceptions to the rules. We know that most modern fishes rely on suction, at least in some part, to capture aquatic prey. So, it is interesting when we find a fish that feeds terrestrially, and cannot use suction because air is not dense or viscous enough, such as the four-eyed fish, *Anableps*, that leaps out of the water to capture prey. What are the performance consequences of feeding in air?

To answer this question, we need to undertake an analysis of the costs and benefits of a particular action or foraging mode. We must determine the important traits or behavioral elements associated with performing the action, and determine the cost or benefit of each of those elements compared with not performing said action. Usually, this requires a comparative approach, whereby individuals or species that perform the action to differing degrees are compared. A challenge for researchers lies in determining the metric to use for determining cost. In the case of avoiding predation, a simple metric is speed. Speed is quantifiable as velocity, for example, and has units that are both easily measured and understood and can be related back to energetics (**see also Swimming and Other Activities:** Energetics of Fish Swimming). What do we quantify with regard to foraging success? What is the value of an individual prey capture attempt? As newer and newer technology is applied to these sorts of research questions (**see also Buoyancy, Locomotion, and Movement in Fishes:** Feeding Mechanics), we begin to find ways to measure variables such as water velocity entering a fish mouth, and muscular work. These sorts of questions will continue to drive our understanding of fish foraging behavior and morphology, and the diversity that exists within these.

Glossary

Aerobic scope The capacity for an animal to increase its level of aerobic metabolism beyond that which is required for maintenance alone; it sets the capacity for oxygen-consuming physiological processes that an animal may perform at a given time. Aerobic scope is the difference between minimal and maximal oxygen consumption rate.

Fitness (Darwinian) Describes the ability of a genotype to reproduce and propagate into the next generation. It is influenced by the survival and fecundity (reproductive output) of individuals.

Foraging Behaviors performed by animals when searching for, identifying, capturing, subduing, and consuming food.

Ideal free distribution A theoretical concept used to describe how animals distribute themselves across food patches; This distribution predicts that animals will disperse across patches in a manner that is proportional to the food available in each patch.

Maximal metabolic rate The maximum metabolic rate achieved by an animal. If measured as O_2 uptake, it would be termed V_{O2max}.

Optimal foraging theory A theoretical framework used to study the foraging decisions of animals. Incorporating several assumptions, it predicts that animals should forage in a manner that maximizes the net energetic intake.

Piscivore An animal that feeds on fish, either exclusively or as part of a wider dietary range.

Planktivore An animal that feeds on plankton, either exclusively or as part of a wider dietary range.

Prey handling Behaviors performed by a predator during the capture and consumption of a prey item, including the subduing, orientation, or sectioning of prey (biting, tearing) before consumption.

Standard metabolism In ectotherms, this term describes the minimal level of aerobic metabolism (per unit time) required for maintenance functions to sustain life. In this sense, it is analogous to basal metabolism in endotherms, though standard metabolic rate (SMR) is strongly influenced by environmental temperature and so it is not always constant within an individual.

Introduction

Fish must consume enough food to satisfy their energetic requirements for maintenance, growth, activity, and reproduction. From an evolutionary perspective, natural selection should favor the most efficient foragers. This concept forms the basis of optimal foraging theory (OFT), which posits that animals should behave in a manner that maximizes the rate of net energy intake. Energy input in the form of food is required to sustain biological function, and so it is assumed that net energetic intake is positively correlated with fitness. To achieve a maximum rate of energy accumulation, a fish must not only optimize energy intake through food ingestion, but also minimize the amount of energy spent on foraging. Another important consideration is time; time spent on capturing or handling prey may detract from further foraging (i.e., energy acquisition), or other important behaviors such as predator avoidance or reproduction.

While OFT provides a useful foundation for predicting how fish should behave while foraging, in reality, fish are subject to constraints that may lead to suboptimal energetic behavior. When observations do not agree with the theoretical predictions of OFT, however, it is often interesting and informative to study why this is so. There are numerous factors (e.g., predator avoidance) that affect fitness besides net energy accumulation, and it is impossible to simultaneously optimize all of these components in the performance of a behavior or physiological process. Furthermore, because all biological functions

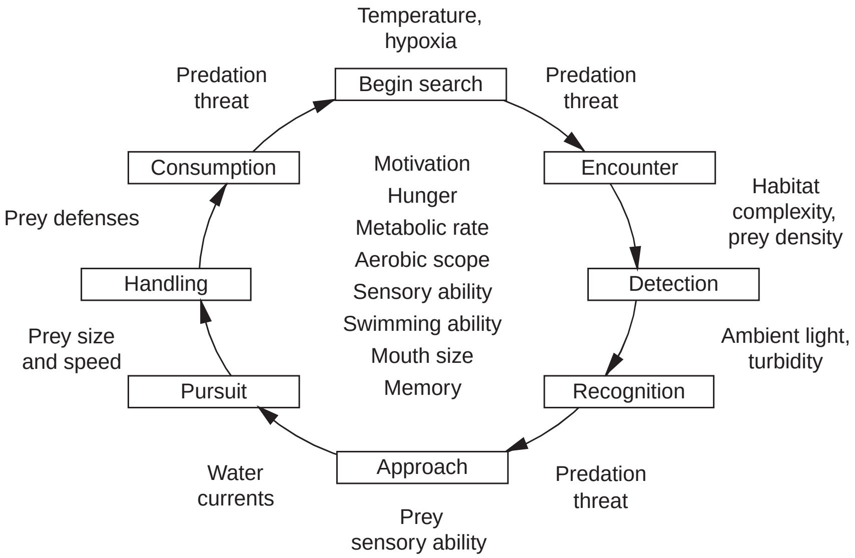

Figure 1 Components of a typical foraging cycle in fish, beginning with the onset of searching for prey and ending with prey consumption. Inside the circle are various internal factors (e.g., physiological and morphological characteristics) that may influence the outcome of the various phases of the foraging cycle. Outside the circle are various external factors (e.g., environmental variables and prey characteristics) that may influence the energy expenditure by the predator that occurs during each phase, the likelihood of each phase occurring, or the outcome. External factors most relevant to foraging energetics are listed alongside points in the cycle where they may have the greatest effect. Note that predation threat may have effects at numerous points along the foraging cycle. This is because a predatory threat could cause a foraging fish to abandon foraging behavior at all points throughout this cycle. Adapted from Hart PBJ (1997) Foraging tactics. In: Godin J-GJ (ed.) *Behavioural Ecology of Teleost Fishes*, pp. 104–133. New York: Oxford University Press, by permission of Oxford University Press.

require finite resources of time and energy, there are often inescapable constraints on their execution that restrict fish from maximizing their net-energy gain. While individual fish may not always forage in a manner that is energetically optimal, they still should adjust their behavior and physiological function within these trade-offs to maximize their overall fitness (**see also Food Acquisition and Digestion**: Dietary Requirements of Fish Under Culture Conditions).

After a fish is motivated to begin feeding, a typical foraging sequence proceeds with a search phase, followed by prey detection and recognition, an approach by the predator and a possible pursuit and attack, some handling of the prey, and then finally, consumption of the prey item by the predator (**Figure 1**).

There are numerous energetic trade-offs and constraints that affect the foraging decisions of fish at all points throughout this sequence.

The Motivation to Feed – When to Forage?

Internal Factors

Hunger

Individuals provided with an unlimited supply of food after fasting will initially display a high feeding rate, presumably due to increased hunger, but this rate will decrease as the animal satiates. Circulating concentrations of certain metabolic substrates and endocrine and paracrine substances are also important in regulating appetite (**see also Integrated Function and Control of the Gut**: Endocrine Systems of the Gut and **Gut Anatomy and Morphology**: Gut Anatomy). For example, injection of glucose, amino acids, or leptin tends to decrease feeding rates, whereas circulating ghrehlin will increase feeding. The change in appetite caused by fluctuations in metabolic substrates is mediated through hormonal and paracrine signaling between the gut and the brain and within the brain itself. Appetite can also be stimulated by certain olfactory and gustatory cues from the environment such as waterborne amino acids and carbohydrates.

Metabolic rate and aerobic scope

It is often hypothesized that the energetic requirements of maintenance may directly influence the motivation to forage in individual fish, possibly by increasing the frequency or intensity of hunger bouts. In ectotherms, the minimum amount of energy required to perform life-sustaining physiological functions can be quantified by measuring standard metabolic rate (SMR) (**see also Energetics**: General Energy Metabolism). While a relationship between resting metabolic demand and foraging motivation is often assumed to exist, there have been few attempts to confirm this link experimentally. Feeding rates tend to increase with temperature in fish, and this is at least partially due to an associated increase in metabolism and energetic demand. Still, the effect of metabolic rate on appetite in individual fish, independent of temperature, is not well understood. Indeed, territorial species may even show a negative correlation between SMR and foraging activity; aggressive individuals with correspondingly high SMRs may initially devote more time and energy to territorial defense as opposed to foraging. In the long term, however, this strategy may lead to increased foraging opportunities once a high-quality territory is established.

Another metabolic trait that may have an important influence on appetite is aerobic scope. Aerobic scope represents the capacity of an animal to increase its level of aerobic metabolism above that which is required for maintenance, and is bounded at its upper limit by an animal's maximal aerobic metabolic rate (MMR; **see also Swimming and Other Activities**: Energetics of Fish Swimming and **Ventilation and Animal Respiration**: The Effect of Exercise on Respiration). This aerobic scope sets a limit on the simultaneous performance of oxygen-consuming physiological processes within an animal. In many fishes, feeding rate correlates well with aerobic scope, presumably because an elevated aerobic scope can accommodate the increase in metabolic rate associated with digestion and nutrient assimilation without compromising other physiological functions. Further research is needed to examine the relationship between appetite, maintenance metabolism, and aerobic scope in fish.

External Factors

Predation threat

Foraging makes animals more obvious to predators and also reduces the vigilance of individuals toward potential threats. For these reasons, fish generally decrease foraging in the presence of a predatory threat, and predator avoidance is a major constraint on the ability to maximize energy intake through foraging. In general, laboratory fish offered food in the absence of a predator eat more and grow faster than when a predator is present. The exact magnitude of such foraging reductions is influenced by the physiological state of an individual. Hungry or food-deprived fish display increased feeding in the presence of a predatory threat relative to that in well-fed fish, and they will resume feeding sooner after fleeing from an attack. It also has been shown that individual fish have distinct personalities, consistently behaving either more or less risky under the threat of predation (**see also Social and Reproductive Behaviors**: Dominance Behaviors). There is evidence to suggest that these behavioral differences among individuals are linked to genotype and intrinsic physiological factors such as metabolic rate, with individuals with increased SMR displaying increased risk-taking behavior during foraging. For example, in juvenile Atlantic salmon (*Salmo salar*), individuals with increased SMR tend to forage outside of covered areas more often and are thus able to attain higher rates of feeding. In contrast, larvae of many fish species decrease foraging under the threat of predation despite their high mass-specific metabolic rate, thereby suffering possible decreased growth, depletion of lipid stores, and increased mortality. However, growth-enhanced transgenic fish have such high appetites that they take more risks to feed, and as a result, are often eaten by predators in experimental situations (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Growth Hormone Overexpression in Transgenic Fish).

Temperature

Feeding in fish increases with increasing temperature until a peak at some intermediate species-specific temperature, and then shows a strong decline with further temperature increases, creating an optimum temperature for feeding and hence growth. The initial increase in feeding with temperature parallels the temperature-driven rise in metabolic rate. Interestingly, metabolic rate generally continues to increase with temperature beyond the point at which feeding rate begins to decline, and so changes in metabolic demand cannot solely be responsible for temperature-related changes in foraging motivation at least at these higher temperatures. Aerobic scope in fish follows a parallel pattern of response to temperature change as does feeding rate. In many species, the temperature at which aerobic scope is highest is also the peak temperature for feeding and growth rates (**see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation, **Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism, **Temperature**: Membranes and Temperature: Homeoviscous Adaptation).

Hypoxia

Decreased environmental oxygen (hypoxia) strongly decreases appetite in water-breathing fish. Indeed, many fishes completely halt feeding when environmental oxygen becomes limiting. This is most likely due to the tremendous decrease in aerobic scope that occurs during hypoxia (both SMR and MMR decrease during hypoxia, but MMR shows a much greater decline), and likely serves to conserve some of the limited aerobic scope for other physiological processes besides digestion (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia and **Hypoxia**: Metabolic Rate Suppression as a Mechanism for Surviving Hypoxia). Despite these constraints, some fish species that live in stratified waters (e.g., anchovy *Anchoa* spp.; mudminnow *Umbra limi*) have been observed to enter hypoxic-water layers briefly to capture prey, though they return to normoxic waters for digestion.

Habitat Selection – Where to Forage?

Food Availability and Predation Risk

As mentioned, fish that reduce foraging activity in the presence of an immediate predatory threat will incur an energetic cost, but such encounters can be avoided altogether if fish occupy a safer habitat. Often, this results in a behavioral trade-off between occupying a dangerous, resource-rich habitat, or a safe, resource-poor habitat. For instance, young lake fishes have increased foraging success while feeding on zooplankton and other prey in open environments. These same habitats, however, leave young fish exposed to being preyed upon, and so they instead may choose to forage in less-profitable but highly structured habitats that provide shelter. Such habitat shifts occur in environments with high predator populations and can cause reduced growth rates in young fish.

The relationship between predator-mediated habitat selection and energetic or nutritional demand in fish has not been investigated directly, though food-deprived fish tend to occupy habitats that are dangerous and more profitable as well. It is possible to estimate the energetic equivalence of predation risk in a dangerous foraging patch by observing predator-induced deviations from the ideal free distribution. Fish foraging on food items that are homogeneously distributed across two foraging patches show a nonequal distribution between the patches when one patch contains a predator. Fewer individuals use the risky patch, but those that do have greater access to food (per fish). The difference in food intake (per fish) between individuals in the risky and safe patches can be considered as the energetic equivalent of the imposed risk. This approach has been useful for gaining insight into the effects of factors such as gender and morphology on habitat selection, and could also be used to investigate the physiological thresholds that cause fish to select dangerous but profitable habitats (e.g., the effect of SMR, RMR, or aerobic scope on habitat selection).

Flow Velocity

For stream-dwelling fishes (e.g., juvenile salmonids), the choice of foraging location is influenced by localized differences in water flow. The encounter rate with drifting prey increases with flow velocity, but the actual number of prey captured declines at relatively high flows because prey are more difficult to catch. The energetic cost of foraging also increases with increasing flow velocity, because fish need to swim faster to keep up with the prevailing current. Furthermore, the energy spent on unsteady swimming during pursuits and prey capture increases with flow velocity due to increased drag. As a result of these opposing costs and benefits, there is an optimal velocity at which the net energy gain will be maximized. Observations in the laboratory and the field have shown that the flow velocity chosen by fish often matches with the predicted optimal velocity, though the exact foraging location selected also depends on factors such as prey size, prey density, the level of predation threat, and competition with other fish.

Territoriality and Aggression

Territoriality for foraging patches is well known in reef fish and stream-dwelling salmonids, though the energetic aspects of territoriality have been primarily studied in the latter (**see also Social and Reproductive Behaviors**: Dominance Behaviors). In juvenile salmonids, more aggressive individuals defend feeding territories by chasing away intruding conspecifics. The energy spent on these behaviors, per unit time, is at least twice the amount used for maintaining position in a flowing stream alone. Still, territorial fish have higher rates of feeding and growth compared to those that are not able to hold territories. Once a territory is established, the resident fish apparently spends less time and energy on aggressive behaviors, while nonterritorial fish continue to engage in aggressive encounters with other fish. Territorial fish also spend less energy on swimming because they spend more time maintaining station as opposed to maneuvering at an angle through currents.

Despite these apparent benefits of territoriality, the profitability of aggressiveness is context dependent. When aggressive and nonaggressive fish are given equal access to food, it is the nonaggressive individuals that grow faster. This may be due to the more-aggressive fish generally spending more energy on activity or having a higher SMR. Therefore, while aggressiveness may be beneficial when food resources are limiting, increased aggression apparently costs in situations where it is not possible to monopolize food resources.

Searching for Food – How to Forage?

Search Speed

Some fish species (e.g., tuna and salmonids) cruise through their environment actively searching for prey, whereas others remain nearly stationary, lying in wait until they ambush unsuspecting prey that happen to pass (sit-and-wait foragers; e.g., pike *Esox* spp.; sculpin *Myoxocephalus* spp.).

Each of these strategies carries distinct costs and benefits: cruise foragers incur greater locomotory costs, but increased prey-encounter rates; ambush foraging is less costly, but prey encounters are relatively rare. Between these two extremes, there is a continuum of search strategies, in which individuals swim through their environment but frequently pause to scan for prey (saltatory foragers; e.g., bluegill *Lepomis macrochirus;* arctic grayling *Thymallus arcticus;* and white crappie *Pomoxis annularis*). Species that use this strategy may be closer to either the cruise or sit-and-wait foraging strategies along the continuum depending on the relative durations of the swimming and pausing phases. This pattern of intermittent movement may allow for better detection of prey during pauses, and heighten the ability to detect predators while foraging. A potential drawback of saltatory foraging is that locomotory costs may be increased due to frequent acceleration and deceleration. On the other hand, saltatory searching may ensure that a given volume of water is searched more thoroughly, and so less swimming will be needed to search a given space.

For planktivorous fishes, including the larvae of many species, rates of prey intake increase with swimming speed, gradually level off, and possibly even decrease at high speeds (**Figure 2**).

At the same time, the costs of locomotion (energy per unit time) increase curvilinearly with swimming speed. Based on these considerations, fish should forage at the speed that provides the greatest difference between energy cost and energy return. Factors such as habitat and prey density also play a role in determining the optimal-foraging speed; fish should (and usually do) swim faster at low prey densities and slower at high prey densities. Fish also swim faster while foraging when they are hungry as compared to when they are well-fed.

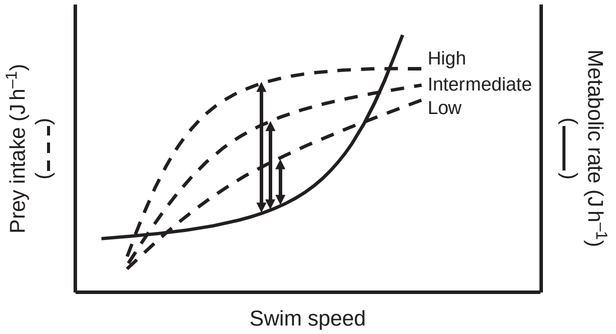

Figure 2 Schematic diagram illustrating changes in prey intake and metabolic rate (as estimated by measuring oxygen uptake) with swimming speed at three different prey densities (high, intermediate, and low). The predicted optimal swim speed at each density is that which allows for the greatest net energetic intake (largest difference between potential energy consumption and the costs of locomotion while foraging). Based on data from Ware DM (1975) Growth, metabolism and optimal swimming speed of pelagic fish. *Journal of the Fisheries Research Board of Canada* 32: 33–41 and Dabrowski K, Takashima F, and Law K (1988) Bioenergetic model of planktivorous fish feeding, growth and metabolism: Theoretical optimum swimming speed of fish larvae. *Journal of Fish Biology* 32: 443–458.

Laboratory and field observations generally match these theoretical predictions, though in some situations they do not. For example, fish foraging at high densities (e.g., fish shoals) tend to swim faster than their theoretically optimal speed. This could be due to the increased density of conspecifics and competition for available food, or differences in hydrodynamic efficiency when swimming in large groups. In other instances (e.g., some flatfish species), fish may not be able to achieve their optimal swim speed due to limited maximal aerobic capabilities. Furthermore, in some species (e.g., juvenile lumpfish *Cyclopterus lumpus*), foraging at the optimal swimming speed may comprise such a significant portion of the available aerobic scope that it would constrain the ability to perform additional physiological functions.

Search Path

Another consideration when actively foraging is the path that will be taken while scanning for prey. In habitats with low prey concentrations or prey that are clumped in small or spatially discrete patches, fish tend to search in a directed manner with low turning rates and low overlap of areas that have been searched already. In this type of directed foraging, the amount of spatial overlap with previously searched areas also decreases with experience and familiarity with a search range, which serves to decrease the energetic costs of searching. By contrast, fish feeding in habitats with high prey concentrations search in a more convoluted path with a higher turning rate and increased spatial overlap. A high turning rate while searching translates to increased foraging costs, but the fish are able to search a patch more thoroughly for prey.

The ability to search a given volume of water is not constant throughout ontogeny. Due to their limited visual range and swimming ability, larval fish have a very restricted search space as they move through the water column. The larvae of a few species have acquired interesting morphological adaptations to improve search efficiency, such as protruding eye stalks that increase visual range and therefore decrease the amount of swimming that is required to search a certain volume. As fish increase in size, their sensory systems and swimming ability improve, allowing them to search larger volumes of water more efficiently.

Foraging Modes

Many species display behavioral flexibility while searching for prey and are able to switch between alternate foraging modes in response to varying environmental conditions. Some species, for example, cruise forage when prey densities are low (e.g., lumpfish, juvenile salmonids, and nase *Chondrostoma nasus*), but become ambush foragers at high prey densities. Among ectothermic species that display search mode-switching behavior, the more energetically costly search mode is generally used when prey is scarce or in dispersed patches, and the less costly mode is used when prey is abundant or aggregated. This pattern is directly opposite to that observed in endotherms, for which the more costly search mode is used at high prey densities. This difference is most likely due to differences in metabolic demand; the relatively high metabolism of endotherms means that active foraging is only economical when prey is abundant. Meanwhile, less energy is required for activity in ectotherms, permitting them to actively seek out food when prey is scarce and conserve energy when prey is abundant. Reducing activity in this manner is also an effective way to conserve space within their aerobic scope, which is already relatively limited as compared to that of endotherms.

Prey Selection – What to Forage?

Prey Type and Size

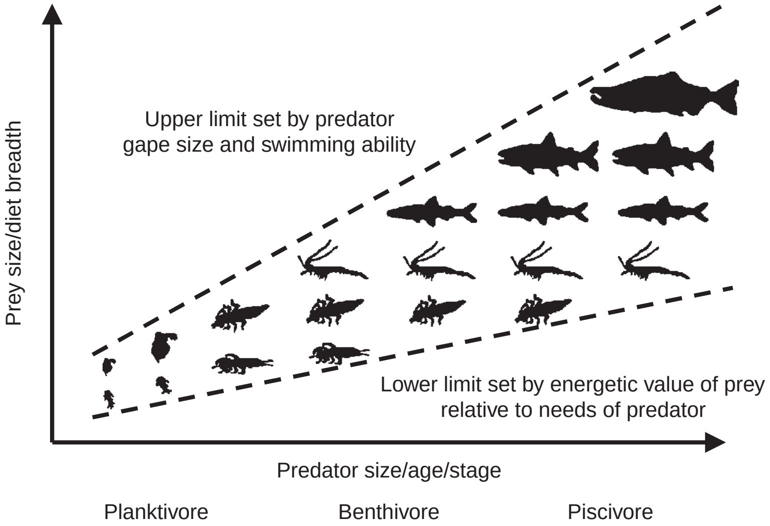
The basic prey model (BPM), an offshoot of OFT, states that when selecting prey, energy gain should be maximized per unit of prey-handling time. Prey-handling time is often defined as the time between prey capture and ingestion, but many researchers also include the time used to pursue prey after detection. For a given prey type (e.g., mussels and minnows), large prey contain more energy than small prey but will take longer to capture, subdue, and consume. In fact, for a given prey type, there is usually an exponential increase in both the time and energetic costs of handling with size. Therefore, a trade-off exits between the energy provided by larger prey, and the time and energy required for their capture and handling. Studies with planktivorous fishes have found general agreement with the BPM, because these species tend to minimize time and energy spent foraging by selecting the largest prey items available. For piscivorous fishes, however, prey are often smaller than predicted. This is likely related to the inherent difficulty in capturing larger prey fishes, and variability regarding the energetic cost during pursuits. Piscivores may preferentially attack smaller fish because of the reduced chances of an escape or unexpectedly costly pursuit. Alternatively, it has been suggested that piscivores are indeed not size selective, but that estimates of prey-size preference based on gut contents simply reflect differential size-based capture success. There are also numerous anecdotal accounts of individual fish attempting to swallow prey items much larger than normally would be expected. For instance, it is not uncommon to observe a shorthorn sculpin *Myoxocephalus scorpius*, an ambush predator, with the tail of a much larger fish protruding from its mouth.

Numerous additional factors may affect moment-to-moment decisions when selecting prey. Habitat type may affect prey selection; fish tend to be less selective when foraging in complex environments. Learned responses by the fish may also alter the relative profitability of prey types, as prior experience with prey types reduces handling times. Prey selectivity may even change over the course of a single foraging bout. Fish tend to be less selective if they are hungry and become more selective as they feed. These factors are often overlooked, but could have important effects on tests of foraging models because they indicate that preferences for prey are highly dynamic. Possible physiological correlates of prey selectivity have not been investigated thoroughly, but there are numerous possible research avenues in this regard. For example, it could be hypothesized that fish with increased metabolic requirements (increased SMR) may be less selective when foraging.

Ontogenetic Diet Shifts

The diet of fish larvae is restricted to the smallest zooplankton, but as they grow, increased mouth gape size and swimming ability can allow for the capture and ingestion of a wider range of prey types. The ingestion of larger prey and increased feeding opportunities allow for increased growth, which in turn allows for the ingestion of even larger prey, and so on. Meanwhile, smaller prey that were once dietary staples may not be consumed at all once fish reach a larger size because of the relatively low energetic value that they provide. Such changes in diet with growth and development are widespread among fish species (**Figure 3**).

Many piscivorous fishes are planktivores as larvae, shift to feeding on benthic prey, and then reach a large enough size to begin feeding primarily on fish. In addition to gape size, an important driver for ontogenetic diet shifts may be changes in metabolic demand during ontogeny. If fish are unable to access larger prey during ontogeny, they can become growth stunted or show decreased body condition. Energetic demand can also change abruptly at certain points during development independent of size (e.g., during metamorphosis), and such changes in metabolism might necessitate changes in diet.



Upper limit set by predator gape size and swimming ability
Prey size/diet breadth
Lower limit set by energetic value of prey relative to needs of predator
Predator size/age/stage
Planktivore
Benthivore
Piscivore

Figure 3 Shifts in diet during ontogeny. As fish grow and develop, increased gape size and improved swimming ability allow for the capture and consumption of a greater range of prey types. More on Prey Handling

Costs of Prey Pursuit and Capture

Maneuvering while chasing prey is more costly than is swimming at a fixed velocity. Juvenile Atlantic salmon in streams are less willing to travel across prevailing currents to intercept drifting prey at increased flow velocities. One reason why prey pursuits are costly is because they often require inefficient burst-type anaerobic swimming. Interestingly, the anaerobic capacity of fish may adapt to their diet. For example, fish that regularly feed on larger prey develop higher concentrations of white muscle lactate dehydrogenase (an important enzyme required for anaerobic metabolism) than those that feed only on smaller prey. This change in muscle biochemistry probably helps prepare these predators for the increased anaerobic performance required for pursuing larger fish. Though it usually does not require an anaerobic contribution, even filter feeding on planktonic prey is costly, because fish must swim constantly with increased drag caused by the flaring of the operculae and movement of water past the gill rakers. For larval fish, the costs of pursuing prey are substantial because the vast majority of larvae are active foragers and must overcome disproportionately large amounts of viscous drag due to their exceedingly small body size.

Prey Orientation and Ingestion

Piscivorous fishes most often attack prey by biting the head and swallowing the prey headfirst. There are a few species (e.g., pike, walleye *Sander vitreus*, and rainbow trout *Oncorhynchus mykiss*) that preferentially attack prey at the tail or middle of the body, but even these fish usually rotate the prey to be swallowed headfirst. This alignment reduces buccal and esophageal abrasion, because any spines protruding from the prey fish will be pushed down instead of outward. From an energetic perspective, headfirst attacks are advantageous for two reasons. First, they reduce overall handling time because the prey does not need to be re-oriented after capture (which often involves repeatedly ejecting and recapturing the prey). Second, rates of escape are increased when attacking the tail. This is especially true when attacking large prey, and piscivores feeding on larger species attack the head more often than when feeding on smaller species.

Some species switch between alternate foraging modes when capturing and ingesting prey. For instance, some species (e.g., American eel *Anguilla rostrata* and bluefish *Pomatomus saltatrix*) will either swallow their prey whole or, for larger items, tear the prey into pieces before ingesting the individual parts. In addition, several Chondrichthyan species (e.g., sawfish *Pristis* sp. and thresher shark *Alopias* spp.) use modified body parts as weapons to stun or injure prey, thus making them easier to subdue and consume. These modes of capture and consumption can allow a species to increase its dietary breadth, but are also energetically costly. Therefore, they are generally only used when prey that are small enough to be easily captured and swallowed whole are not available.

Glossary

Apparent digestive efficiency Digestive efficiency not accounting for nondietary fecal material.

Detritus Degraded organic matter from nonfossil sources, including microbes.

Digesta Food in the GI tract that is in the process of being digested.

Digestive efficiency The ratio of energy or nutrient assimilated to energy or nutrient ingested.

Food intake The amount of food consumed.

Gastric Of or relating to the stomach.

Ingesta Food that has been ingested.

Intestinal bulb An outpocketing or enlargement of the proximal intestine that is not separated from the esophagus or intestine and lacks oxynticopeptic cells.

Nondietary fecal material Biochemical constituents in the feces that were not ingested with food; usually borne of the fish (endogenous input, such as sloughed intestinal cells and mucus) or endosymbiotic microorganisms residing in the fish's gastrointestinal tract.

Pyloric ceca Blind, finger-like projections stemming from the proximal intestine that contain pancreatic tissue and secrete digestive enzymes, thus facilitating digestion in some species.

Rectum The distal-most portion of the intestine, just preceding the anus, which acts to store fecal material before defecation.

Stomach An outpocketing of the proximal gastrointestinal tract that is separated from the esophagus and intestine by sphincter muscles, and features oxynticopeptic cells that produce hydrochloric acid and the proteolytic enzyme, pepsin.

True digestive efficiency Digestive efficiency after accounting for nondietary fecal material.

Concepts in Digestive Efficiency

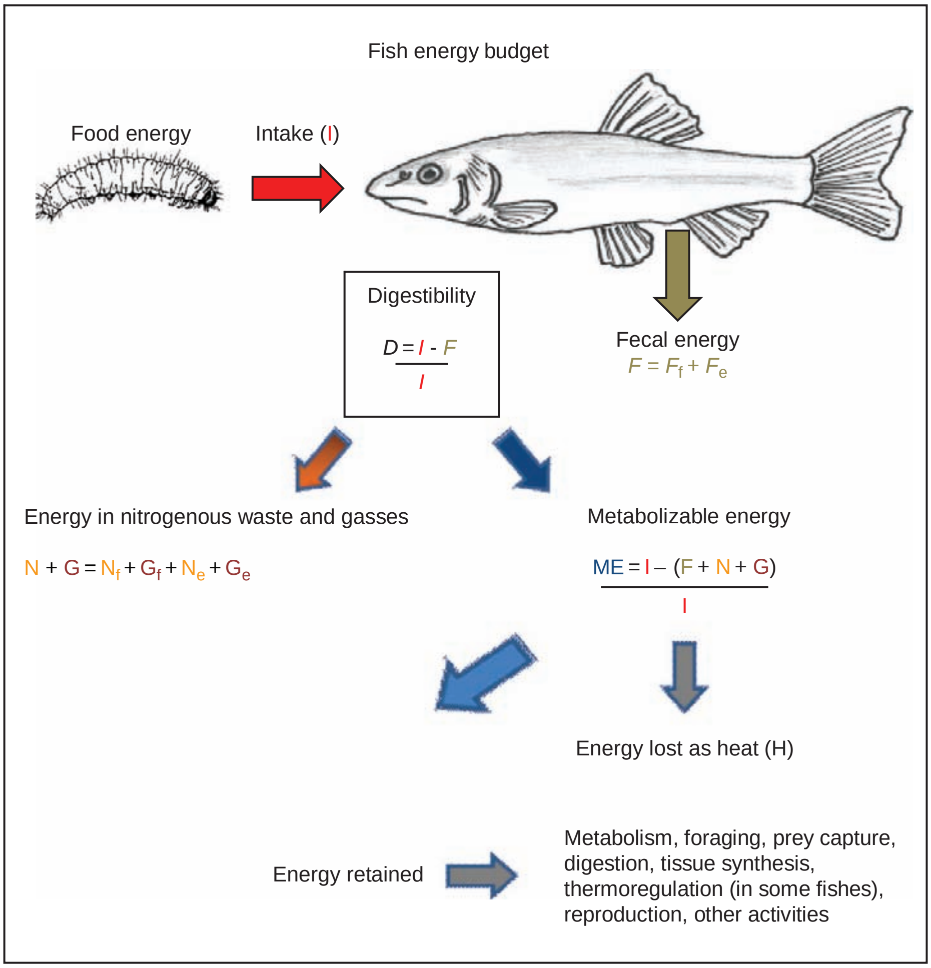
To better understand what a fish is capable of absorbing from their food, one must determine the nutrients available in a given food type and account for losses that occur during digestion and absorption (**Figure 1**). Of all the losses, those to the feces are the greatest, and conveniently, the simplest to measure. Thus, digestibility is calculated as the ratio of food absorbed to the food ingested (**Figure 1**). Digestibility, or more appropriately, digestive efficiency, has important implications in the study of fish nutritional ecology, resource use, ecosystem-level studies, and aquaculture (**see also Energetic Models**: Bioenergetics in Aquaculture Settings).

However, before one can begin to study the digestive efficiency in fishes, the units of measurement must be clear. In many cases, energy may be the best currency against which to measure digestive efficiency, but in others, a different component of a fish's diet may be used (e.g., dry matter, organic matter, and protein; **see also Food Acquisition and Digestion**: Dietary Requirements of Fish Under Culture Conditions).

Essentially, efficiency concerns itself with the process of absorption, excluding pre-ingestive and post-absorptive processes, and thus, this article will focus on aspects of food consumption, digestion, and absorption as they relate to digestive efficiency.

When measuring digestive efficiency, the common practice is to allow a captive fish to eat a predetermined amount of food, or better, offer the fish unfettered access to food, allowing them to control the intake. Following defecation, feces are collected and the energy and/or nutrient content is measured in the food and in the feces (**Figure 1**). Included in the fecal material are not only undigested components of food origin, but also endogenous material from the fish itself (e.g., sloughed intestinal cells and mucus) or nondietary material from microorganisms residing in the fish's gastrointestinal (GI) tract. These nonfood inputs to the feces are commonly called 'metabolic fecal dry matter', or 'nondietary fecal nitrogen'. For this article, the more general term 'nondietary fecal material (NDFM) will be used.

If the NDFM of the feces is not accounted for, the digestive efficiency is 'apparent digestive efficiency', whereas if allowances are made for NDFM, it is called 'true digestive efficiency'. True digestive efficiency is the ratio of the quantity (i.e., energy and/or nutrients) absorbed to the quantity ingested and is greater than the apparent digestive efficiency by the amount of NDFM.



Fish energy budget

Metabolism, foraging, prey capture, digestion, tissue synthesis, thermoregulation (in some fishes), reproduction, other activities

Figure 1 Relationships among energy terms used in this chapter. F_e, N_e, and G_e correspond to endogenous energy (i.e., lost directly from the fish), whereas F_f, N_f, and G_f represent food energy lost directly in feces, nitrogenous waste, or gases, respectively. Total heat production is divided into several processes including thermoregulation, which is observed in some fish taxa (e.g., Tunas). River Chub (*Nocomis micropogon*) drawn by L.T. Crummett. Modified from Hume ID (2005) Concepts of digestive efficiency. In: Starck JM and Wang T (eds.) *Physiological and Ecological Adaptations to Feeding in Vertebrates* pp. 43–58. Enfield, NH: Science Publishers.

Because it is difficult to measure NDFM, true digestive efficiencies are not commonly reported for fishes. NDFM can be determined in fish by feeding isocaloric diets with a gradient (from low to high concentrations) of the nutrient of interest and plotting fecal loss as a function of nutrient intake (**Figure 2**). The point at which the regression line intercepts the *y*-axis can represent NDFM for that nutrient (or energy if a gradient of joules is used instead). However, this estimate of NDFM should be treated cautiously because it is an estimate. In a

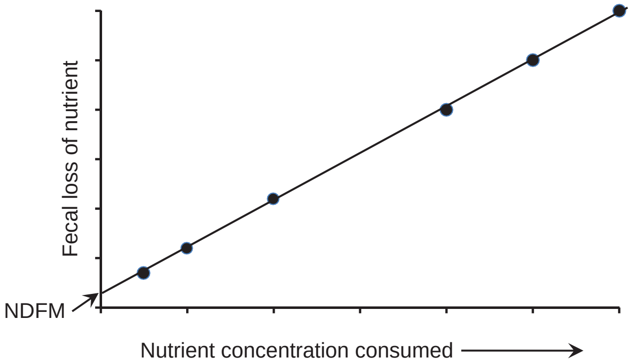

Figure 2 Determination of nutrient losses in feces as a function of nutrient ingested. Nondietary fecal material (NDFM) can be estimated by the *y*-intercept of the regression line.

nutritional physiology context, apparent digestive efficiency represents digestive efficiency in a natural setting because the losses of energy or nutrients to NDFM are real and must be replaced by the fish.

Attempts to measure digestive efficiency in wild-caught fishes have been made. These field measurements of digestive efficiency are performed by dissecting out a fish's GI tract immediately upon capture, obtaining digesta from the proximal and distal regions of the gut, and comparing nutrient or energy concentrations of the digesta from these two gut regions. This method assumes that digesta from the most proximal portion of the gut represent the nutrient or energy content of food and the digesta from the distal intestine represent the nutrient or energy content of the feces. Although these observations provide some insight into the digestive efficiency for fish in the wild, this methodology is problematical because food from the proximal GI tract is already being digested (and, thus, cannot be representative of food before it was consumed), and it is difficult to discern true fecal material from other digesta in the distal intestine. The sampling of digesta that are not completely digested, and thus cannot technically be considered fecal material, will lead to the underestimation of the digestive efficiency (**Table 1**). This is confounded by the fact that many fishes lack a discernable rectum. Therefore, digestive efficiency is best observed under controlled conditions using true fecal material.

An important point in the measurements of digestive efficiency is that a gram of food does not translate into a gram of fecal material. Because digestive efficiency is the comparison of concentrations, which are mass dependent, differences in mass between the amount of food consumed and feces produced must be accounted for. This is generally done in one of the two ways. First, and most accurately, is the total collection of food and feces. This is done with a specialized aquarium design, where feces and uneaten food fall through a grating at the bottom of a tank, where they can be collected and the fish cannot disturb them. The uneaten food or debris (commonly called 'orts') can be used to calculate the actual mass of food consumed (assuming that the amount of food offered to the fish is known). By knowing exactly how much food a fish ate and exactly how much feces they produced, a researcher can directly compare the energy or nutrient contents of one to the other, weighting the calculations by the mass of each:

$$1 - \frac{F}{I} \qquad [1]$$

where, I is the total amount of energy or nutrient consumed, and F is the total amount of energy or nutrient defecated (note that this equation is mathematically synonymous with the digestibility equation shown in **Figure 1**, $D = (I - F)/I$). Second, a researcher can use an inert marker that is indigestible by the fish, such as chromic oxide, titanium dioxide, or acid-insoluble ash. In these instances, the total amounts of food consumed and feces produced are unknown, and thus, the equation must be weighted for the amount of the indigestible marker in the feces and food:

$$1 - \left[\frac{a_i}{a_f} \times \frac{\mathrm{m}_f}{\mathrm{m}_i}\right] \qquad [2]$$

where a_i and a_f are the amount of indigestible marker in food and feces, respectively, and m_i and m_f are the amount of energy or nutrient in food and feces, respectively. Because acid-insoluble ash naturally occurs in food, it is commonly used in aquaculture and field digestive efficiency studies (**see also Food Acquisition and Digestion**: Dietary Requirements of Fish Under Culture Conditions).

However, ash is composed of minerals and some minerals are absorbed and excreted by fish during digestion, a process that can vary with the mineral balance of a particular fish and the fish's digestive tract anatomy (e.g., presence of an acidic stomach; see below). Thus, digestibility estimates based on ash can be biased based on the marker. Moreover, it is especially important to use acid-insoluble ash as opposed to total ash because marine fishes secrete carbonates in their feces (**see also Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation); not accounting for this will lead to overestimates of digestibility using total ash (by decreasing the ratio of a_i:a_f). Therefore, total collection is the most accurate way to measure digestive efficiency, but when this is not possible, an added marker (i.e., other than ash) may be a better option, as long as the marker is truly indigestible and does not interfere with digestion.

Table 1 Effects of fecal collection methods on estimation of digestive efficiency for different food components

	Digestive efficiency (%)		
Method	*Dry matter*	*Protein*	*Lipid*
Netting/siphoning from tank	84	95	97
Dissection (removal from true rectum)	80	90	97
Anal suction	79	90	97
Dissection (removal from distal intestine)	73	78	62

Reproduced from Jobling M (1994) *Fish Bioenergetics*. New York: Chapman and Hall, p. 107.

A consistent issue with digestibility studies is the potential leaching of nutrients or minerals from food or feces as they sit in water. Because fecal material for many fish species is encased in a mucus capsule, leaching occurs more readily from the food than from the feces. Leaching is a serious problem more so for soluble components (e.g., starches) in a diet or fecal material than for fibrous (e.g., cellulose) components, and it is recommended that feces be collected as frequently as possible to minimize contact with the water and potential leaching. Given the importance of an indigestible marker to a digestibility calculation, leaching could pose a serious problem for the accuracy of digestibility calculations reliant upon a leachable marker. For example, leaching of a marker from fecal material can cause an overestimation of digestive efficiency, whereas leaching of a marker from food can cause an underestimation. By not accounting for leaching, digestibility estimates based on a marker can become dubious.

Calculating losses of energy to nitrogen excretion (**Figure 1**) can be difficult in fishes in comparison to terrestrial animals, mainly because nitrogen excretion occurs in several locations in the fish, but primarily across the gills (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish; **Nitrogenous-Waste Balance**: Ureotelism and Excretion of Ammonia). Thus, metabolizable energy is not commonly used in studies of digestive efficiency in fish for nutritional-ecology purposes. However, nitrogen excretion and metabolic rates are commonly measured in aquaculture settings to gain insight on food conversion efficiency in fish (**see also Energetic Models**: Bioenergetics in Aquaculture Settings and **Food Acquisition and Digestion**: Dietary Requirements of Fish Under Culture Conditions).

Inherent in all digestive-efficiency measurements is the digestive strategy a fish takes to obtain nutrients from a meal. That is, does a fish maximize digestive efficiency for an overall meal, or the rate of intake of energy or nutrients? The theoretical frameworks available for fish digestion suggest that fish GI tracts are geared for maximal rate of net energy or nutrient gain. Moreover, compartment models of digestion suggest that there are several stages to the digestive process (**Figure 3**).

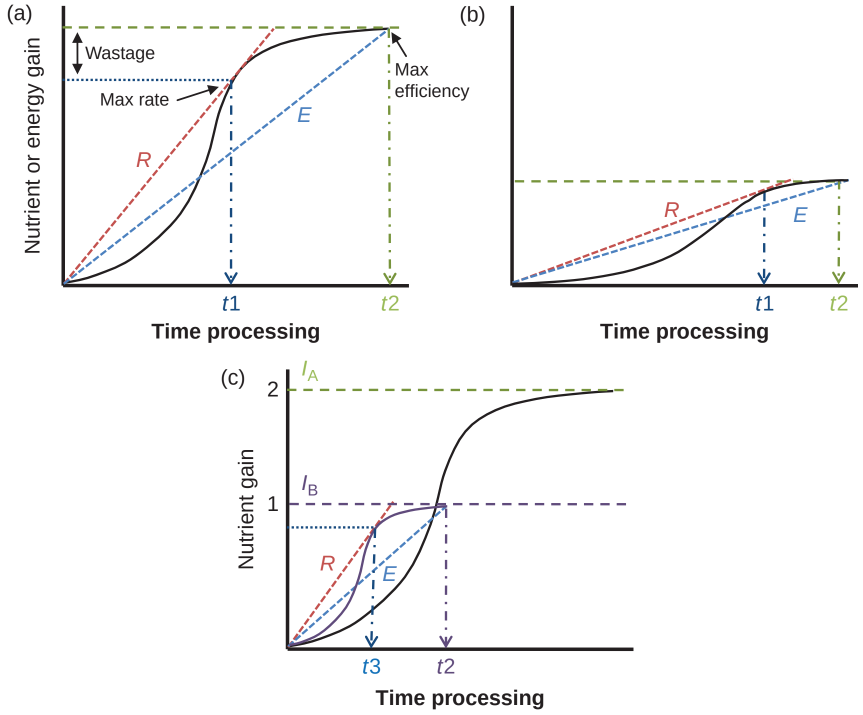

Figure 3 Cumulative nutrient or energy gained by a fish as a function of time spent processing a meal. (a): For high-quality food; (b) for low-quality food. The green horizontal dashed line represents the extractable nutrient ingested in the meal. The slope of the red line *R* represents the maximum rate at which the nutrient or energy can be absorbed from the meal. This is achieved by evacuating the contents at time 1 (*t*1) and taking a new meal, although a portion of the nutrient or energy consumed is lost in the feces (wastage). Maximum efficiency (blue line *E*) is attained by extending processing time to time 2 (*t*2); however, this is done at the cost of reduced digestive rate. For the low-quality food, long retention is unavoidable for maximum digestive rate. (c) For two ingested nutrients, I_A and I_B. Nutrients I_A and I_B are contained in the food in a 2:1 ratio, and thus, twice the amount of nutrient I_A is consumed as I_B. The fish is capable of assimilating the nutrients in a reciprocal 1:2 ratio, however, if they void the contents at time 3 (*t*3), since this is the point at which the rate of gain of nutrient I_B is twice that of I_A. Lines and times needed for maximum rate (*R*) and maximum efficiency (*E*) provided. Modified from Clements KD and Raubenheimer D (2006) Feeding and nutrition. In: Evans DH and Claiborne JB (eds.) *The Physiology of Fishes*, 3rd edn., pp. 47–82. Boca Raton, FL: CRC.

First, the fish must get past the structural defenses of the ingested food, which in many cases (e.g., for piscivorous fish), may be negligible. However, for fishes consuming lower-quality prey (e.g., plants or arthropods), there may be considerable energy expenditure gaining access to the more digestible components of a meal (i.e., getting past the structural polysaccharides in plant cell walls or arthropod exoskeletons to access the digestible inner tissues). Thus, the curves in (a) or (b) of **Figure 3** begin with shallow slopes (or may initially dip below the *x*-axis and be negative when considering that energy will be expended initially in prey handling and digestive processes), and rapidly rise once the digestible components of a meal are accessed. Following the period of rapid digestion, digestive rate progressively slows as less-tractable components of the meal remain. Line *R* in **Figure 3**, which runs from the origin tangential to the curve, depicts the optimal digestive rate, and suggests that digesta should be voided and a new meal taken at the point where *R* touches the main curve. Optimal digestive rates can be slower for lower-quality foods (**Figure 3(b)**), but optimal rates can also vary with the nutrient concentrations of the meal (**Figure 3(c)**).

A few predictions arise from this theoretical framework. First, optimal digestive rates will vary with diet. Second, because of lower nutrient or energy gain per amount of food consumed, fishes eating lower-quality foods should eat more, and, hence, have longer and larger digestive tracts than fishes consuming higher-quality foods. Finally, a fish should maximize retention of food for optimal absorption of the limiting component of their diet, whether it be energy (**Figures 3(a) and 3(b)**) or a specific nutrient, such as protein (**Figure 3(c)**). These predictions in relation to diet and fish GI tract structure and function will be explored throughout the rest of the article.

Dietary Effects on Digestive Efficiency

As the most species-rich group of vertebrates, fishes are found in waters throughout the planet and they consume nearly every type of food ranging from sediment, detritus, fruit, algae, and wood, to slime, scales, blood, arthropods, mammals, and other fish. Generally, animal material is higher in protein and more digestible than plant or detrital material (**Table 2**; **Figure 4**). There are differences in digestibility among animal and plant matter because fish generally lack the enzymes (e.g., cellulase and xylanase) that digest plant structural polysaccharides, such as cellulose and hemicellulose. Although some fish species (e.g., Silver drummer *Kyphosus sydneyanus*) have evolved symbioses with microbes that digest structural

Table 2 Digestive efficiencies of nutrients from natural foods consumed by fishes

Food type	*Family of representative species*	*Digestive efficiency (%)*	
		Protein	*Energy*
Detritus	Cichlids, loricariids	45–49	∼40
Macroalgae	Gobiids, pomacentrids, cichlids, stichaeids	45–80	30–70
Aquatic macrophytes	Cichlids, cyprinids	60–80	30–60
Oligochaetes	Salmonids, percids, cyprinids, pleuronectids	80–95	70–85
Crustaceans	Salmonids, percids	∼90	80–88
Fish	Percids, gadids	85–98	80–97

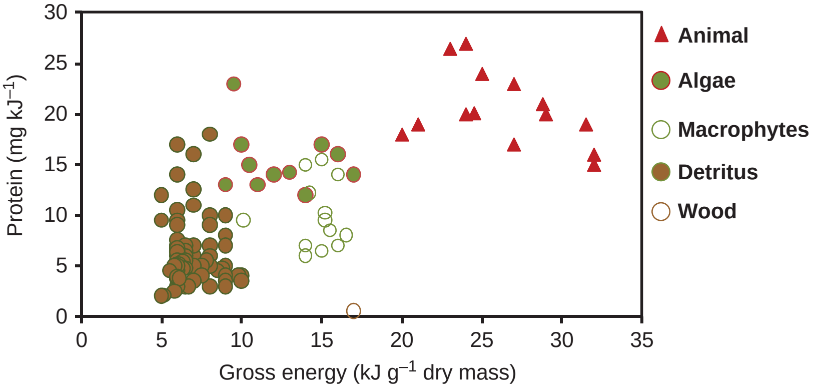

Figure 4 Protein and gross energy in food resources consumed in aquatic habitats. Redrawn from Bowen SH, Lutz EV, and Ahlgren MO (1995) Dietary protein and energy as determinants of food quality: trophic strategies compared. *Ecology* 76: 899–907.

polysaccharides in their GI tracts, many fish do not rely on microbial endosymbionts to do so; the fish largely ignore the recalcitrant polysaccharides in their diet and digest the soluble components of their food through the action of endogenous digestive enzymes (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion).

Nutrient Classes

Fishes consume a diversity of foods, but all require approximately the same 40 nutrients at the cellular level, and the general categories of macronutrients – proteins, lipids, and carbohydrates (**see also Food Acquisition and Digestion**: Dietary Requirements of Fish Under Culture Conditions). In terms of energy, lipids contain more than twice the energy (37.7 kJ g^{-1}) as protein or carbohydrate (each around 16.7 kJ g^{-1}). Clearly, fishes consuming different foods will encounter the macronutrients in different concentrations (e.g., carnivores will consume more protein and lipid and herbivores more carbohydrates) and, thus, will use different nutrients as fuel sources and will exhibit differences in digestive efficiencies of these nutrients (**Table 3**).

In general, fishes efficiently digest protein from most feedstuffs, regardless of their natural diet. Considering that 65–75% of fish carcass dry mass is protein, fishes need to efficiently absorb protein from food, if for nothing else, tissue maintenance and growth (although many carnivorous fishes metabolize amino acids for energy). Moreover, estimates of the fish dietary protein requirements from many taxa are 2–4 times greater than the amount needed by other vertebrates.

Many fishes consuming lipid-rich prey (e.g., carnivores and diatom-consuming fishes) primarily use lipids as an energy source, allowing protein to be utilized primarily for tissue maintenance and growth.

Carbohydrate utilization tends to be greater in herbivorous and omnivorous fishes than in carnivores for the obvious reason that carnivores naturally encounter less carbohydrate than herbivores or omnivores. In fact, some carnivorous fishes cannot tolerate high levels of carbohydrate in their diet. The differences between herbivores, omnivores, and carnivore are reflected in different digestive physiology (see below; **see also Integrated Function and Control of the Gut**: Intestinal Absorption and Gut Secretion and Digestion).

Dietary Quality

The quality of plant material (including algae) is gauged by the ratio of cell-wall components to digestible cell contents, which include soluble carbohydrates, proteins, and lipids. The cell-wall component to cell content ratio tends to be lower for algae and aquatic plants than for terrestrial plants because the former are buoyed by water, and hence, require less structural components than their terrestrial counterparts.

Comparatively, few species of fish (e.g., grass carp (*Ctenopharyngodon idella*)) feed on terrestrial plant material relative to the large number of algae-eating fish species (>400 species). Nevertheless, algae do possess structural polysaccharides (e.g., k-carrageenan and alginate) and some algal species synthesize toxic secondary compounds that can interfere with fish digestion. Although some algae can be relatively rich in protein (**Figure 4**), high-protein algal species are not always

Table 3 Summarized digestive efficiencies of protein, lipid, and carbohydrate in fishes with different natural diets consuming artificial feeds

		Digestive efficiency (%)		
Common name (species name)	*Natural diet*	*Protein*	*Lipid*	*Soluble carbohydrate (starch)*
Nile tilapia (*Oreochromis niloticus*)	Herbivorous/detritivorous	88–96	72–98	83–96

(2002) *Nutrient Requirements and Feeding of Finfish for Aquaculture*. New York, NY: CABI Publishing.

preferred by herbivorous fishes. Detritus, which is defined as degraded organic matter, including microbes, is a food resource uniquely utilized by fishes (and some tadpoles) among vertebrate animals. Although detritus can be rich in many nutrients, including protein (**Figure 4**), it is often consumed with indigestible components, such as sediment, and is often dilute.

What a fish eats can vary as a function of habitat and/or season. For example, resources are relatively scarce in the deep sea (**see also Deep-Sea Fishes**), and, because of a lack of photosynthetic organisms, deep-sea fishes are almost exclusively carnivorous and eat intermittently when they encounter food. The deep-sea environment, because of the sparseness of resources, may therefore provide an example of circumstances where fish would maximize digestive efficiency over digestive rate (**Figure 3**).

Food availability varies by orders of magnitude among seasons in many aquatic systems (especially freshwater habitats), and algal biochemistry varies with season and nutrient input. Thus, what a fish consumes and how much they eat can change on different timescales. Many fish species consume an array of food items, counteracting deficiencies of particular nutrients in other consumed foods. For example, omnivory can be viewed as an effort to complement an abundant food source (e.g., algae) with one rich in protein (i.e., animal material).

Fish Digestive Strategies

Intake and Transit Time

Intake is perhaps the most important characteristic of fish feeding that is affected by dietary quality (**see also Food Acquisition and Digestion**: Energetics of Foraging Decisions and Prey Handling). In general, the lower the quality of the food (low-protein and/or low-energy content), the more the fish will have to eat to meet their demands. Higher intake in fish consuming lower-quality foods has been observed in aquaculture settings, in the laboratory, and in nature. However, when a fish is eating more food, they will pass digesta through the gut more quickly, which can compromise digestive efficiency (**Figure 3**).

Thus, there is a clear trade-off between intake, transit time, and digestive efficiency. A fish can deal with this in one of two ways. First, they can eat more at a given GI-tract size at the cost of evacuating their gut contents before they reach optimal digestive rate. However, this can be overcome by passing more material (and thus, energy and nutrients) through their gut per unit time to eventually meet their nutrient or energy demands. Conversely, fishes can increase the size and digestive capacity of their guts to accommodate increased intake and rapid gut transit without sacrificing digestive efficiency. Examples of both exist in the literature. One issue that arises in the second example above is that an increase in GI-tract size and function is energetically costly to maintain. Therefore, a fish has a further trade-off of increased energy expenditure on GI-tract maintenance to maintain digestive efficiency with higher intake (**see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation). Some fish can ingest 50% or more of body mass and digest the meal over at least a week, whereas for others 2% of body mass represents satiation and they can eat to satiation daily.

Intake is not affected solely by dietary quality, but also by temperature, body mass, and ecological factors (**Figure 5**; **see also Food Acquisition and Digestion**: Energetics of Foraging Decisions and Prey Handling; Energetics of Prey Capture: From Foraging Theory to Functional Morphology; **Energetics**: General Energy Metabolism; and **Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism). A fish will eat more as temperature increases, but only to a point where physiological disruption begins. Obviously, larger fish will eat more food on a gross-mass level than smaller fish. However, body mass directly affects intake in proportion to mass-specific metabolic rate (i.e., scales approximately as body mass$^{-0.25}$; **see also Energetics**: General Energy Metabolism), and thus, on a given diet, smaller fishes consume more food relative to their body mass than do larger fishes. Many fish species undergo ontogenetic dietary shifts (e.g., from carnivory to herbivory) and, thus, dietary differences can become a confounding variable in comparisons of intake among different-sized fishes of the same species.

Transit time through the gut is directly affected by ingesta particle size: the larger the particle, the slower the initial transit, as the surface area of a larger particle must be reduced by digestive processes before assimilation of nutrients can occur. Smaller particles tend to be easier to digest because of the shorter diffusive distance

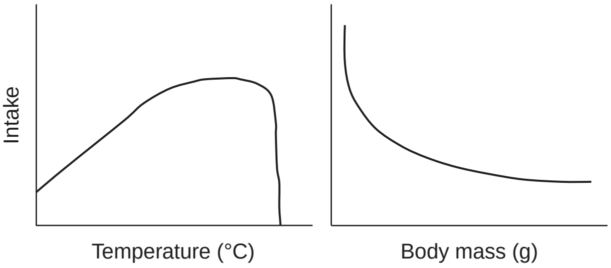

Figure 5 Influence of water temperature and body mass on intake in fish.

for digestive fluids to penetrate the digesta. Furthermore, different-sized particles can travel through the gut at different rates, usually with fluid and smaller particles traveling quicker. Because herbivorous and detritivorous fishes consume more food per day than carnivorous fishes, gut-transit time may be longer in carnivores than in herbivores/detritivores, especially in sit-and-wait predators that feed intermittently. However, herbivorous fishes that utilize hindgut fermentation to meet some portion of their daily energy needs can have longer retention of digesta in the hindgut than other species to allow sufficient time for microbial fermentation to occur.

Gut Morphology

One of the primary ways a fish can control transit time of digesta through the GI tract is through compartmentalization. In this regard, the transit of material from one compartment to another can be controlled, usually by particle size. Many fishes possess a gastric stomach that is separated from the intestine by a pyloric sphincter. The stomach is usually acidic (pH 2–4), and digestion begins in this region of the GI tract. In fishes that possess a stomach, up to 75% of transit time can be explained by residence time of digesta in the stomach alone, with digesta transit through the intestine happening relatively rapidly. However, not all fishes have an acidic stomach. Nearly 7600 species of fish (~25% of all described taxa) are considered 'agastric' (**see also Gut: Anatomy and Morphology**: Development of Fish Gut); some completely lack any outpocketing of the proximal region of the gut, whereas others maintain an alkaline muscular stomach that is more of a grinding apparatus, and others, an intestinal bulb (**Figure 6**). Some clades of fishes have co-opted

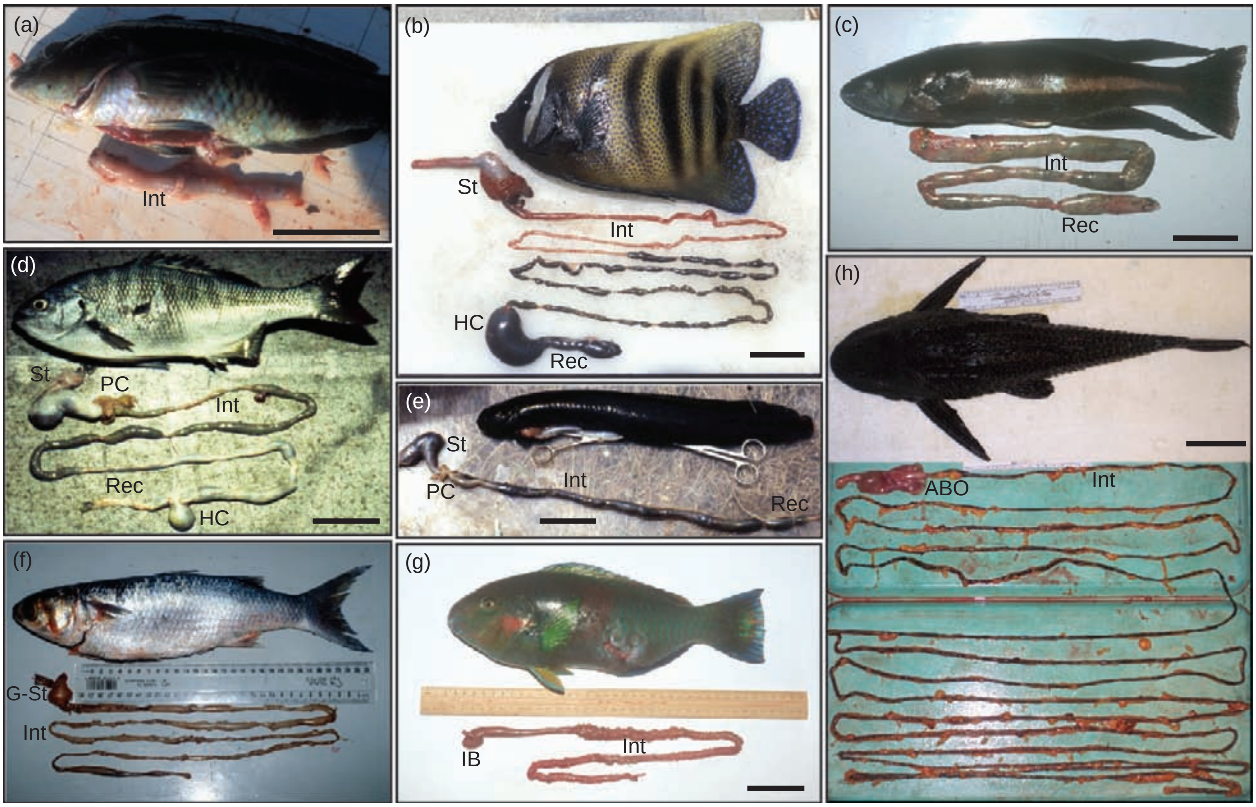

Figure 6 Fish GI tract morphology. (a) Yellow-saddled wrasse (*Notolabrus fuciola*, family Labridae), carnivore, with stomachless intestine; (b) Sixbar angelfish (*Pomacanthus sexstriatus*, family Pomacanthidae), omnivore, with stomach, long intestine, and hindgut chamber; (c) Butterfish (*Odax pullus*, family Labridae), herbivore, with stomachless intestine; (d) Zebra-perch sea chub (*Hermosilla azurea*, family Kyphosidae), herbivore, with stomach, pyloric ceca, intestine, and hindgut chamber; (e) Monkeyface prickleback (*Cebidichthys violaceus*, family Stichaeidae), herbivore, with stomach, pyloric ceca, and intestine; (f) Flathead grey mullet (*Mugil cephalus*, family Mugilidae), detritivore, with gizzard-like stomach, and long intestine; (g) Rivulated parrotfish (*Scarus rivulatus*, family Labridae), detritivore, with proximal intestinal bulb and sacculated intestine; (h) Vermiculated sailfin catfish (*Pterygoplichthys disjunctivus*, family Loricariidae), detritivore, with proximal stomach, which is an air-breathing organ (ABO) and not involved in digestion, followed by long intestine. their stomachs for something else entirely: breathing air. Many loricariid catfishes have a thin-walled, alkaline proximal gut pouch that is not involved in digestion in any way (**Figure 6**(**h**),; **see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction and Circulatory Adaptations for Air-Breathing Fishes). Less common than an acidic stomach is a hindgut chamber, which is also separated from the intestine by a sphincter, and can slow digesta flow (**Figures 6**(**b**) and **6**(**d**)). Many fish possess a sphincter separating the distal intestine from the rectum, also allowing for control of digesta-transit rate and particle passage in the distal intestine. Any type of 'colonic separating mechanism' and/or antiperistalsis allowing for selective retention of small particles, as observed in voles and rabbits, are unknown in fishes. However, scarines (parrotfishes) possess a sacculated intestine (**Figure 6**(**g**)) that may create vortices in the digesta flow, thereby allowing for selective retention of small particles and fluids within the sacculae, and allowing larger, less-digestible particles to pass through the lumen of the intestine. Selective retention of particles and fluid can allow a fish to have higher intake without the metabolic cost of increasing gut length.

Gut Length

One of the predictions of the models presented in **Figure 3** is that animals eating lower-quality foods will consume more food on a daily basis and, hence, will have larger digestive tracts than fishes consuming higher-quality foods. However, given that fishes exhibit a wide range of digestive tract morphologies (**Figure 6**), and these morphological features are also affected by phylogenetic history, these patterns are not always clear.

For example, fishes in the family Labridae (including Scarines and Odacines) tend to have short, stomachless GI tracts that lack chambers or ceca, regardless of the diet. However, within specific fish clades, in which all of the fish share a common evolutionary history, herbivores tend to have larger and longer guts than do carnivores, with omnivores sometimes showing intermediate gut lengths. Detritivorous (**Figures 6**(**f**)–**6**(**h**)) and coralivorous fishes tend to show the longest gut lengths because they generally have higher intake than fishes with other diets, largely due to the dilute nature of a detrital or coral-based diet. It is unclear whether an increase in gut length in fishes provides an increase in gut capacity, but in the few studies performed on atherinopsid fishes and loricariid catfishes, an increase in gut length translates into an increase in absorptive surface area (i.e., microvilli surface area) of the intestine. The folding patterns of the intestinal epithelium and microvilli on the surface of enterocytes act to increase the absorptive surface area in fish intestines (**Figure 7**).

An increased gut length does not always translate into longer retention of food in the gut, as this is largely determined by intake. For example, the detritivorous

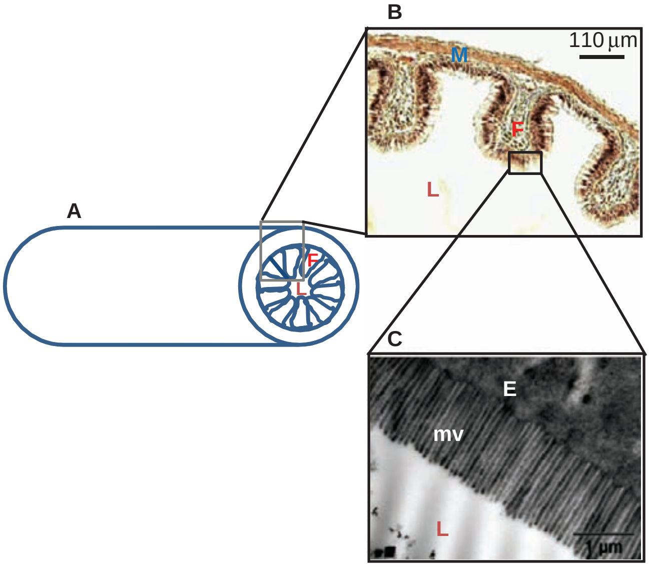

Figure 7 General structure of a fish intestine. (a) Illustration of a cross section of an intestine showing the intestinal folds along the mucosal lining of the intestine that increase the surface area. (b) Light micrograph of a histological preparation of the mid intestine of *Pterygoplichthys disjunctivus* showing the intestinal folds. (c) Transmission electron micrograph of the microvilli on the surface of epithelial cells of the mid intestine of *Pterygoplichthys disjunctivus.* The microvilli further increase the surface area of the intestine. loricariid catfishes *Pterygoplichthys disjunctivus* and *Ancistrus triradiatus*, which each have gut lengths exceeding 18 times their body lengths, have digesta retention times of <4 h, whereas the herbivorous stichaeid fish *Cebidichthys violaceus* has a gut length averaging <2 times their body length and has retention times of digesta of >18 h. Thus, gut length offers little predictive power relating to digesta transit rate when comparing fish species with different evolutionary histories. Studies performed on a single species show that feeding a higher-quality diet (e.g., rich in protein) leads to a decrease in intake, an increase in gut-transit time, and in some cases, a decrease in gut length.

Mastication and Trituration

It is a general rule that fish do not chew food in their mouths as mammals do. However, fishes in many lineages possess well-developed pharyngeal teeth that act to grind and crush foods into smaller particles; these fishes are considered 'pharyngognathus'. Moreover, at least two families of fishes (Mugilidae and Acanthuridae) feature a gizzard-like stomach in which food is triturated against ingested sand or carbonates by muscular contractions of the stomach. Interestingly, pharyngognathus fishes and those with a gizzard-like stomach tend to be agastric, although some fish lineages (e.g., some cichlids) contain species that are pharyngognathus and possess an acidic stomach.

Digestive Enzyme Activities and Nutrient Transporters

Fishes possess the same suite of endogenous digestive enzymes as other vertebrates (**Figure 8**) and, based on the adaptive modulation hypothesis, one would predict that fish digestive-enzyme activities would be maintained at levels for optimal digestive rate of energy or nutrients from their diet. For carbohydrates, this largely appears to

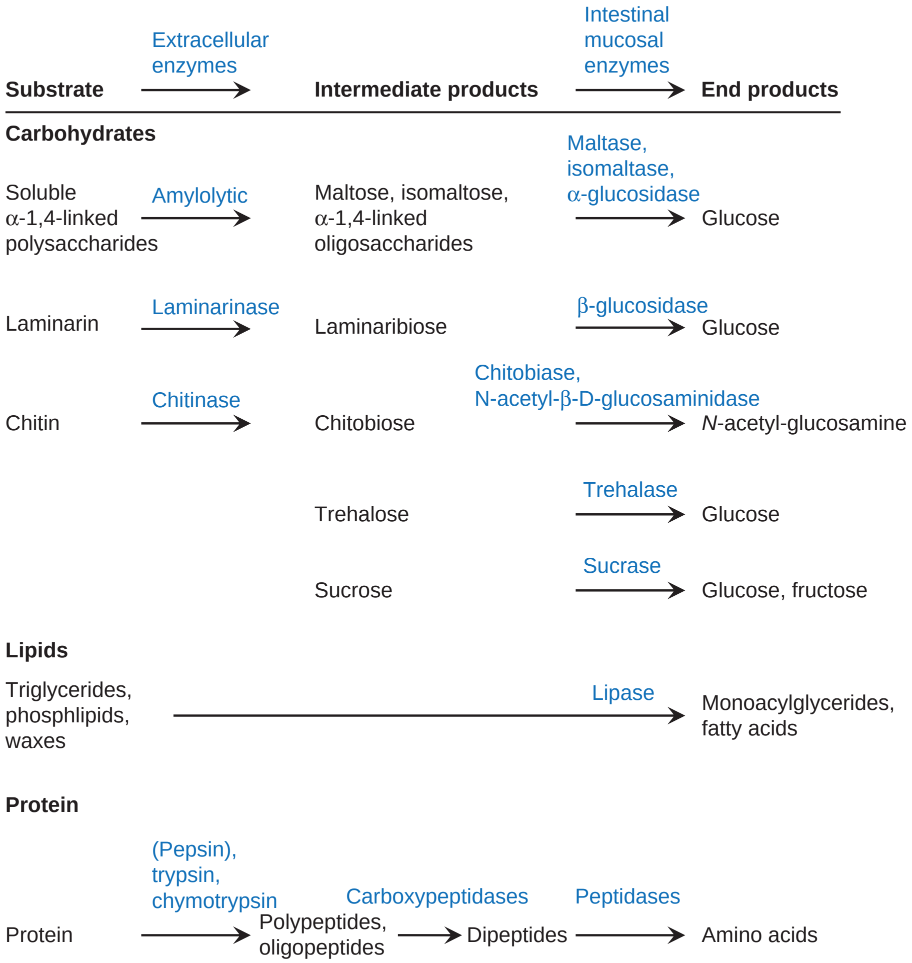

Figure 8 Principal nutrients in food and the endogenous digestive enzymes fishes produce to hydrolyze them. Note that the digestion of complex carbohydrates and proteins requires multiple steps, beginning with initial hydrolysis in the lumen by extracellular enzymes, and followed by membrane digestion by intestinal mucosal enzymes. Under protein, the enzyme pepsin is listed in parentheses because agastric species (i.e., those that lack an acidic stomach) generally lack this. Modified from Karasov WH and Martínez del Rio C (2007) *Physiological Ecology: How Animals Process Energy, Nutrients, and Toxins*. Princeton, NJ: Princeton University Press.

be true: herbivores and detritivores usually have higher carbohydrase activities (including polysaccharidase and disaccharidase activities) than carnivores, even when raised in the laboratory on a common low-starch diet.

However, as mentioned above, protein may be a limiting nutrient to many fish species, regardless of diet, so no consistent pattern relating to proteolytic enzyme activities has emerged. The same can be said for lipase activities.

Nevertheless, when digestive enzyme activities are put in the context of intake and digesta transit rate, herbivorous and detritivorous fishes, which eat more and pass food through their guts more quickly, may produce more digestive enzymes on a daily basis than carnivorous fishes, again illustrating the trade-off between intake, transit rate, and digestive efficiency. In those fish species that have endosymbiotic microorganisms involved in the digestive process (e.g., the herbivorous fish *Kyphosus sydneyanus*), digestive enzymes produced by microbes (e.g., carrageenase) may play a significant role in nutrient assimilation (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion).

As with digestive enzymes, fish possess similar intestinal-nutrient transporters as do other vertebrates, although fishes are less-well studied in this regard (**see also Integrated Function and Control of the Gut**: Intestinal Absorption). Generally, herbivorous fishes possess similar amino-acid-transport capabilities to those of carnivorous fishes (on the level of summed uptake capacity for the whole gut), again illustrating the importance of protein assimilation. However, herbivores and omnivores generally have higher glucose-transport rates than do carnivores. Moreover, this pattern appears to be fixed, as the feeding of a high-protein, low-starch diet to herbivorous and carnivorous fishes does not change the ratio of glucose transport to amino-acid transport.

Beyond nutrient-transport rates, the overall absorptive-surface area is important in comparisons of fishes with different diets. For example, herbivores have higher microvilli surface areas than carnivores among atherinopsid fishes, and loricariid catfishes consuming a low-quality detrital diet had higher microvilli surface areas than conspecifics consuming a high-quality algal diet. These studies suggest that fishes consuming lower-quality foods invest more energy in absorptive capacity as a mechanism to overcome their low-quality diet. The intestinal surface area of fishes (including intestinal folding patterns and microvilli surface area; **Figure 7**) decreases from the proximal to the distal intestine in all the fishes measured, suggesting that most absorption of nutrients from digestion occurs in the proximal and mid-intestine, although some protein absorption (and certainly ion and water absorption) may occur in the distal intestine. (**see also Integrated Function and Control of the Gut**: Intestinal Absorption).

Assimilation Markers

Beyond traditional methods of determining digestive efficiency, other chemical tracers can be used to quantify assimilation of different nutrients. For example, ^{14}C-labeled substrates (e.g., glucose and acetate) can be used to trace the direct assimilation of a nutrient into a fish. Because no ^{14}C is naturally excreted in the feces of the fish, digestive efficiencies using this technique represent true digestive efficiency, although losses to the water (e.g., urinary or incomplete ingestion) must be accounted for. The use of stable isotopes (e.g., δ^{13}C and δ^{15}N) in fish-feeding ecology has expanded in recent years. Although digestive efficiencies cannot directly be determined using stable isotopes, they do provide a mechanism to observe what portion of a diet is being assimilated into a fish's tissues based on its stable-isotopic signature.

Glossary

Postprandial Period after ingesting a meal.

Specific dynamic action The additional amount of oxygen or energy consumed above SMR as a result of feeding, measured during the period after feeding until metabolic rate returns to SMR; SDA represents the energetic cost of digestion, assimilation, and protein turnover.

Standard metabolic rate (SMR) The minimum metabolic rate of survival. Typically, SMR is measured on resting, unstressed adult animals in the post-absorptive state under normothermic conditions. For fish, normothermic is defined as a temperature well within the species tolerance limits for which the animals have had ample time to acclimate.

Introduction

For all organisms, the repertoire of metabolic expenditures includes the energy that is spent on meal digestion and assimilation. The ingestion of a meal sets into motion cascades of cellular and enzymatic activities that result in the breakdown of the food, and the absorption, transport, and assimilation of its nutrients. The many steps involved in this nutritive journey each require an input of energy. The collective energy that is expended is commonly referred to as the specific dynamic action (SDA) of the meal. Also coined heat increment of feeding (HIF) and thermal effects of food (TEF), SDA is a mandatory component of an individual's energy budget, accounting for as much as 25% of its daily energy expenditure.

From the miniscule goby to the gigantic whale shark, all fish eat and hence experience an SDA response with each meal. Homer Smith's inaugural studies in the early 1930s on the air-breathing African lungfish, *Protopterus aethiopicus*, were the first to document fish SDA. Following a 30-year gap, the study of fish energetics was resurrected in the 1960s by the efforts of Canadian researchers William Beamish, Roly Brett, and Richard Saunders, who collectively laid the ground work for experimental studies in fish SDA. These studies demonstrated that the magnitude and duration of the SDA response are sensitive to meal size, type and composition, and body temperature and fish size. Many studies have been conducted on species important to commercial or recreational fisheries with an aim to manage better fish growth by minimizing the energy lost to SDA. For fish species not commercially important, studies have primarily explored ecological correlates of SDA.

First reviewed by Malcolm Jobling in 1981, fish SDA has continued to capture the interests of physiologists and aquaculturists, owing to the growing interest in postprandial metabolic responses and the contribution of digestive energetics to nutrition, growth, and the capacity for activity. Since Jobling's review, nearly 70 new studies (85 overall) have examined the postprandial metabolism of fishes. The following presents a brief description of the methods to quantify fish SDA, a taxonomic overview of fish SDA, the factors that influence SDA, and the energy-expending processes that generate the SDA response.

Measuring Fish SDA

The study of fish SDA is generally undertaken following a relatively simple experimental design. First, a baseline set of metabolic measurements, generally the standard metabolic rate (SMR) quantified as rates of oxygen consumption (V_{O_2} or M_{O_2} depending on whether the volume or mass of oxygen, respectively, is measured), are taken from individual fish at rest and postabsorptive (**see also Energetics**: General Energy Metabolism). If the fish maintains the same swimming speed after feeding, then the prefeeding cost of SMR and swimming can be subtracted from postprandial V_{O_2} to calculate SDA. An alternative approach is to measure V_{O_2} of postabsorptive fish over a range of swimming speeds (**see also Ventilation and Animal Respiration**: The Effect of Exercise on Respiration) and regress V_{O_2} against

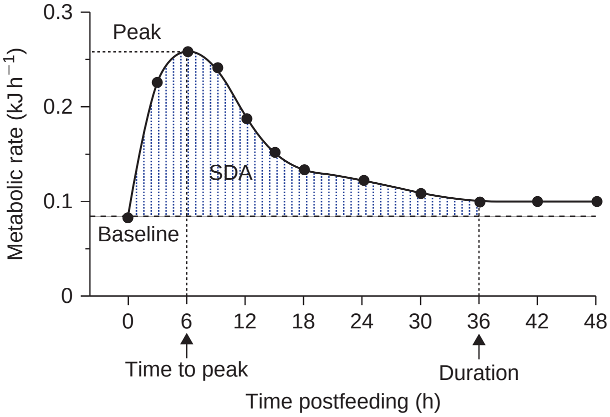

Figure 1 Hypothetical postprandial metabolic profile of a fish following ingesting a 20 kJ meal plotted against time postfeeding. Noted are variables commonly reported in studies of fish SDA.

swimming speed and assign the *y*-intercept (zero swimming speed) as SMR.

Once a baseline V_{O_2} is established, the fish are fed a natural or formulated diet to a targeted percentage of body mass or to satiety. Metabolic measurements are then resumed and thereafter recorded continuously or intermittently until metabolic rates return to baseline values. The postprandial metabolic response is characterized by plotting metabolic rate as a function of time postfeeding (**Figure 1**). SDA can then be quantified from the extra oxygen consumed above baseline values and assumptions regarding the substrate(s) being metabolized. Variables frequently quantified and analyzed (illustrated in **Figure 1**) include baseline (i.e., SMR, 0.088 kJ h^{-1}), postprandial peak in V_{O_2} (0.26 kJ h^{-1}), time to the peak V_{O_2} (6 h), factorial scope of peak V_{O_2} (peak V_{O_2}/SMR = 2.95), the duration of significantly elevated V_{O_2} (36 h), SDA (2.44 kJ), and the SDA coefficient (SDA as a percentage of meal energy = 12.2%).

Taxonomic Account of Fish SDA

Of the more than 30 000 known species of fish, the SDA response has been documented in at least 65 species. These species range in size from the 0.5 g zebrafish, *Brachydanio rerio*, to the 11 kg bluefin tuna, *Thunnus maccoyii* (**Table 1**). Experimental temperatures for SDA studies have ranged from −1 to 30 °C, with the majority of studies conducted between 20 and 28 °C. For many studies, especially those examining the effects of meal composition, fish were fed a pelleted diet with a formulated content of protein, carbohydrate, and lipid. Other studies used natural diets including mollusks, crustaceans, and other fish. Meal mass ranged from 0.25% to 24.2% of body mass, averaging 3.35 ± 0.23% (SE) of body mass. **Table 1** summarizes published fish SDA studies (a single study per species) for fish mass, relative meal size, meal type, the scope of peak postprandial metabolism, SDA, and the SDA coefficient.

Elasmobranchii

SDA has been examined in three species of elasmobranchs, the swellshark, *Cephaloscyllium ventriosum*, the spotted dogfish, *Scyliorhinus canicula*, and the spiny dogfish, *Squalus acanthias*. In these studies, body temperatures were maintained at 12–16 °C and sharks consumed either fish or squid meals that weighed 5.1–6.5% of the shark's body mass. Each species experienced a rapid postprandial increase in V_{O_2} that peaked 7–15 h after feeding at 1.9–3.0 times fasting levels (**Figure 2**(**a**)). Following the peak in V_{O_2}, metabolic rates declined, returning to fasting levels by 15 h and up to an estimated 120 h after feeding. For the three species, the SDA coefficient varied only between 12.0% and 19.8% (**Table 1**). Interestingly, juvenile *S. canicula* experienced a much lower SDA coefficient (6.0%) compared with adults (12.5%), partly, due to a shorter duration of their SDA response (46 h vs. 85 h).

Dipnoi

Of the six extant species of lungfishes, postprandial metabolism has been explored only for the African lungfishes, *Protopterus aethiopicus* and *P. annectens*, the former species being the first fish species to be examined for SDA. In that inaugural study by Homer Smith, lungfish forcefed pieces of beef heart (∼ 1% of body mass) responded with a rapid increase in metabolic rate that peaked within 24 h after feeding, followed by a subsequent decline in V_{O_2} that continued until the next meal. The study on *P. annectens* observed a sixfold increase in metabolic rate during the digestion of a chironomid-larval meal equaling 3.3% of lungfish body mass and determined that 60% of postprandial V_{O_2} is obtained from lung ventilation (**Figure 2**(**b**)).

An asterisk (*) next to species name indicates that SDA and/or SDA coefficient were calculated from published information. Meal mass (%) is the mass of the meal relative to fish body mass. Scope is quantified as maximum postprandial rate divided by basal metabolism. The SDA coefficient is quantified as SDA as a percentage of meal energy.

Actinopterygii

Anguilliformes

SDA has been examined in the European eel, *Anguilla anguilla*, and the American eel, *A. rostrata*, following the feeding on a formulated diet, which for *A. rostrata* varied in protein content from 30% to 40%. For both species, postprandial V_{O_2} peaked approximately 12 h after feeding and declined thereafter for the next 6–12 h (**Figure 2**(**c**)). For *A. anguilla*, the observed 11-fold increase in V_{O_2} is the largest known factorial increase in postprandial metabolism for a fish (**Table 1**).

Cypriniformes

The postprandial metabolic response has been quantified for a dozen species of cypriniforms, ranging in body mass from 0.1 to 318 g. Meals in these studies have included algae, tubificid worms, brine shrimp, and formulated pellets weighing 1–8% of fish body mass. The factorial scope of the peak in V_{O_2} averaged 2.51 ± 0.26%, while the SDA coefficient averaged 20.4 ± 2.5%. Studies on the common carp (*Cyprinus carpio*) have explored variation in SDA due to differences in meal type, meal composition, and meal size (**Figure 2**(**d**)).

Siluriformes

Although only five species of siluriforms have been studied for their SDA response, the southern catfish *Silurus meridionalis* has been examined meticulously for the impact of meal composition, meal size, feeding frequency, fasting duration, and body temperature on SDA (**Figure 2**(**e**)). Meal size has a profound impact on the postprandial metabolic response and SDA of *S. meridionalis*, as well as for the Chinese catfish, *S. asotus*. For both species, SDA increased stepwise with each increase in meal size. Across all experimental treatments (e.g., meal size, meal composition, and body temperature), *S. meridionalis* and *S. asotus* experienced a SDA coefficient that ranges between 7.7% and 24.7% (mean = 13.8 ± 0.6%).

Salmoniformes

Dominating the SDA studies on salmoniforms are those conducted on the rainbow trout, *Oncorhynchus mykiss* (**Figure 2**(**f**)). A goal for most of those studies was to determine the impact of meal composition, specifically protein and lipid concentrations, on SDA. Using diets formulated to different concentrations of protein and lipid, these studies aimed to determine the optimal combination of feed nutrients that would minimize SDA and maximize growth. Recent studies on rainbow trout have explored the relationships between postprandial metabolism and cardiovascular performance (**see also Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation).

Gadiformes

The commercial importance of the Atlantic cod, *Gadus morhua*, and haddock, *Melanogrammus aeglefinus*, has sparked studies examining the effects of body

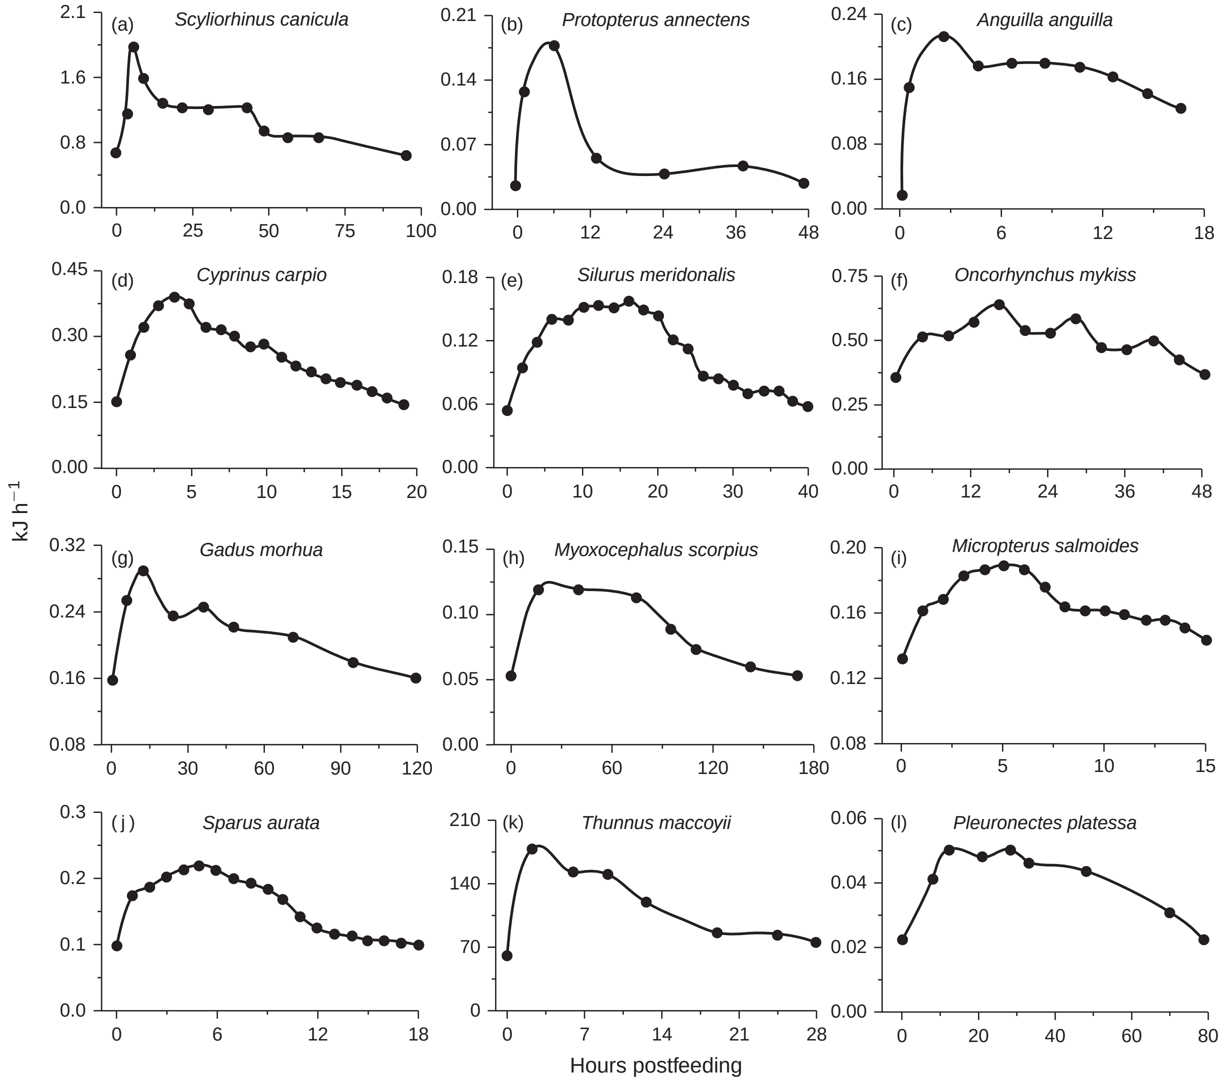

Figure 2 (a–j) Postprandial metabolic profiles of 12 species of fish representing three classes and 10 orders. Fish generally respond to feeding with a rapid increase in metabolic rate that generally peaks within 10 h after feeding. After the peak, metabolic rates return to prefeeding levels more slowly. Each figure was drawn from data presented in published articles. Among these studies, duration of postprandial measurements ranged from 15 to 180 h.

temperature, meal size, and body size on their SDA (**Figure 2**(**g**)). The SDA response has been quantified for cod larvae as small as 0.25–0.75 mg (dry mass) using microcalorimetry. Given that cod may be exposed to hypoxic events, research has determined that hypoxia decreases the postprandial peak in cod V_{O_2}, while increasing the duration of the metabolic response and SDA.

Scorpaeniformes

Two studies have separately quantified the SDA of the sablefish (*Anoplopoma fimbria*) and the shorthorn sculpin (*Myoxocephalus scorpius*) (**Table 1**). When exposed to two temperature regimes (5 and 15 °C) and digesting shrimp meals weighing 12.7–15.5% of fish body mass, the sculpins experienced a 160–250% increase in metabolic rate that generates an SDA equivalent to 16–17% of the meal's energy (**Figure 2**(**h**)).

Perciformes

Half of the fish species for which SDA studies have been conducted occur within the order Perciformes (**Figures 2**(**i**)–**2**(**k**)). Dominating this group are studies on the bluegill sunfish (*Lepomis macrochirus*), largemouth bass (*Micropterus salmoides*), and Nile tilapia (*Oreochromis niloticus*). Studies range from a simple description of the postprandial metabolic response to a single meal at one temperature to studies examining interactions among several variables on SDA. Once again, the aim of studies on commercially important species (e.g., *Dicentrarchus*, *Lepomis*, *Micropterus*, and *Oreochromis*) was to identify the mixture of protein and lipid within the diet that minimized SDA and hence increased the energy that can be allocated to growth. For all perciform species, postprandial oxygen consumption peaked at 2.36 ± 0.07 times standard or resting metabolism, and the SDA coefficient averaged 16.8 ± 1.0%.

Pleuronectiformes

The European plaice (*Pleuronectes platessa*) is the only member of this fish order to be studied for postprandial metabolism (**Table 1** and **Figure 2**(**l**)). For young individuals (16–50 g), an increase in meal size increased SDA, variation in body temperature did not impact SDA, and varying protein content altered SDA. A separate study on larger individuals (30–2000 g) likewise observed an increase in SDA with meal size.

Determinants of Fish SDA

A goal of many fish SDA studies has been to identify the impact that features of the meal, characteristics of the fish, and/or environmental conditions have on the postprandial metabolic profile and the magnitude of SDA. Discussed below are the various determinants of fish SDA.

Meal type

Although a wide variety of natural food types (e.g., algae, shrimp, worms, clam, and various fishes) have been fed to fish to assess their SDA response, only a single study has measured SDA to more than one natural food item. For *L. macrochirus*, *M. salmoides*, and the donko, *Odontobutis obscura*, the SDA coefficient was less for the goldfish meal compared with that for the tubificid worm or earthworm meal. This difference may reflect partly in lower energy value of the worm meals (hence, SDA becomes a larger percentage of meal energy), rather than lower energy required to digest and assimilate the goldfish meals.

Meal composition

Whereas few studies have addressed how SDA differs among natural meals, considerable attention has been directed at how variation in nutrient composition, specifically levels of protein and fat, impact fish SDA response. The impetus for these studies is to identify the best balance of carbohydrates, lipids, and proteins that satisfies the fish's nutritional requirements, minimizes SDA, and maximizes growth. Meals have varied in relative carbohydrate, protein, and lipid content by as much as 100% protein, 100% carbohydrates, or 30% lipids, with various combinations of each. An earlier established prediction is that protein-based meals will generate a larger SDA response than either a high-fat or high-carbohydrate meal. This has been found to be true for studies on *M. salmoides, O. mykiss, P. platessa*, and the grass carp, *Ctenopharyngodon idella.*

A second prediction is that SDA increases with an increase in meal protein content. In support, 50%, 150%, and 700% increases in percent meal protein generated respective increases of 23%, 78%, and 300% in SDA for the fishes *O. mykiss, C. carpio, and O. niloticus* (**Figure 3**(**a**)). On the other hand, SDA did not increase with higher meal protein content in studies on *L. macrochirus* and the European seabass, *Dicentrarchus labrax.* Likewise, varying lipid content, while maintaining protein concentration constant, generated mixed results. An increase in lipid content reduced SDA for *D. labrax* and *O. niloticus*, whereas variation in lipid content had little effect on the SDA of *O. mykiss.* Whereas the emphasis in the past has been just on protein content, the combination of all three major nutrients may need to be taken into account when evaluating the impact of meal composition on SDA. Another difficulty in comparing diet composition is that the changes need to result in isocaloric diet treatments, which has not always been the case.

Meal size

Well documented among all vertebrate taxa is the impact of meal size on SDA. By controlling for meal type, body size, and body temperature, an increase in meal size, and thus in the work of digestion and assimilation, will result in a larger SDA response. Such has been the case for a number of fish studies that have measured SDA for 2–7 different meal sizes. In almost all studies, the postprandial peak in metabolism, duration of elevated metabolism, and SDA increase incrementally with an increase in meal size (**Figure 3**(**b**)). For the catfishes *S. meridionalis* and *S. asotus*, respective 37.5- and 32.2-fold increases in meal size resulted in respective 2.7- and 3.3-fold increases in peak V_{O_2}, 5.7- and 4.2-fold increases in duration, and 33.8- and 24.5-fold increases in SDA. Expectedly, a doubling of meal size, and hence effort, would double SDA. For those studies that varied in meal size while maintaining other variables constant, the response coefficient (Q_{2x}), which is the factorial increase in a parameter in response to a doubling of demand, can be calculated for postprandial peak V_{O_2}, duration, and SDA. For 13 fish studies, Q_{2x} averaged 1.29 ± 0.04 for peak postprandial V_{O_2}, 1.46 ± 0.06 for duration, and 2.00 ± 0.09 for SDA. As predicted, a doubling of meal size and hence the workload of digestion and assimilation generates a doubling in fish SDA.

Meal energy

While not mutually exclusive to meal composition, meal type, and meal size, meal energy is possibly the best predictor of SDA for a fish. The relationship between meal energy and SDA is generally linear with a slope between 0.1 and 0.2. Hence, regardless of meal composition, type, and size, for any fish under any condition, SDA is typically equivalent to 10–20% of ingested energy. **Figure 3**(**c**) illustrates data from studies with fishes <500 g wet body mass. The slope of the regression line is 0.131 ± 0.004 and meal energy can explain 81% of the variation in SDA.

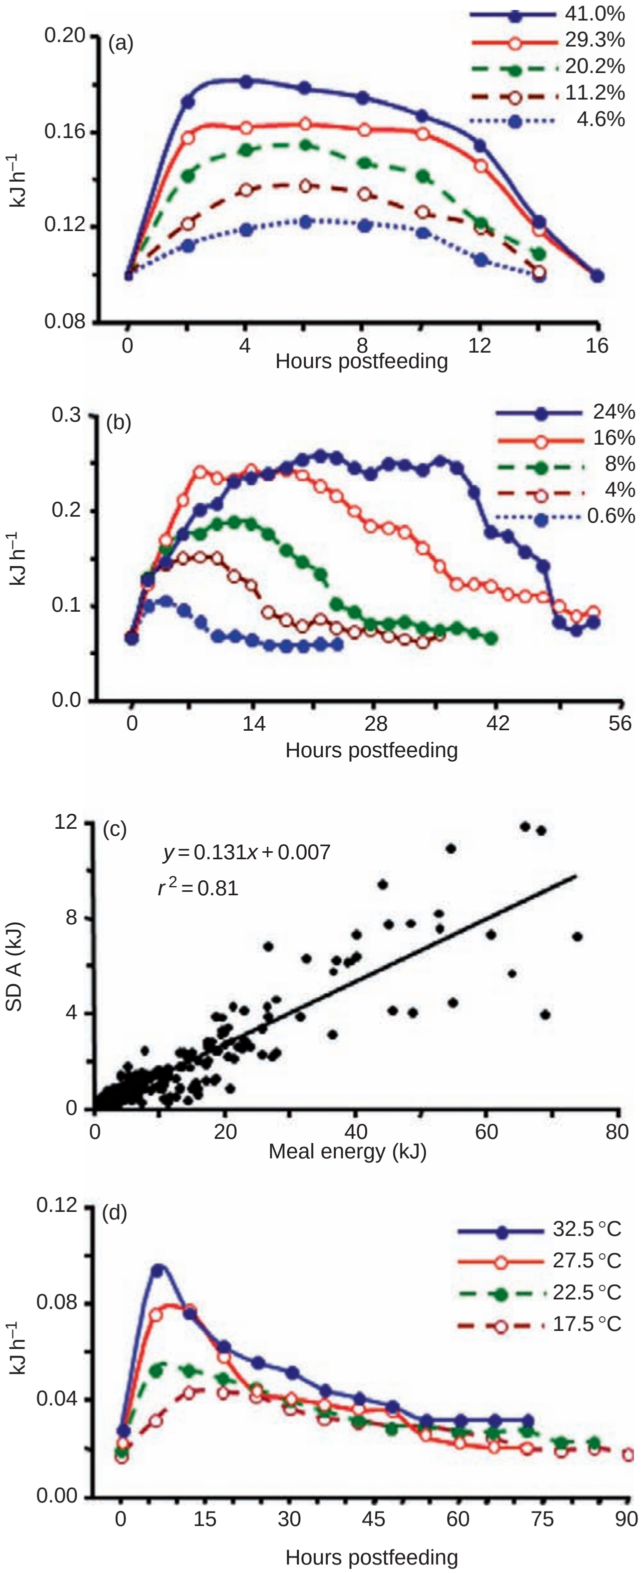

Figure 3 (a) Effects of protein content on the postprandial metabolic response of *Oreochromis niloticus*. With an increase in protein content, there is a corresponding increase in the magnitude of the SDA response. (b) Effects of meal size (% of body mass) on the postprandial metabolic response of *Silurus meridionalis*. As meal size increases, there is a matched increase in the magnitude and duration of the SDA response. (c) Linear relationship between meal energy (kJ) and SDA (kJ). This data set includes fishes that were less than 500 g at time of study. (d) Effects of body temperature on the postprandial metabolic profile of *Silurus meridionalis*. As body temperature increases, the postprandial profile becomes more elevated and shorter in duration.

Body size

With an increase in body size and a corresponding increase in meal size, absolute SDA should also increase. This is certainly true for those few fish studies that have examined body size effects on SDA. For young cod on the same diet, a 5.1-fold range in body mass was matched by a 5.3-fold range in SDA. For the yellowbelly rockcod, *Notothenia neglecta* digesting shrimp meals at −1 °C or 0.5 °C, a 90% and 140% increase in body mass for these respective temperatures generated 100% and 150% increases in SDA. Similarly, for the Antarctic plunderfish, *Harpagifer antarcticus*, digesting a krill diet and matched for relative meal size, a two- to threefold increase in body mass equaled the increase in SDA.

Body temperature

As ectotherms, fish are thermal conformers (with a few exceptions) whose metabolic rates vary as a function of ambient, and hence, body temperatures. A shift in body temperature alters not only basal and peak metabolism, but also the shape of the postprandial profile (3d). With an increase in body temperature, the postprandial profile becomes narrower and taller as the postprandial peak is reached sooner after feeding. With temperature influencing both basal and peak V_{O_2}, the factorial scope of peak V_{O_2} generally does not vary significantly with body temperature for fishes within a certain temperature range (**see also Temperature**: Membranes and Temperature: Homeoviscous Adaptation and Effects of Climate Change). Assuming that a fixed amount of energy is expended to digest and assimilate a given meal regardless of body temperature, SDA should not vary with temperature. This has been found to be the case in studies on *D. labrax, P. platessa, O. obscura*, and the European minnow, *Phoxinus phoxinus*. Counter to this prediction, SDA was found to increase with body temperature for *G. morhua, S. meridionalis*, and the gilthead seabream, *Sparus aurata*.

Source of the SDA Response

What are the processes responsible for the SDA response? This question has intrigued scientists for more than a century. The list of possible actions include the sensory stimulation of metabolism by feeding, the actual work involved in meal breakdown and absorption, the assimilation and catabolism of proteins, fats, and carbohydrates, and protein cycling and synthesis (**see also Design and Physiology of the Heart**: Intracardiac Neurons and Neurotransmitters in Fish). A popular view for earlier fish studies was that SDA was partitioned between 'mechanical SDA', the cost of grasping, chewing, and gut peristalsis, and 'biochemical SDA', the cost of chemical breakdown, nutrient transport and circulation, catabolism of assimilated nutrients, and the synthesis of macromolecules (e.g., proteins and urea). Alternatively, as presented below, the processes contributing to SDA can be divided into pre-absorptive (prior to the entry of nutrients into circulation) and post-absorptive (after intestinal absorption) events.

Pre-absorptive contributions to fish SDA

Whether eating and swallowing constitutes a postprandial event and hence contributes to SDA is debatable. Fish undoubtedly vary in the effort expended to chew and swallow due to differences in meal size and type. Unfortunately, this cost is seldom measured since metabolic measurements typically begin after swallowing. Given their very short esophagus, there would be little contribution of esophageal peristalsis to SDA.

Fish vary tremendously in their ingested meal, from microscopic plankton to small fragments of a prey, to large intact prey. Regardless of meal type, the ingested item is broken down in the stomach (for those species that possess a stomach) to a soup-like chyme before it passes into the small intestine. Gastric breakdown of food is achieved by mechanical churning of the food by alternating contractions of circular and longitudinal smooth muscles and by the chemical actions of the proteolytic enzyme pepsin and hydrochloric acid (HCl) (**see also Integrated Function and Control of the Gut**: Gut Motility and Gut Secretion and Digestion). Muscle contraction, the production of pepsinogen (inactive precursor of pepsin), and the pumping of H^+ into the gastric-pit lumen (to form HCl) are energy-consuming processes. Given that one adenosine triphosphate (ATP) is utilized by the H^+/K^+ATPase for each H^+ pumped out of the gastric oxyntopeptic cell, the maintenance of an acidic gastric lumen during digestion contributes to the SDA response.

Intestinal activities that consume energy during digestion would include peristalsis, production, and actions of enzymes (e.g., disaccharidases and aminopeptidases), the production and secretion of regulatory peptides (e.g., cholecystokinin, gastric inhibitory polypeptide, and secretin), the transmembrane transport of nutrients (requiring ATP-driven maintenance of a sodium gradient), and any post-transport synthesis within intestinal cells (e.g., cellular hypertrophy and formation of chylomicrons). Even though these activities occur during digestion, it has been assumed that intestinal effort contributes modestly (if at all) to SDA. This view stems largely from studies for which fish were fed an inert compound (not absorbable) in their meal and their metabolic response was significantly reduced.

Post-absorptive contributions to fish SDA

Historically, investigators viewed fish SDA largely as a post-absorptive phenomenon, dominated by the costs of oxidative deamination of amino acids and protein synthesis. In support, a study on the channel catfish

(*Ictularus punctatus*) observed a significant 80% increase in V_{O_2} following the infusion into the caudal artery of an amino acid solution. The magnitude of this response was similar to that generated from the oral ingestion of the amino acids. Because absorbed amino acids are not stored, they must be rapidly incorporated into new proteins and/or catabolized. For the latter, fish expend energy to deaminate the absorbed amino acids, transaminate the amino group, oxidize the carbon residues or channel the carbon into gluconeogenesis or ketogenesis, and secrete the residual ammonia. Granted, the cost of ammonia production and secretion is generally assumed to be insignificant since it is readily diffused to most surrounding waters (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia and Ureotelism).

Amino acids, together with glucose and lipids that are not immediately catabolized, are instead directed into energy-consuming synthetic pathways. Fed fish experience a two- to fourfold increase in protein synthesis. The contribution of protein synthesis to SDA is realized when protein synthesis is experimentally blocked by the administration of cycloheximide, and the normal postprandial metabolic response is largely abolished. It has been estimated for the cod that protein synthesis accounts for 20–40% of SDA. Combined with the more modest contribution from the synthesis of glycogen and fat, the cost of biosynthesis (i.e., the cost of growth) is a dominant contributor to fish SDA.

Future Directions

Our understanding of fish bioenergetics and SDA would benefit from explorations directed at:

1. examining the SDA of more diverse species that possess unique feeding habits and ecologies;
2. identifying the pre-absorptive and post-absorptive events that generate the SDA response;
3. determining the impact that changes in salinity and oxygen tension have on SDA; and
4. investigating the interplay between the competing metabolic demands of activity (swimming) and digestion in dictating SDA.

Glossary

Dispensable amino acid (DAA) An amino acid that may be biochemically produced endogenously from precursors in sufficient quantity to meet the needs of the animal.

Indispensable amino acid (IDAA) An amino acid that must be supplied in the diet to meet the needs of the animal.

Introduction

About half of seafood consumed globally is farmed. Modern aquaculture includes a wide diversity of species and conditions – from carnivores to herbivores and from freshwater to marine species. Most of the global aquaculture production generally involves freshwater herbivores that are reared at low density in 'green water' ponds where nutrients are obtained within the pond, with little or no supplemental prepared feeds.

This paradigm is changing. Much of the recent growth in aquaculture has involved an increase in culture intensity, with fish being grown at higher densities. Many fish (especially carnivores like salmon) have required prepared supplemental feed from their inception as aquaculture species, and even those traditionally reared in green water environments are increasingly fed prepared feeds as their culture densities have increased.

An artificial fish feed for intensive aquaculture must meet the target species' nutrient requirements and this requires knowledge of what these nutritional requirements are. Matching dietary nutrients to the needs of the target species is important to permit maximum growth, greatest efficiency of feed utilization, and reduced environmental nutrient loading (pollution).

Nutritional scientists have developed a set of research approaches for determining nutrient requirements. Many aspects of animal nutrition are common among species enabling a transfer of knowledge from work with terrestrial animals to aquaculture. Consequently, great strides in a relatively short time (about 35 years) have been made in understanding the nutrient needs of fish species, resulting in considerable improvement in aquaculture feeds. However, considerable variability exists in specifics. In addition, the difficulties inherent in working in aquatic environments (nutrient leaching, uncertain feed consumption, etc.) have meant that the quantitative nutritional information obtained is generally less robust. Thus, for aquaculture to continue to grow in a sustainable fashion requires generation of feeds that efficiently meet the needs of the cultured species and this will require new basic understanding of nutritional needs at the species level and how these can be met by a variety of traditional and novel ingredients.

This article is concerned with nutrient requirements of cultured fish and the research approaches involved in their quantification. The Further Reading section contains reviews of nutrient requirements of cultured fish, including numeric values.

Nutrient Functions and Their Requirements

Animals are composed of a great number of substances, some of which are produced from precursors by operation of endogenous metabolic pathways and some of which are not. Substances that cannot be produced endogenously in sufficient quantities to meet the needs of the animal must be obtained exogenously, that is, from the diet (oxygen, water, and some minerals may be obtained through the gills or by drinking). Nutrients are substances derived from the diet that are necessary for life. Some nutrients supply energy, although energy is not itself a nutrient; it is a property of some substances that provides the capacity to do work (fuel).

Categories of nutrients include: amino acids (AAs; protein), fatty acids (lipids), vitamins, minerals, and carbohydrates. Water is a nutrient, but is not usually considered as such for aquatic animals. Some nutrients function only in the form in which they are ingested (e.g., vitamins and minerals). Others are subjected to catabolic and anabolic processes after being eaten and may have multiple roles. For example, AAs and fatty acids not only function as structural components of proteins and cell membranes, but are also sources of biochemical energy. Dietary carbohydrates, in contrast, predominantly function as energy sources. For example, starch is only a nutrient because it is a source of energy and is only useful to the extent that it is broken down into its constituents (glucose) and absorbed. Some carbohydrates when present in a diet have probiotic activity, that is, they act to promote the growth and/or activity of beneficial bacteria in the digestive tract, but this does not constitute a dietary requirement *per se*. Once a nutrient is used for energy it is functionally indistinguishable from other substances, whereas the specific structure of vitamins, minerals, some AAs, and fatty acids is necessary to retain their functionality.

Since nutrients are defined as substances needed for life, and since some nutrients are needed in the form they are in and cannot be produced endogenously to any great extent, it follows that there will be a dietary intake level of these nutrients below which the functioning of the animal will be impaired. These are essential nutrients. The lowest level of intake of an essential nutrient that permits maximum functioning, assuming that all other nutrients are present at requirement levels, is the requirement for that nutrient. The meaning of functioning is intentionally left vague, because there are different performance criteria that may be of interest. In aquaculture, growth is frequently the primary concern and the nutrient intake needed to maximize growth is used to define the requirement. Other important indices include: feed efficiency (weight gain per unit consumption), survival, resistance to stress or infection, and reproductive success. (Although feed conversion ratio (FCR) is more commonly seen, feed efficiency (FE) is preferable because it is in line with other responses. Weight gain and protein efficiency increase, so does FE, whereas FCR, which is an inverse index, decreases.)

Nutrient requirements are best described in terms of consumption (gram ingested per day as proportion of body mass), but are more frequently described in terms of proportion of diet (percent or milligram per kilogram diet) for convenience. The digestibility of a meal (what percentage is absorbed) is factored into such values. There is often not much difference between expressing requirements in terms of consumption or as proportion of diet, as there is a relationship between what an animal needs and its growth or metabolic rate, which is in turn affected by its feed intake. The requirement for some specific nutrients is described in terms of their relationship with other nutrients, when there is a close relationship between the two. For example, vitamin E (tocopherol) is an anti-oxidant protecting highly unsaturated fatty acids (which are also nutrients) from destructive oxidation and therefore the dietary requirement of vitamin E is positively related to the dietary level of these fatty acids.

Nutrient balance is important when considering nutritional requirements, as nutrients can interact with each other; one nutrient can improve the utilization of another (e.g., vitamin D improves calcium uptake and utilization), or nutrients can interfere with each other (some AAs compete with each other for intestinal absorption). Some nutrients, even when necessary for health, growth, and reproduction, may become toxic when present in excess (e.g., vitamins A and D, the mineral selenium). While toxic effects are rarely acute under practical conditions, they may become manifest if dietary excess continues for extended periods (**see also Toxicology**: The Toxicology of Metals in Fishes).

Although requirements can be determined with reasonable confidence, there is always some uncertainty and usually requirements are established based on results of several experiments. Given the uncertainty in requirement estimates, and the importance of ensuring that sufficient levels of all nutrients are present in a diet, allowances (requirement level plus an additional amount, a 'margin of safety') are sometimes used in practical situations.

AAs/Protein

Functions of AAs/Physiological Basis for Requirements

AAs are supplied in diets generally in the form of proteins. Although there are species differences, of the 20 or so AAs found in proteins, most aquatic animals studied require the same 10 of them – the indispensible AA (IDAA), sometimes referred to as the essential AA (EAA). The dispensable AAs (DAAs) are those that can be produced endogenously, either from simple compounds or from other AA. It is the IDAA requirement that is the basis for the protein requirement. In the body, AAs are found in the protein fraction; there is no storage depot for AA, as there is for lipids and carbohydrates, although the production of DAA can be accelerated as needed and IDAAs are obtained from catabolized proteins when physiological demand is greater than the supply from the diet. In addition to acting as the building blocks for protein, AAs are important source of biochemical energy. If an animal's energy needs exceed what is available from the diet, AA may be preferentially directed to catabolic processes with the liberation of energy. Conversely, adequate dietary energy reduces the catabolism of AA for energy, thereby reducing the overall dietary need for protein. This effect is known as protein sparing.

Beyond providing the material for protein anabolism and energy, AAs are precursors for many specialized biomolecules, including hormones, neurotransmitters, coenzymes, etc. For example, tyrosine is the precursor of the catecholamines dopamine, norepinephrine, and epinephrine and of the thyroid hormones triiodothyronine (T3) and thyroxine (T4), which are important in regulating the metamorphosis of flatfish and may play a role during adaptation of salmonids to seawater during smoltification. Serotonin and melatonin are derived from tryptophan and histamine is derived from histidine. While the generation of these and other biomolecules is dependent on the presence of the precursor AA, it is not likely that AA requirement is driven by the production of the biomolecules. In other words, the metabolic demand for the individual AA for protein synthesis is likely much greater than what is needed for generation of alternative biomolecules. Production of these hormones is highly regulated and not generally responsive to their dietary levels, although there is evidence for high dietary levels of some AAs affecting hormonal status under certain conditions. Serotonin in the diet has been shown to influence consumption of the amount and type of feed selected.

High circulating levels of specific AA can have considerable effects on the endocrine system of fish. For example, dietary level of the IDAA arginine influences plasma insulin levels. Most studies examining the requirements for specific AA focus on growth rate or other production values and do not consider the nonprotein aspects of AA nutrition, although this could provide valuable information.

Methods Used to Estimate AA Requirements

Most published studies on nutrition requirements for aquaculture examine protein and AA requirements because protein makes the greatest contribution to feed cost. Even so, IDAA requirements are known for only a handful of the myriad of aquatic species being cultured, and the values obtained are less refined than for most barnyard or laboratory animals as a result of technical difficulties (water leaching, uncertainty of consumption rate, etc.). By adapting techniques first used for terrestrial animals, most methods involve some form of dose–response, whereby the response is measured for a group of fish fed one of a series of diets containing graded levels of a specific AA. Usually, multiple responses are measured, including growth, protein accretion, feed efficiency, survival, and circulating levels of the AA. The lowest level giving the maximum response is declared the requirement.

There are significant practical difficulties with this approach, however. One is the development of a basal diet deficient in the AA being tested that fish will actually consume for the duration of the trials. Halver and co-workers, using an approach used in mammal research, developed a diet in the late 1950s that supplied all AAs as free AAs, thereby allowing independent manipulation of individual AA levels. This method permitted requirements to be worked out for a number of salmonid species, and this method was adopted for many other cultured fish species, including carp and eels, by other researchers. For animals that lack an acid stomach (e.g., carp; **see also Integrated Function and Control of the Gut**: Intestinal Absorption), neutralizing the diet with a strong base (sodium hydroxide) greatly improves the growth of the animals on the test diet (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion). Alternatively, a protein source that is imbalanced for one or two IDAA may be used to determine requirements. An example of this is zein, a corn protein that is available in purified form that is extremely low in arginine and lysine.

Diets with AA in the free form are not well utilized relative to those contained in dietary protein, however. Yamada and co-workers force-fed rainbow trout (*Oncorhynchus mykiss*) diets containing either the milk protein casein or a mixture of free AA with the same profile. They found that the free AA peaked in the plasma of the fish at about 12 h postfeeding, while in the casein-fed fish, the peaks were about a third lower and were reached after about 24 h. The poorer utilization of dietary free AA relative to AA from protein is believed to be due to the rapid influx of AA flooding the body at levels beyond which the protein synthetic machinery can efficiently cope with. Since there is essentially no storage of AA or protein, any excess AA in the plasma will be directed toward catabolism, whereby they are broken down into other molecules with chemical energy released. This then could elevate the typical postprandial ammonia load to toxic levels (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia). In AA requirement studies in which only one or a few AAs are supplied in free form, this effect would be magnified, as the balance of AA available for protein synthesis would be out of balance, with the free form arriving sooner after a meal and at higher proportions than the other IDAA derived from a meal. To counter this problem, free dietary AAs are often mixed with a binder that slows their rate of intestinal absorption. Examples of feed additives that have been used to slow the rate of absorption of free AA in requirement studies include gelatin, carboxymethyl cellulose, alginate, and carrageenan. Also, feeding smaller meals more frequently may reduce the disparity of timing and levels of free AA in the body. Interestingly, researchers have used the postprandial plasma levels of AA in fish as an indication of the maximum growth response. In this model, when a diet that contains a deficient level of a specific AA is fed, the AA is almost entirely used for protein synthesis leaving relatively low levels in the plasma, but when the level of the AA exceeds the requirement, more is available than can be used for protein synthesis and the plasma levels will be elevated.

Determining a dietary requirement, that is, the lowest level giving the maximum response, is not always as simple as it may seem. A number of analytical models are employed, each with its own benefits and concerns. Among the simplest of these is the broken-line model, under which the response (growth, feed efficiency, health, etc.) is expected to be linearly and positively related to dietary nutrient input up to the break point where there is no further increase, that is, an independence of input and response, which is the dietary requirement. Graphically, an upward-sloping straight line is followed by a horizontal line (**Figure 1**). Although this model gives a definite value to the requirement and has been successfully employed in many studies, it is sometimes criticized because it assumes that there is no variability in requirement among individuals. An alternative approach has used various smooth curved models, which in many cases provide a better fit than does the broken line and include quadratic, enzyme-kinetic (**Figure 2**), and exponential models. There can be considerable difference in the requirement value obtained from application of the different models. No matter which model is selected, the reliability of the findings will depend on the quality of the work. One of the most important considerations is that there must be sufficient data to establish the maximum. In the case of the broken-line model, this requires at least two, preferably three, levels producing responses below the maximum and at least three levels above it. Other considerations to improve reliability of AA requirements include ensuring that the growth, feed efficiency, and survival of the animals in the best-performing groups are not much less than what can be expected from animals fed a complete diet (a standard diet with an established history of producing good growth with the species under test).

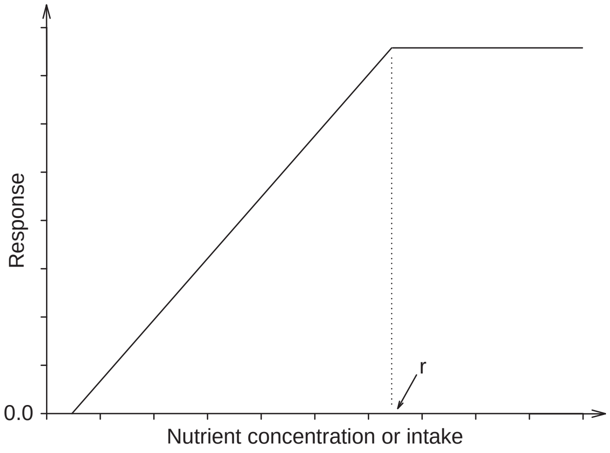

Figure 1 The relationship of physiological response to the level of a dietary nutrient, using the broken-line model. The sloped part of the line on the left represents the positive response to higher dietary nutrient levels under deficient conditions. The horizontal portion on the right indicates that there is no further change in response once the requirement has been reached. The concentration corresponding to the intersection of the two line segments is the requirement (r).

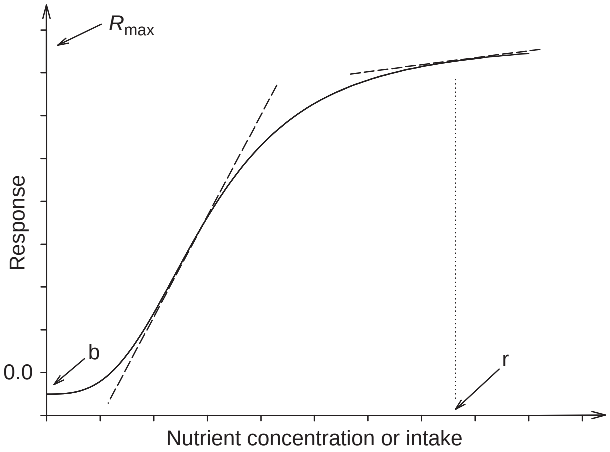

Figure 2 Relationship of physiological response to the level of a dietary nutrient, using enzyme-kinetics model. The dashed line on the left represents the maximum slope of the response curve. The dashed line on the right is the tangent of the response curve at 5% of the maximum slope and the requirement (r) is the corresponding concentration. R_{max} is the theoretical maximum response (asymptote of the curve) and b is the response at zero nutrient intake.

It is argued that it is necessary to establish the upper limit (tolerance) for requirements to ensure that the maximum has been achieved. This requires that dietary treatments be included to provide levels sufficiently high to induce a reduced response. This is not done very often. Mercer adapted an enzyme kinetics model to include a term describing a negative response to excessive dietary nutrient level – dietary inclusion levels above which the response is diminished. The double broken-line model can include a region in which the response is negatively related to dietary nutrient level.

An alternative method for estimating AA requirements is to relate the IDAA profile in muscle or whole body to that of the requirement for one AA. This method was first used in fish by Arai and co-workers and has been found to be effective at least as a first approximation, but should be followed up with more direct work (i.e., by dose–response).

Balance and Impact of Other Nutrients

In poultry some AAs, when present in a diet in high abundance, interfere with the utilization of other AA.

For example, high dietary levels of either lysine or arginine reduce growth rate unless the other AA is also increased. This effect between AA is known as antagonism. Lysine and arginine are known antagonists of each other, as are the branch-chained AA, leucine, isoleucine, and valine. The basis for this effect is at the level of intestinal absorption, where these AA groups utilize common routes of uptake which can be overwhelmed by excess levels of a specific AA.

In other instances, elevated levels of an AA will reduce the dietary need for a different AA. An example of this is the relationship of two sulfur-containing AAs: methionine and cysteine. Cysteine is produced from the IDAA methionine via a biochemical pathway that includes the DAA serine, and is thus not an IDAA. When cysteine is low in the diet, however, some of the methionine is converted to cysteine, increasing the dietary need for methionine for maximum protein synthesis (growth). If there is sufficient methionine in the diet, then the requirement for cysteine is low or nonexistent. Ensuring that there is sufficient cysteine in the diet reduces the need for dietary methionine, at least to the point where methionine is no longer converted to cysteine. Dietary cysteine is said to spare methionine and, generally, when reporting the methionine requirement for a species, the level of dietary cysteine is indicated. Frequently, the sum of methionine and cysteine requirements is reported. The IDAA phenylalanine may be converted to tyrosine and these two AAs have a similar relationship as methionine and cysteine.

Fatty Acids

Fatty acids are used both for biochemical energy and as structural components of cells. It is the structural functions of fatty acids that dictate their nutritional requirements. Not all functions are well understood, but most have to do with their role in the lipid bilayer of cell membranes and the production of certain signaling chemicals, such as prostaglandins.

Fatty acids are long chains of carbon atoms linearly strung together by single or double bonds, with one end terminating in a methyl group and the other in a carboxyl group. There are several kinds of fatty acids, defined by the chain length, the degree of unsaturation (number of double bonds), and the location of the double-bond closest to the methyl end. In standard nomenclature, the fatty acid designated as C18:4n-3 (stearidonic acid) has 18 carbon atoms in a row (C18), with four double bonds (:4), and with the last double-bond being 3 carbons from the methyl end (n-3). Saturated fatty acids (no double-bonded carbons) are readily produced from acetyl-CoA (CoA, coenzyme). Fatty acids can be elongated in pairs of carbons by enzymes called elongases, and so they exist in even chain lengths: 18, 20, and 22 carbons being the most important. The bonds between the carbons can be desaturated to form the various types of unsaturated fatty acids, provided that the appropriate desaturation enzyme (a desaturase) is expressed in the cells of the fish. Vertebrates lack the desaturases for desaturating carbons greater than position 9 from the carboxyl end (delta-9), so fatty acids of one kind (n-6 or n-3) can be elongated (e.g., C18:2n-6 to C20:4n-6), but not changed from one to the other (e.g., C18:2n-6 cannot be the basis of C18:3n-3 synthesis in vertebrates).

Determination of fatty acid requirements is similar to that for AA, but there are important differences. Obtaining bulk quantities of purified fatty acids for dose–response trials is much more expensive than it is for AA, so fatty acid requirement studies are much less common. The n-3 series of fatty acids are essential to maintain normal health and growth in aquatic species. It was thought that the sum of the 18, 20, and 22 carbon length n-3 fatty acids constituted the n-3 fatty acid requirement. It is now known, however, that the longer-chain unsaturated fatty acids, 20:5n-3 (eicosapentaenoic acid, EPA) and 22:6n-3 (docosahexaenoic acid, DHA), are the most important nutritionally and that the ability of fish to elongate and desaturate alpha-linolenic acid (18:3n-3) to generate these longer-chain fatty acids, while variable among species, is generally inefficient. Most commercial fish feeds are formulated with sufficient sources of EPA and DHA to meet the fatty acid requirement of fish. Cell membranes consist largely of a bilayer of phospholipids, each of which contains two fatty acids and a phosphate group. Cell membranes with high levels of EPA and DHA are more fluid and thereby functional at lower temperatures than those containing higher levels of fatty acids that are more saturated. Consistent with this is the loosely supported tendency for cold water fish to have a higher content of EPA and DHA relative to warmer water fish. The nutritional requirement for EPA and DHA is evidently higher for cold water species than for warm water ones. EPA and DHA are highly susceptible to auto-oxidation (degradation through oxidation) and diets that are especially high in these fatty acids generally are formulated with extra antioxidants. The level of vitamin E, which protects lipids from oxidation, needed by fish increases as the level of EPA and DHA increases.

Studies reported by Bell, Sargent, and others indicate that arachidonic acid 20:4n-6 plays an important role in some fish species, especially with regard to reproduction. Arachidonic acid regulates steroid production in at least some species, perhaps through conversion to a prostaglandin or thromboxane. As for DHA and EPA, arachidonic acid can be produced from shorter-chain fatty acids, notably linoleic acid 18:2n-6. It is proposed that the optimum ratio of DHA:EPA:arachidonic acid for marine fish is 10:5:1, which approximates the ratio of these fatty acids in fish eggs.

Minerals and Vitamins

Minerals have a myriad of functions in the body. Minerals cannot be manufactured from other constituents and so they must be acquired from sources external to the animal. Fish can obtain many minerals directly from their environment. Marine fish drink continuously to replace the water lost through their gills to the environment from osmotic action. To maintain a suitable osmotic internal environment, fish in saltwater actively excrete excess minerals into the intestinal lumen (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). In freshwater, the salinity is higher internally than externally and water floods into the fish through the gills. As a consequence, in freshwater, fish do not drink but excrete copious amounts of dilute urine. Clearly, the dietary intake of specific minerals that meets the nutritional needs of the fish in either seawater or freshwater will be highly modulated by the elemental concentration in the water.

Considerable levels of minerals are provided in most practical fish feeds from the principal protein sources; for example, meals made from terrestrial or aquatic animals. For this reason, and because supplemental minerals do not contribute greatly to the cost of feed, considerably less research has been done on mineral requirements than for AA. As terrestrial plant proteins are becoming more prominent in diets for fish in replacement of fishmeal, however, there is increased interest in mineral nutrition. This is especially true of phosphorus, which is an element that is required in greater amount than it can be acquired from the water. Most meat meals are good sources of phosphorous; however, plant protein products, while containing phosphorus, are poor sources, because the phosphorus is contained in phytate (the salt form of phytic acid) which is essentially unavailable to nonruminants. Phytate can also bind with divalent cations, for example, calcium, zinc, and magnesium, to render these unavailable. It is important to know the level of phytate present when considering the nutritional value of a feed because the minerals may be unavailable due to binding with phytate.

Like the other classes of nutrients, vitamins have several metabolic roles in animals, and need to be obtained through the diet. Under culture conditions, the cost of meeting the needs of the animals through supplements is generally sufficiently low so that there is relatively little research on quantifying the requirements for most species (ascorbic acid, vitamin C, is an exception to this). Requirements are determined using dose–response techniques, using growth, health, tissue levels, and enzyme activity (for those vitamins that act as coenzymes) as responses. The fat-soluble vitamins A and D have potential for accumulating in lipid stores to toxic levels. This is rare, but needs to be considered when developing feeds using alternative lipids, for example, lipids of marine origin from fish processing by-products, which may contain the fat-soluble vitamins A and D at above tolerable levels.

Glossary

Anabolism Synthesis of materials via metabolic processes; a series of chemical reactions that builds larger molecules from smaller components, usually requiring energy in the process.

Bioenergetics Quantitative analysis of the energetic processes of living organisms.

Catabolism Metabolic processes that result in the release of energy from organic molecules.

Darwinian fitness Contribution of an individual to the gene pool of the next generation, often estimated as lifetime reproductive success (LRS).

Joule (J) Energy exerted by a force of 1 N acting to move an object through a distance of 1 m. It is the SI unit of energy.

Ontogeny Changes in the phenotype of an individual during its life span. Ontogeny is the outcome of a developmental program, encoded in an organism's genes, as well as interactions between the genotype of the individual and the environments it encounters, together with any maternal effects mediated through the egg itself.

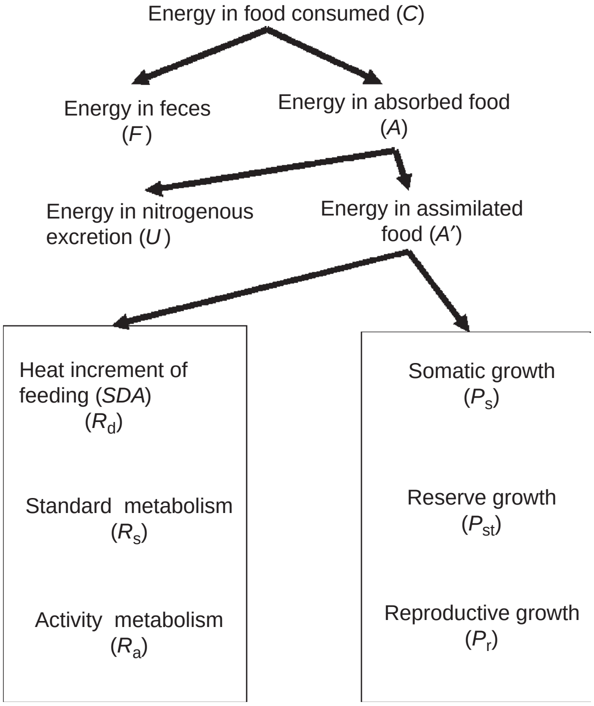
Parameter A numerical constant in a quantitative relationship.

Somatic Body of an individual excluding the gonads.

Watt Rate of doing work, a measure of power as J s^{-1}.

Introduction

Growth, like all other physiological processes, is constrained by the laws of physics and chemistry. The laws of thermodynamics are of particular importance in the study of the bioenergetics of growth, forming the basis for the quantitative study of growth. The laws impose the constraints that during growth, energy can be neither created nor destroyed and that as useful work is done during the synthesis of materials required for growth, energy will be dissipated as heat. In studies of natural populations of fish or in aquaculture, growth is usually measured as changes in mass or length. However, growth can also be estimated as the change in energy content of fish, where energy content is measured by the heat generated when fish mass is burnt in an atmosphere of oxygen (bomb calorimetry), measured as joules (J), with the energy concentration $[E]$ expressed as J g^{-1}. The rate at which a fish uses energy can be expressed as power, measured in watts (J s^{-1}). Once growth is measured in energy units, energy conservation requires that growth = energy input − energy output, where energy input is the energy content of the food consumed and energy output is the energy lost in the form of fecal waste, excretory products (especially ammonia), maintenance metabolism, and as useful work is done. Growth is the energy retained in the body of the fish in the form of the energy of the chemical bonds in the organic molecules that have accumulated in the body. The relationship, growth = energy input − energy output, is a truism and can be applied, in principle, to any organism. The challenge is how to develop this principle in



Energy in food consumed (*C*)
Energy in feces (*F*)
Energy in absorbed food (*A*)
Energy in nitrogenous excretion (*U*)
Energy in assimilated food (*A*′)
Heat increment of feeding (*SDA*) (R_d)
Standard metabolism (R_s)
Activity metabolism (R_a)
Somatic growth (P_s)
Reserve growth (P_{st})
Reproductive growth (P_r)

Figure 1 Pattern of energy allocation in individual fish described by Davis and Warren model.

a way that allows quantitative predictions to be made about the pattern of growth in specific circumstances for the identified species or groups of species of fish.

Growth has three components (**Figure 1**). The first is structural growth that builds the body of the fish, with its skeleton, muscles, nerve cells, and other tissues and organs, which allow the fish to function in its environment. In fish, the energy costs of this growth are predominantly the energy costs of the synthesis of proteins and structural lipids together with any costs of organizing the synthesized material into functioning components. The second component is reserve, or storage growth. This component provides a reservoir of energy that can be mobilized when the energy input in the form of food is insufficient to meet the individual's needs, but replenished when food availability is high. In fish, lipids generally form the main storage material, but some fish (e.g., the lungfish *Protopterus*) specialize in protein storage. Carbohydrates usually play only a minor role. The third component of growth is reproduction, represented by the germ cells, sperm, and eggs, which are eventually released during reproduction. For eggs, the main component is the yolk, made up of lipoprotein, while sperm are essentially packets of DNA wrapped in a lipid membrane.

Energy Budget

The three components of growth can be related to other aspects of the bioenergetics of the individual fish in the framework of an energy budget that itemizes the intake and output, the latter including growth over a defined time period. The budget must balance, because energy can neither be created nor destroyed (**see also Energetics**: General Energy Metabolism and **Energetic Models**: Bioenergetics in Aquaculture Settings). The basic equation is

$$C = F + U + R + P$$

where C is the food consumed, F the fecal waste, U the excretory losses produced by the metabolism of nitrogenous compounds, particularly proteins, R the heat lost during metabolism, and P is the total growth. All the items are measured in energy units. The heat-loss component, R, can be broken down into subcomponents:

$$R = R_S + R_D + R_A$$

where R_S is the standard metabolism, which is approximated as the heat expenditure of a resting, unfed individual; R_D the heat expenditure associated with the processing of the food consumed (sometimes called specific dynamic action, SDA); and R_A the additional heat expenditure of an active fish (**see also Energetics**: General Energy Metabolism). The growth component, P, can be subdivided as

$$P = P_S + P_{ST} + P_R$$

where P_S is the energy content of the structural growth, P_{ST} the energy content of the storage growth, and P_R the energy content of reproductive growth.

Conceptually, it is also useful to define absorbed energy (A) as $A = C - F$; and assimilated energy (A') as $A' = A - U$ or $A' = C - (F + U)$. A' is essentially the energy available to do useful work and to accumulate as growth.

Growth Efficiencies

The efficiency of a system is defined as output divided by input, where output and input are explicitly defined. Thus, in the context of the energy budget of an individual fish, the efficiency of growth can be defined. Three growth efficiencies are defined, depending on the input. For total growth, P, the efficiencies (expressed as percentages) are: $K_1 = 100PC^{-1}$ in which growth is related to the food consumed; $K_2 = 100PA'^{-1}$, where growth is related to assimilated energy; $K_3 = 100P(C - C_{\mathrm{MAIN}})^{-1}$, where growth is related to the energy of food consumed that is in excess of the maintenance ration (C_{MAIN}). C_{MAIN} is the level of food consumption when the individual fish is neither increasing nor decreasing in energy content, so growth and growth efficiency are zero.

Typically, for machines, including living organisms, it is not possible to maximize both the efficiency of a process and the maximum rate of that process. This suggests that a growing fish cannot maximize its growth rate and its growth efficiency simultaneously.

Energy Allocation and Its Fitness Consequences

An individual is faced with the problem of how the energy obtained by its feeding activities should be allocated among the components of the energy budget (**Figure 2**). From moment to moment, the fish must solve the problem of what pattern of energy allocation will maximize its Darwinian fitness, which here can be defined as lifetime reproductive success (LRS). The allocation must be made in the context of limitations of the time available for energy acquisition, the need to shelter from predators or adverse physical conditions, the intensity of competition for food, and eventually the need to devote time to achieve reproductive success (**see also Food Acquisition and Digestion**: Energetics of Prey Capture: From Foraging Theory to Functional Morphology and Energetics of Foraging Decisions and Prey Handling). These limitations will mean that there are trade-offs. Energy allocated to maintenance, including expenditure on repair and defense against pathogens and parasites, will tend to increase the fitness component of survival. However, that energy is not available to be allocated to growth or reproduction. Energy allocated to somatic growth is not available for allocation to storage or reproductive growth. However, somatic growth means that the size of the fish increases, which also tends to increase the fitness component of survival. In addition, because fecundity in fish generally increases with fish size, allocation to somatic growth tends to increase future fecundity at the cost of allocation to present reproduction. Rapid somatic growth can also reduce the age at which the fish becomes sexually mature, thus decreasing the risk that it will die before reproducing. However, rapid growth can also diminish swimming performance. Allocation to storage growth has two possible advantages. It may allow the fish to survive adverse periods when feeding is poor, when the fish can mobilize its stored energy. Second, it may allow the fish to reproduce at times or in places that are advantageous to the progeny, but disadvantageous to the parents. Given these trade-offs, the optimal allocation of energy will change during the ontogeny of the individual fish and is dependent upon the abiotic and biotic environments. The pattern of energy allocation over the ontogeny of the fish defines the life-history pattern of that fish.

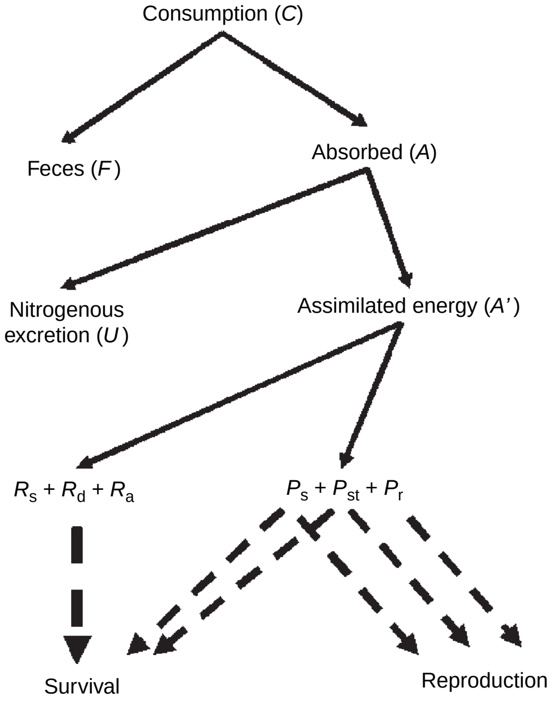


Figure 2 Effect of components of energy budget on components of fitness, that is, survival and reproduction, of an individual fish, indicated by broken lines.

Growth Models of Fish Based on Bioenergetics

von Bertalanffy model

In studies of fish biology and fisheries, the von Bertalanffy model has been probably the most influential growth model based on bioenergetic principles (**Figure 3**). Its development is associated with the names of Pütter and von Bertalanffy, and it was proposed as a general model of animal growth. It argues that growth rate is the difference between the rate of synthesis (anabolism) and the rate of breakdown (catabolism) of proteins, lipids, and

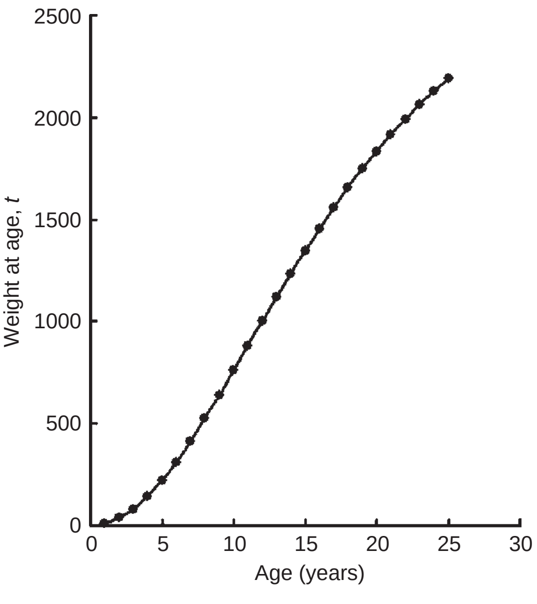

Figure 3 Example of von Bertalanffy growth model based on parameters describing growth of North Sea plaice (*Pleuronectes platessa*).

carbohydrates, with the anabolic and catabolic rates being related to body size. It then assumes that the rate of anabolism is determined by the surface area of the individual, but the rate of catabolism is directly proportional to body mass. Thus, growth rate (dW/dt) is expressed as $dW/dt = hW^{2/3} - kW$, where W is the body mass, and h and k the coefficients of anabolism and catabolism, respectively. A further assumption is that as the individual grows, it does not change in shape, that is, growth is isometric. That is, mass, W, and body length, l, have the relationship: $W = al^3$, where a and b are parameters. From these assumptions, von Bertalanffy growth equations are derived. For length, the model is $l_t = l_\infty\ [1 - e^{-k(t - to)}]$, and for mass, the model is $W_t = W_\infty\ [1 - e^{-k(t - to)}]^3$, where l_t is the length at age t, l_∞ the asymptotic length, W_∞ the asymptotic mass, e the base of natural logarithms, k a constant that defines the rate at which the growth curve approaches the asymptote, and t_o a constant that determines the hypothetical age at which the size of the fish is zero. The three constants, l_∞ (or W_∞), k, and t_o, determine the shape of the relationship between size and age, that is, the shape of the growth curve. Although based on physiological principles, the von Bertalanffy model has been used to fit curves to plots of size against age. In this role, it played a part in the derivation of the important Beverton and Holt model used in fisheries management.

A surprising feature of the von Bertalanffy model is that it does not include a term describing the rate of food intake. Growth cannot take place without an input of food that provides the required materials and energy; so, for a growth model to be predictive as well as descriptive, it has to include a term describing the rate of food consumption. This has led to a re-definition of the von Bertalanffy model in which the anabolic term is replaced by a term describing the rate of energy assimilation: ($j\ W_t^d$), where j and d are parameters. The rate of food consumption, C, is given by $C = (j\ W_t^d)a^{-1}$, where a is the assimilation efficiency ($A'C^{-1}$).

If $d = 2/3$, then the von Bertafanffy model is now expressed in terms of food assimilation and catabolism. Simulation studies indicate that the estimates of food consumption using this model are highly sensitive to the value of the parameter d.

Winberg model

Well before the modifications to the von Bertalanffy model that replaced the anabolic term by an assimilation term, Winberg introduced a balanced energy budget to describe the relationship among food consumption, growth, and metabolism. He identified input as the energy content of food consumed (C) and the outputs as growth (P) and metabolic expenditure (R). From a survey of the data then available, he suggested that assimilated energy represented 70% of the consumed energy, that is, $0.7C$. The energy budget was then expressed as $P = 0.7C - R$. Winberg argued that for fish in natural populations, R could be approximated as twice the standard metabolism measured under laboratory conditions; thus, $P = 0.7C - 2R_S$. In early studies of the bioenergetics of fish, this simple formulation provided a useful approximation of the magnitudes of growth and food consumption in natural populations. An early experimental study of the bioenergetics of the European perch, *Perca fluviatilis*, suggested that the Winberg equation could give a reasonable estimate of the maintenance metabolic rate, that is, when growth is zero, and of the metabolic rate of a fish on an unrestricted ration.

Davis and Warren model

A further step in the development of a bioenergetics model of growth was provided by the Davis and Warren model. This model is a flow diagram of the partitioning of the energy income among the energy outputs, the latter including any growth (**Figure 1**). The model thus provided a framework in which the pattern of energy allocation, in principle, could be described quantitatively. Each term in the energy budget equation for growth $P = C - (F + U) - R$ (see earlier) can be measured experimentally under defined conditions of individual body mass, water temperature, food availability, and other relevant environmental conditions. If four of the five terms in the energy budget equation are estimated empirically under defined conditions, the fifth can be obtained by calculation. For example, if C, F, U, and R are measured, P can be calculated, providing a prediction of growth under those conditions. That prediction can then be tested experimentally, by estimating the growth (in energy units) of individuals raised under the defined conditions.

The energy budget under defined conditions can be described in terms of the percentage allocation. The allocation by the grass carp, *Ctenopharyngodon idella*, when the fish were fed duckweed was summarized as $100C = 35F + 51R + 9P$, but, when fed tubificid worms, $100C = 9F + 8U + 61R + 22P$. This illustrates the effect of the better-quality animal diet on growth. A comparison of carnivorous with herbivorous species in terms of an energy budget suggested values of $100C = 27(F + U) + 44R + 27P$ for carnivores and $100C = 43\ (F + U) + 37R + 20P$ for herbivores.

Wisconsin growth model

The Davis and Warren model lies at the heart of the Wisconsin bioenergetics model that has found the most use as a predictive tool in fisheries biology (**see also Energetic Models**: Bioenergetics in Ecosystems). The model was made available as a computer package with a comprehensive manual, including data for a range of species on the parameters required to estimate the components of the energy budget. The model uses the energy budget equation to predict the growth of a fish of a given initial mass over a selected time period, typically 24 h. The mass of the fish at the end of the 24 h is then used as the starting point for the prediction of growth over the next 24 h and so on for as many days as required. Relevant factors such as temperature can also be changed on a day-by-day basis. The computer package allows the growth in body size of fish in different age classes (cohorts) to be simulated and so the bioenergetics of the individual fish can be extended to the bioenergetics of the population of fish.

In the Wisconsin model, growth energy, P, is converted to the increase in mass, ΔW, by dividing P by the energy density of the fish $[E]$, so $\Delta W = P\,[E]^{-1}$. A flavor of the model can be given by describing some of the relationships used to quantify components of the Davis and Warren energy budget. Food consumption, C, is estimated as $C = pC_{\mathrm{MAX}}\,f(T)$, where p is the proportion of C_{MAX} consumed, $f(T)$ is a function that describes the effect of temperature on food consumption, and the maximum rate of consumption $C_{\mathrm{MAX}} = a\,W_t^b$, where a and b are parameters. C is converted into energy units for use in the mass-balance equation by multiplying by the energy density of the food $[E_{\mathrm{FOOD}}]$. Metabolic expenditure, R, is estimated as $R = (\mathrm{ACT})R_{\mathrm{S}}\,g(T) + R_{\mathrm{D}}$, where ACT is a multiplier to define the level of activity and $g(T)$ is a function describing the effect of temperature on metabolism. If $\mathrm{ACT} = 2$, then active metabolic rate is twice the resting rate. Each of the relationships used has to be defined for the species of interest.

The Wisconsin model has been used to guide management strategies, especially for the Great Lakes in North America. A list of its uses includes the following: (1) the evaluation of the factors that constrain fish growth; (2) the evaluation of the impact of fish predators on prey populations; (3) quantification of the dynamics of bioaccumulation of contaminants such as polychlorinated biphenyls (PCBs); (4) prediction of the waste loads produced by an aquaculture system; and (5) enhancement of an understanding of the role that fish play in ecological processes in aquatic systems. The Wisconsin model is also incorporated as a subcomponent of individual-based models of fish life history and population dynamics.

The Wisconsin model also illustrates some of the problems in using bioenergetics models to predict growth in natural populations. The first problem is obtaining a realistic estimate of the level of activity of fish in a natural population so that the metabolic costs of activity can be estimated. A second problem is estimating the rate of food consumption in natural populations in the context of the availability of suitable food items (**see also Food Acquisition and Digestion**: Energetics of Prey Capture: From Foraging Theory to Functional Morphology). This means that the Wisconsin model is often used to estimate food consumption on the basis of observed growth, rather than growth from observed consumption. A third problem is that the Warren and Davis and its successor, the Wisconsin model, do not include an explicit model of how energy should be allocated between the different outputs to maximize fitness. Although the structure of the Wisconsin model is general for any fish species, to apply it to a specific population of a species requires knowledge of a high number of parameters to define the relationships among the components of the energy budget and body mass, temperature, and other relevant factors. This means that care must be taken to examine the sensitivity of the predicted growth to the values of the parameters used in the model.

Dynamic energy budget model

A comprehensive bioenergetics model has been developed by the Dutch biologist, SALM Kooijman. Although this model is, in principle, applicable to all living organisms, it has been adapted to simulate the growth of fish. The crucial feature of this model is that it does explicitly include a rule for the allocation of energy among outputs. It assumes that assimilation rate is proportional to body surface area, that is, to $V^{2/3}$, where V is the structural volume of the individual, while maintenance rate is proportional to body volume, V (these proportionalities recall those used in the von Bertalanffy model). The assimilated products then enter a reserve pool, from where they are allocated to maintenance, somatic growth, and reproduction. A fixed fraction of the reserve, K, is allocated to maintenance and growth, while the remaining fraction, $1 - K$, is allocated to development and reproduction. If the rate of assimilation is low, priority is given to maintenance, and if the rate of energy utilization from the reserves cannot meet the costs of somatic maintenance, the individual eventually dies.

The dynamic energy budget (DEB) model (**Figure 4**) uses two state variables to describe an individual fish: the volume of the somatic body, V, and energy density of the reserves $[E]$, which describes the quantity of reserves, E, per unit of structural body volume. The DEB model clearly distinguishes between structural body and reserves. With these assumptions, the DEB generates a growth equation, which is mathematically, if not conceptually, equivalent to the von Bertalanffy model. Extensions of the basic model apply to embryos, which do not feed or reproduce, and juveniles, which feed, but do not reproduce. In some extensions of the model, a further allocation rule is proposed, which governs the allocation between somatic growth and stored reserves. A disadvantage of the DEB model is that the parameters used to develop the model are difficult to estimate.

In a simplified form, the DEB model has provided some insight into the nature of compensatory growth in salmonid fishes, and the simulation of the growth of Atlantic salmon, *Salmo salar*, in a Scottish stream. Although the model is

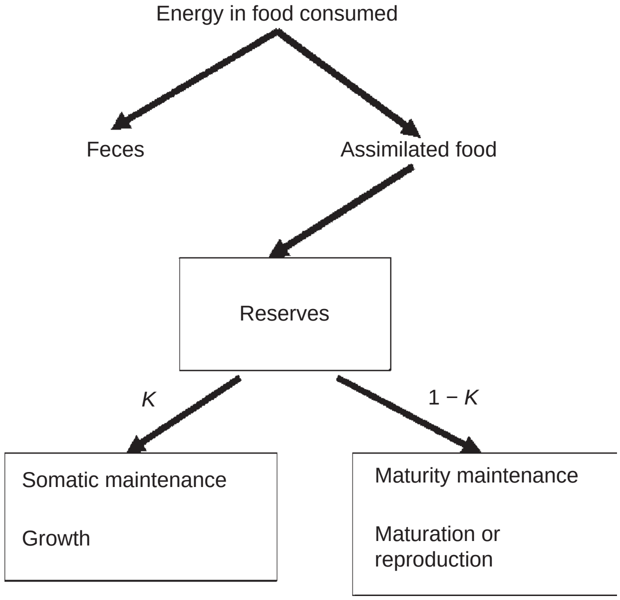

Figure 4 Dynamic energy budget (DEB) model of energy allocation in individual fish, showing *K*-rule.

conceptually more realistic than the Wisconsin model, because it does incorporate an allocation rule, it has not matched the use of the Wisconsin model in practical studies of fish growth.

Conclusion

As bioenergetic models of growth are based firmly on the laws of thermodynamics, they offer the prospect of providing realistic simulations of growth under defined environmental conditions. Even under conditions of relatively stable long-term environmental conditions, the ability to predict the growth trajectories of fish in natural populations or in aquaculture is valuable for conservation and resource management. With the predicted long-term changes in global temperatures and the consequences for the climate, the ability to predict the effects of the changes on the growth rate and related traits of fish will be essential to devise strategies that will reduce, as far as is possible, the impact of these changes. The models also provide a framework within which physiological studies on the neuroendrocrine control of energy allocation in the individual fish can be conducted. There continues to be the need to verify and validate the bioenergetic model used, by carefully designed laboratory and field studies that result in improvements to the structures of the models and the estimates of the parameters used in the models.

Glossary

Abiotic The chemical and physical (nonbiological, physical) variables of the environment (e.g., temperature).

Ad libitum Amount of food consumed when food is always present for individual fish.

Anabolism Synthesis of materials via metabolic processes; a series of chemical reactions that builds larger molecules from smaller components, usually requiring energy in the process.

Biotic Environmental factors related to living organisms. The biological variables of the environment, e.g., predation and competition.

Catabolism Metabolic processes that result in the release of energy from organic molecules.

Conspecifics Other individuals of the same species.

Dominance Behavioral ability of an individual to sequester resources in the presence of other individuals.

Ectothermic An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Heterospecifics Individuals from different species.

Ontogeny Changes in the phenotype of an individual during its life span. Ontogeny is the outcome of a developmental program, encoded in an organism's genes, as well as interactions between the genotype of the individual and the environments it encounters, together with any maternal effects mediated through the egg itself.

Photoperiod Durations of day and night during the 24-h diel cycle.

Ram ventilation A passive method of driving oxygen-containing water over the gills. The fish swims with its mouth open, so water flows in through the mouth and out past the gills.

Thermocline Zone of high rate of temperature change that separates a shallow, less-dense, warm water layer (epilimnion) from a deeper, more-dense colder-water layer (hypolimnion) in lakes, seas, and estuaries.

Introduction

Growth is central to the ecology of fishes because many factors relevant to fitness are size dependent, including prey size, risk of predation, survival during harsh conditions, and fecundity of females. In terms of the energy content of fish, growth is the difference between energy obtained in the food and the outputs of energy in the form of fecal and excretory losses and the heat generated by metabolic processes (**see also Energy Utilization in Growth**: Energetics of Growth).

The growth that an individual fish achieves depends on three constraints. The first is the genetic constitution of the individual. Growth responds to artificial selection indicating that there is underlying heritable, genetic variation for growth in fish populations. Second, the abiotic environment experienced by the fish will set constraints on growth. Third, the biotic environment will determine the extent of the growth potential that the fish can achieve as defined by its genotype and the abiotic environment experienced.

This article focuses on the effects of abiotic and biotic factors on growth. In analyzing the effect of abiotic and biotic factors on growth, a further factor has to be included. If the quality and quantity of food available does not change significantly, the growth rate, expressed as specific growth rate, g, decreases as the size of the fish increases. Specific growth rate is a measure of the size-specific growth rate. In mathematical terms, it is $g = \mathrm{d}W/W\ \mathrm{d}t$, where W is size (mass, length, or total energy content).

Abiotic Factors

Temperature

Metabolism, both anabolic and catabolic, is a set of chemical reactions catalyzed by enzymes; consequently, all physiological rates depend on temperature (**see also Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism). Temperature controls the maximum rate at which growth can occur when food availability or other factors are not restricting growth rate. As the majority of fish are ectothermic (for exceptions, **see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks), their body temperature will essentially follow the temperature of the surrounding water. Experimental studies on the effect of temperature on growth rate show that three temperatures can be defined. There is a minimum (T_L) and a maximum temperature (T_U) at which the growth rate is zero. Between the minimum and maximum temperatures for growth, there is a temperature at which growth rate is maximized, identified as the optimum temperature for growth (T_{OPT}). This means that the relationship between growth rate and temperature is an asymmetric bell shape (**Figure 1**). This pattern largely reflects the relationship between *ad libitum* food consumption and temperature. For fish supplied with maximum rations, T_L, T_{OPT}, and T_U for growth in the European trout, *Salmo trutta*, a cold-water species, are approximately 5, 14, and 23 °C, respectively. Experimentally determined values will also depend on the population from which the experimental fish are taken and the details of the experimental protocols. If the ration size is restricted, the optimum temperature for growth decreases (**Figure 1**), reflecting the lower metabolic costs at low temperatures (**see also Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism).

Most laboratory studies of the relationship between growth and temperature use constant temperatures. However, fish in natural populations may experience cyclical changes in temperature, either because of day–night cycles in temperature or because voluntary movements of the fish take them into different thermal regimes. Experimental studies on the effect of cyclical temperature regimes on growth have not provided consistent results, probably because of differences in the experimental designs. The vertical migrations of juvenile sockeye salmon, *Oncorhynchus nerka,* through the thermocline, in some lakes in summer, may reflect the advantage of feeding in the warm surface waters, but metabolizing the results of feeding in the cooler, deeper waters.

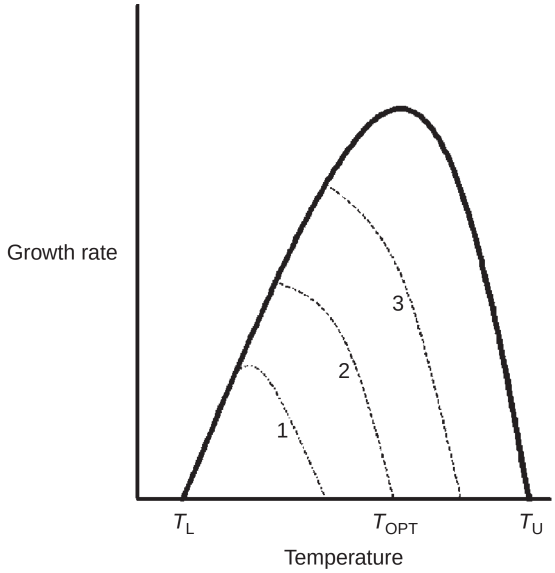

Figure 1 Schematic diagram of the relationship between growth rate and temperature, identifying the minimum, T_L; optimum, T_{OPT}; and maximum, T_U, temperatures for growth. Unbroken line shows relationship when fish fed *ad libitum*, broken lines show the relationship at restricted rations levels with level 1 < level 2 < level 3.

The relationship between temperature and growth rate for a given species of fish may vary with latitude. Experimental studies on the Atlantic silverside, *Menidia menidia*, which is found along the Atlantic seaboard of North America, demonstrated a pattern of counter-gradient selection. At a given temperature and with abundant food, silversides from northern populations grew faster than fish from southern populations. This was true even at high temperatures, even though the temperatures in which the northern population naturally live are lower throughout the year. This counter-gradient variation means that although silversides in the northern populations have a shorter growing season than that in the south, the higher growth potential of the northern fish means they can reach a size similar to that of the southern fish by the end of the growing season.

Oxygen

Oxygen is required for the aerobic metabolic processes that make energy available to do useful work (**see also Energetics**: General Energy Metabolism). However, oxygen has a low solubility in water, and this solubility decreases as water temperature increases. The oxygen content of water can be expressed either as the absolute concentration in mg L^{-1} or as a percent of saturation. Due to the effect of temperature on the solubility of oxygen, 100% saturation at a high temperature represents a relatively low absolute concentration (**see also Transport and Exchange of Respiratory Gases in the Blood**: O_2 Uptake and Transport: The Optimal P_{50}). Thus, at 10 °C and 100% air saturation (at sea level), dissolved oxygen is at a concentration of 11.3 mg L^{-1}, but at 25 °C, the oxygen concentration at 100% air saturation is at 8.2 mg L^{-1}. A further complication is that the oxygen concentration also decreases with an increase in water salinity.

There is the possibility that the rate of oxygen uptake by the fish is too low to support the rate of growth that would be permitted by the prevailing temperature. Thus, in some circumstances, oxygen can act as a limiting factor on growth and observed growth is lower than that predicted for the given temperature and available food (**Figure 2**). The

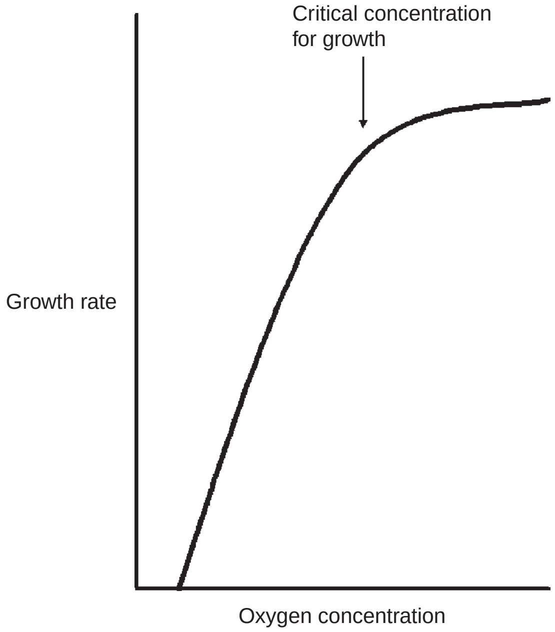

Figure 2 Schematic diagram of the relationship between growth rate and oxygen concentration, showing a representative critical oxygen concentration for growth.

environmental conditions in which oxygen may act as a limiting factor on growth are unusually high water temperatures, water in which there is a high demand for dissolved oxygen by decaying organic matter (biological oxygen demand, BOD), high densities of fish in a limited volume of water, and low rates of oxygen diffusion from air to water because of a barrier formed by ice or snow or stratification.

Experimental studies suggest that across a range of species, the critical threshold level of air saturation at which growth starts to be inhibited by hypoxia (i.e., low oxygen) is 50–70%. In the freshwater tropical species *Poecilia reticulata*, the critical concentration was about 3.0 mg L^{-1} and at 30 °C, 100% saturation would be about 7.6 mg L^{-1}. Most laboratory studies of the relationship between growth and oxygen level use a constant oxygen concentration. In natural environments, fish may experience regular or stochastic changes in oxygen concentrations such as those associated with day–night cycles in oxygen generated photosynthetically, or through water mixing induced by winds and storms.

Salinity

Fish have to do metabolic work to maintain a homeostasis of ionic concentrations in their body fluids. For those species that live the whole of their lives either in the sea water or in freshwater, this metabolic work will be consistent. However, some fish species move between waters of different salinities. Many salmonid species, for example, are anadromous, moving from freshwater, where they spend an early juvenile phase, into the seawater, where they undergo growth to sexual maturity. As a consequence, energy that could have appeared as growth (**see also Energy Utilization in Growth**: Energetics of Growth) is expended on ionic homeostasis (**Figure 3**). Salinity acts as a masking factor for growth. The costs of ionic homeostasis will change as the fish move between salinities. The juveniles of some species that spawn in the sea, such as the European sea bass, *Dicentrachus labrax,* move into estuaries, perhaps because of the growth advantage accrued by living at a reduced salinity. For a range of euryhaline species ($N = 23$), the best growth was achieved at salinities ranging from 0 to 35 ppt, but with a median value of 15 ppt. A study of growth in the early juvenile, glass-eel stage of the American eel, *Anguilla rostrata*, found that they grew faster in brackish water than freshwater, but that growth rates differed depending on the sites in eastern Canada from which the eels had been collected. This may be an example of an interaction between an abiotic factor and the genetic capacity for growth in eel populations.

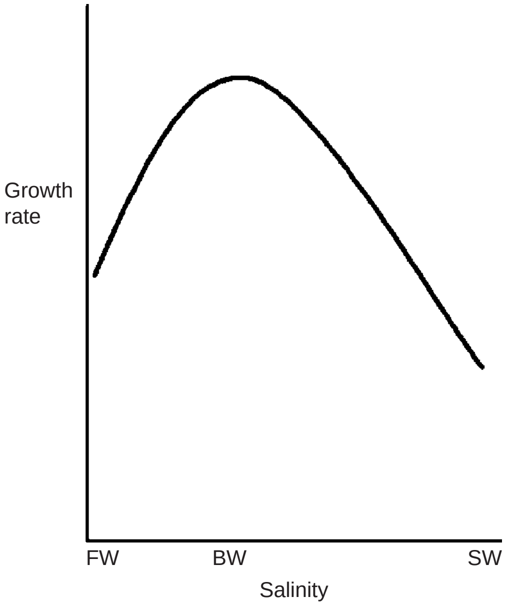

Figure 3 Schematic diagram of the relationship between growth rate and salinity for a euryhaline species. FW, freshwater; BW, brackish water; SW, seawater.

Current Speed

The speed of water flow potentially has opposing effects on growth. First, the energy the fish spends in swimming against a current will not be available to invest in growth. Second, the current flow may allow the fish to use, at least partly, ram ventilation for respiration, rather than the energetically more costly method of pumping the dense and viscous water over the gills. In some salmonids, including European trout and Arctic charr, *Salvelinus alpinus*, fish grew faster when forced to swim at speeds of about 1.5 body lengths s^{-1}. This is a relatively slow speed for salmonids. However, some species of fish showed no effect or even reduced growth if subjected to exercise, including the goldfish (*Carassius auratus*). A preliminary study detected no effect of speed of swimming over the range 0–1.0 body lengths s^{-1} in juvenile cod, *Gadus morhua*, a marine species.

Photoperiod

The effect of the diel cycle of light and dark on the growth of fish has, potentially, two components. For species that depend primarily on vision to detect their food, a longer period of light during the cycle will provide more time in which to feed. Other things being equal, this should result in faster growth. A second effect may be mediated through the control systems of the fish, due to the effect of photoperiod on the neuroendocrine system – as a consequence of light reception at the retina of the eye, the pineal gland, or perhaps other extra-retinal light receptors. In many species, these effects of photoperiod on the neuroendrocrine system control important processes in the life cycle, most notably sexual maturation. In salmonids, photoperiod is important in the control of smoltification, the physiological processes that prepare the juvenile salmonid for life in the sea. Experimental studies and studies using aquaculture systems demonstrate an increase in growth rates in some species, including Atlantic salmon, *S. salar*, subjected to long day lengths or even continuous light. Three possible mechanisms may lead to higher growth: the increased time for feeding; neuroendocrine changes that stimulate feeding; and neuroendocrine changes that direct resources into growth rather than other activities. Most of the research on the effect of photoperiodic regime on growth has focused on the light regimes that increase growth rates under aquaculture conditions and less has been directed at teasing apart the mechanisms by which higher growth rates are achieved.

Other Abiotic Factors

Although temperature, oxygen, salinity, and photoperiod are likely to be the most important factors influencing growth rates, in some contexts, other abiotic factors may become important. At high fish densities and low water-filtration/replacement rates, the ammonia/ammonium excreted by the fish can reach levels, in the water, that inhibit growth. Growth can also be inhibited at low pH levels or high [CO_2] such as those observed in areas affected by acid rain or decomposition of organic molecules.

Interactions of Abiotic Factors

Although experimental studies on the effects of abiotic factors on fish growth tend to study only one or two factors, under natural conditions, fish experience many factors simultaneously, with some of those factors showing short- and long-term variations. The factors also interact (e.g., the effects of temperature and salinity on oxygen concentration), while some are confounded (e.g., day length and temperature in temperate and boreal areas). Thus, while experimental studies are essential for an understanding of the effects of abiotic factors on growth, care needs to be taken in extrapolating experimental results to natural populations.

Biotic Factors

The abiotic factors provide the framework, which defines the maximum rate at which an individual fish can grow. Biotic factors determine what proportion of that maximum can be realized.

Food

Food is the biotic factor that controls the rate of growth (**see also Energy Utilization in Growth**: Energetics of Growth). If a fish cannot obtain food, it will lose mass and eventually starve, although fish can often survive long periods without food. Both the quantity and the quality of food available control the growth rate.

Food Quantity

Experimental studies show that the relationship between the growth rate and the quantity of food consumed is an asymptotic, curvilinear relationship (**Figure 4**). This relationship is defined by four levels of consumption. The growth rate of starved fish, that is, the rate at which the fish is losing mass, is defined by the value at which the curve intercepts the *y*-axis. The maintenance ration, C_{MAIN}, is defined by where the curve intercepts the *x*-axis. At this ration, there is no growth; the fish maintains a constant size. The optimum ration, C_{OPT}, is the ration at which the conversion of food into fish flesh is most efficient. Finally, C_{MAX} is the maximum ration the fish will consume under the prevailing abiotic conditions. With an increase in temperature, the loss of mass with starvation and C_{MAIN} increase, reflecting the effect of temperature on the rate of metabolism. Initially, C_{OPT} and C_{MAX} also increase, but at higher temperatures, beyond the optimum temperature for growth, they decline. The relationship also shows that a fish cannot maximize its growth rate and its growth efficiency simultaneously. Detailed, quantitative descriptions of

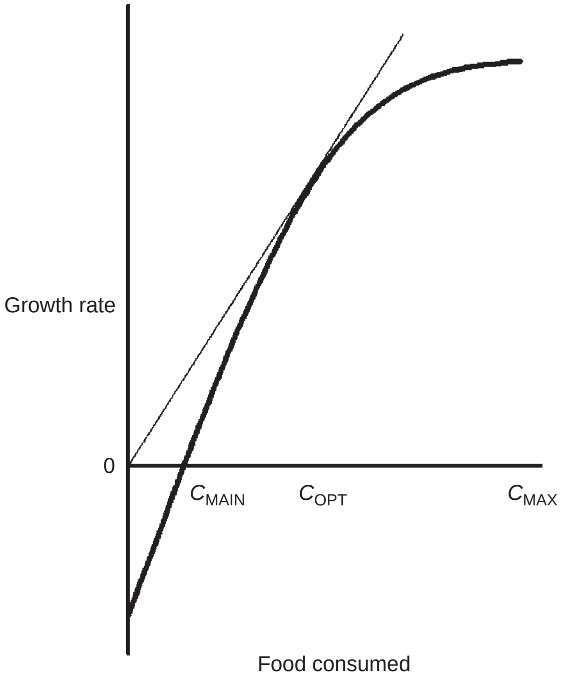

Figure 4 Schematic diagram of the relationship between growth rate and food consumption, identifying the maintenance ration, at which growth is zero, C_{MAIN}; ration at which growth efficiency is maximized, C_{OPT}; and growth rate with *ad libitum* food consumption, C_{MAX}.

the relationship between growth, rate of food consumption, and temperature have been determined for the European trout. A feature of these results was that the temperature and ration size at which growth efficiency was maximized were both lower than the temperature at which the growth rate was maximized. However, there are still relatively few studies on other fishes that define the relationships in detail as is available for the European trout.

Food Quality

Food quality in relation to fish growth has two aspects. The first is the nutritional quality of the food. Fish tend to have high requirements for protein and lipid in their diets. This is particularly true of carnivorous fish, such as the salmonids and gadoids. A consequence of this is that in the aquaculture of such species, to obtain good growth, the food provided contains good-quality protein, usually in the form of fish meal (**see also Energetic Models**: Bioenergetics in Aquaculture Settings). Omnivorous species such as the roach, *Rutilus rutilus*, one of the most common freshwater fishes of Western Europe, consume both plant and animal material. Roach fed on mealworms grew far faster than roach fed on grass, though the rates of consumption in both diets were close to the maximum. The growth efficiency for the roach fed on grass was 9%, whereas for those fed on mealworms it was 46%. These differences reflect the higher quality of animal foods.

A second aspect of food quality is the size of the prey eaten (**see also Food Acquisition and Digestion**: Energetics of Prey Capture: From Foraging Theory to Functional Morphology; Energetics of Foraging Decisions and Prey Handling). As fish grow, the size of the mouth (gape size) increases, which allows the fish to take larger prey, with the result that each prey taken provides more energy. However, the time taken to handle an individual prey tends to increase with prey size. Consequently, for a fish of a given size, there is a prey size that maximizes the rate of return per unit time. This is the optimum prey size. In species such as the European perch, *Perca fluviatilis*, or the European trout, if an individual can reach a size that allows it to switch from feeding exclusively on invertebrate prey to feeding on fish, the individual often shows an increase in growth rate after this switch. This is a reflection of the increased profitability of the prey. In aquaculture, the size of the food pellets fed to the fish reflects the changing size of the gape of the fish as they grow.

Social Interactions

The social environment of the individual fish can affect growth though several mechanisms, which influence the rate of feeding. The amount of food available can be affected by the presence of other animals. The propensity to feed may be affected by the presence of other, more dominant fish, even when food is available. Interactions with other animals can affect the time that can be spent on feeding or the energy expended on interactions. Social dominance is an excellent example of a social interaction (**see also Social and Reproductive Behaviors**: Dominance Behaviors) that results in differential growth.

Presence of conspecifics

The effect of conspecifics on feeding and hence growth depends on the nature of the behavioral interactions. One possibility is that there is competition by exploitation for food. This occurs simply because items of food consumed by one individual are then not available for being eaten by another individual. When food availability is limiting, individual fish have essentially the same chance of obtaining food. Differences in food consumption and, therefore, differences in growth are largely determined by the chance of encountering suitable food items.

However, if the behavioral interactions include dominance relationships, the dominant fish can sequester food at the expense of the subordinate fish. This leads to depensatory growth. The dominant fish grows at a faster rate than the subordinate fish and so the variance of fish size increases over time. Since dominance in fish is often related to fish size, as the dominant fish grow faster, their size advantage over the subordinate fish increases, which reinforces the ability of the dominants to sequester food. Observations on stream populations of salmonid fishes suggest that dominant fish can acquire the better localities for feeding. In the aquaculture of salmonids, fish are size-graded at regular intervals to reduce the differences in size among fish kept in a single tank, in an attempt to reduce the depensatory growth.

Even when food is readily available, the presence of dominant fish may inhibit the food intake of subordinate fish. The presence of the dominant fish stresses the subordinates and this leads to a loss of appetite in the subordinates. The importance of such a behavioral inhibition of feeding and hence growth in natural populations is uncertain (**see also Social and Reproductive Behaviors**: Dominance Behaviors).

In contrast, in fish species that typically live in shoals, the presence of conspecifics may stimulate feeding. This is because for such fish, isolation is a stressful condition, again leading to a suppression of appetite.

Presence of heterospecifics

If species that coexist in the same habitat have similar diets, there may be interspecific competition for food, with adverse consequences on the growth of individuals. In some North American lakes, juveniles of bluegill (*Lepomis macrochirus*) and pumpkinseed sunfish (*L. gibbosus*) both occur in the littoral zones and have similar diets and act as interspecific competitors. As they increase in size, the diets of the two species diverge such that interspecific competition relaxes.

The presence of predators can also affect growth rates because the predators may restrict their prey to habitats that are less favorable for feeding. Largemouth bass, *Micropterus salmoides*, feed on juvenile bluegill sunfish. In the presence of the largemouth bass, the bluegill juveniles tend to be restricted to the vegetated littoral and are not able to move in to more open water, where zooplankton is an abundant source of food, but the risk of predation by largemouth bass is much higher. The presence of a predator may also inhibit a fish from foraging for food.

Such interspecific interactions and their effect on fish growth can be complex. An example can be found among European perch and roach in lakes in northern Europe. In the early life-history stages, the two species can be interspecific competitors for zooplankton, with roach tending to be the superior competitor. Later in ontogeny, the perch may become predators of roach. The presence of roach may both inhibit and stimulate the growth of perch, depending on the ontogenetic stages of the individuals that are interacting.

Compensatory Growth

Compensatory growth is a phenomenon which has been demonstrated in the laboratory, but whose importance in natural populations is still uncertain. It occurs when fish, which have experienced a period of unusually slow growth (e.g., due to low rations or high levels of swimming activity), are returned to favorable conditions (e.g., in which food is unlimited and/or activity is low). Such fish then grow at an unusually high rate and may catch up in size with individuals that have never suffered the growth depression. It is of interest because it suggests that, even in good conditions, fish tend to grow at a rate slower than their maximum physiological capacity. This suggests, also, that there are costs, in terms of fitness, of high growth rates. Notably, some studies have described an inverse relationship between growth rate and swimming performance. Growth rates may be regulated by neuroendrocrine and endocrine mechanisms to reduce these costs.

Conclusion

Growth patterns are adaptive responses to the environmental conditions. The growth potential of an individual is defined by its genotype. However, the extent to which that potential can be realized will depend on the abiotic conditions experienced during the ontogeny of the individual, further modified by biotic factors, particularly the availability of food.

Glossary

Aerobic metabolic scope The extent to which a fish can raise its aerobic metabolic rate above the minimal rate required to maintain life processes. The magnitude of the scope depends upon the ability of the respiratory and cardiovascular systems to provide oxygen and nutrients for aerobic activities.

Bio-logging and biotelemetry The measurement of physiological or physico-chemical information with sensors attached to (or inside) free-swimming fish. The information can be either stored (logged) or transmitted to a receiver (telemetered).

Cost of transport The unit cost of transporting a unit mass over a unit distance. This can be measured by respirometry of fish swimming at known speeds.

Drag power The inertial forces exerted by a viscous fluid such as water; the fish must exert an equal and opposite thrust power in order to move, which is generated by muscular work.

Excess post-exercise oxygen consumption (EPOC) The amount of oxygen that is consumed after exercise has stopped, which represents the oxygen cost of recovering from the exercise bout and includes the replenishment of oxygen stores and metabolites.

Red muscle Striated skeletal muscle that generates ATP aerobically and is used to perform sustained low-intensity swimming. Red muscle has many mitochondria and a good blood supply to provide oxygen and nutrients.

Swim-tunnel respirometer A piece of equipment that is designed to exercise fish at known speeds and measure their metabolic rate by respirometry.

Respirometry The measurement of metabolic rate as gas exchange, also known as indirect calorimetry.

White muscle Striated skeletal muscle that generates most ATP equivalents anaerobically and is used to perform bursts of high-intensity swimming. White muscle has few mitochondria and less blood supply than red muscle.

Introduction

Swimming is a defining feature of fish, almost all species swim at some point in their lifecycle. Fish swim routinely to find food, to escape predation, or to engage in social interactions such as territorial defense or reproduction. Some species inhabit lotic environments, which require them to swim just to maintain station. Many species swim to change their habitat, either as part of seasonal movements or for reproductive migration. The most famous long-distance migrants are salmonids of the genera *Salmo* and *Oncorhynchus* and eels of the genus *Anguilla* (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle and Eel Migrations).

Swimming requires energy because it is muscular work, primarily by the large blocks of axial muscle arrayed along each side of the body, known as myotomes, which are such a dominant anatomical feature of most fishes. Although active contraction occurs by the same adenosine triphosphate (ATP)-consuming molecular mechanisms as in all vertebrate skeletal muscle, fish have distinct muscle types. Each type uses specific metabolic pathways for the primary generation of ATP (aerobic vs. anaerobic) and power different types of swimming. Thus, swimming can range from gentle aerobic activity over long periods to brief bursts of intense anaerobic activity, depending on the context. In the laboratory, the energetic costs of such activities have been measured with swim flumes and techniques of respirometry. Respirometry estimates rates of ATP utilization indirectly as rates of oxygen uptake, because they are stoichiometrically related through oxidative phosphorylation (**see also Energetics**: General Energy Metabolism and **Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming). One of the most difficult things to estimate is how much energy fish spend on swimming in their natural environment, because they are so difficult to study and follow underwater. This is becoming possible, however, through recent technological developments in biotelemetry and bio-logging (**see also Fish Migrations**: Tracking Oceanic Fish and Eel Migrations).

Why Swimming Requires Energy

Water is a dense, viscous medium that exerts inertial forces known as pressure drag. In order for a fish to move, it must replace the momentum lost to pressure drag by transferring kinetic energy from its body to the water. The amount of energy that is required depends on the shape of the fish and the texture of its body surface, as well as the nature of its propulsive movements (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming). The overall rate of energy loss for a body relative to a water flow, often called the drag power (P_D), is described by the following equation:

$$P_D = 0.5\rho S C_b U^3 \qquad (1)$$

where ρ is the density of water, S is the wetted surface area of the body, U is the velocity, and C_b is a dimensionless drag coefficient. Body shape has a major influence on drag power, and many fishes have evolved a streamlined form. In order to move, the fish must generate thrust power that is at least equal to the P_D, but the propulsive movements themselves cause a large increase in C_b, by a factor of between three- and fivefold. Furthermore, because P_D is dependent on the cube of U, the energy required for swimming increases exponentially with increasing velocity.

The energy to overcome pressure drag comes from the hydrolysis of ATP in active muscle contraction. The largest proportion of work is performed by the swimming muscles themselves, which are composed of skeletal muscle fibers (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops). There are also minor proportions of energy expended for gill ventilation, cardiac pumping (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping), and fin placement for maneuvering (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability). Some energy is also required for the nervous control of swimming activity.

Types of Fish Muscle and Swimming Activity

Fish swim with two types of striated skeletal muscle, aerobic red muscle and anaerobic white muscle (**Figure 1**). Aerobic red muscles, which typically maximally represent only about 10% of the total muscle mass, are used for slow to moderate, steady swimming. Anaerobic white muscles form the majority of the myotomal muscle blocks in most fishes, as well as the greatest proportion of body mass (sometimes over 50%), and are used for brief bursts of high-speed swimming. Laboratory research has investigated energetic costs of exercise in fish, often using protocols that take fish to extremes of their aerobic or anaerobic performance. This research has revealed much about the physiological mechanisms that support the costs of swimming, and what sets the energetic limits to each of these types of activity.

Aerobic Red Muscle and Sustained Aerobic Activity

This muscle is composed primarily of slow-twitch oxidative (SO; type I) fibers, which produce most power at low contraction (i.e., twitch) frequencies, and generate their ATP by mitochondrial oxidative phosphorylation, which produces 36 molecules of ATP for each glucose equivalent (**see also Energetics**: General Energy Metabolism). This requires substrates (lipids, proteins, and carbohydrates) to burn as fuel and a supply of oxygen as the terminal electron acceptor. The substrates and oxygen are generally

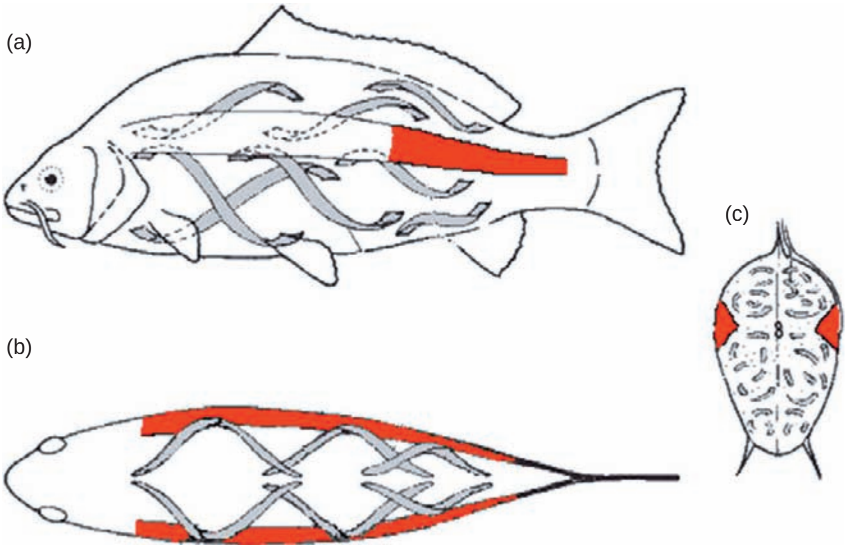

Figure 1 Longitudinal (a), dorsal (b) and transverse section (c) views of the position of different types of muscle in a representative teleost fish, the carp *Cyprinus carpio.* The red muscle is in red, a thin strip in the midline just below the skin. The white muscle is in gray and represents the majority of the myotomal muscle mass. Adapted from Rome LC, Funke RP, Alexander RMcN, *et al.* (1988) Why animals have different muscle fiber types *Nature* 355: 824–827.

provided to the muscle via the bloodstream, and red muscles have a rich blood supply and a high density of mitochondria (**see also Temperature**: Mitochondria and Temperature). They also have intracellular myoglobin, a transient oxygen store that, along with the many capillaries, gives them their characteristic red color. Thus, aerobic exercise performance depends upon factors that influence rates of substrate delivery for aerobic metabolism, such as gill morphology and surface area (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics), cardiac muscle function, and pumping capacity of the heart (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping and **Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming).

The largest red muscle mass in most fishes is a strip that runs along each side of their body (**Figure 1**). This is used to beat the tail, in what is known as body-caudal fin (BCF) swimming (**see also Buoyancy, Locomotion, and Movement in Fishes**: Undulatory Swimming). This red muscle is used to swim at slow to moderate speeds, for activities that must be sustained for extended periods, such as foraging, holding station in rivers, or long-distance migration. Many fishes can also swim by moving their fins, in what is known as median-paired fin (MPF) locomotion (**see also Buoyancy, Locomotion, and Movement in Fishes**: Paired Fin Swimming and Maneuverability). The muscles powering the fins are generally skeletal red muscles and, in most species, MPF locomotion is for slow maneuvering. This ability is most pronounced in species that inhabit complex habitats, such as coral reefs. Some coral reef fishes actually can swim remarkably fast with particular sets of fins, notably the labriform and balistiform swimmers (from similarly named families, among others). Some species swim exclusively with fins, for example, the knifefishes of the Gymnotidae family, which have a modified anal fin that extends along much of the ventral side of their body, and which they undulate to propel themselves forward (or backward) through the water.

Most of what we know about aerobic swimming energetics comes from laboratory studies that utilize swim flumes or swim-tunnel respirometers. A schematic representation of one type of swim tunnel respirometer is shown in **Figure 2**. These are instruments that are designed to create a uniform (nonturbulent) water flow, and where the velocity of the current can be controlled. The fish swims spontaneously against the current, by a reflex known as rheotaxis, and different levels of swimming activity can be created by adjusting the speed of the water current. Their energetic costs can then be measured indirectly by respirometry (**see also Energetics**: General Energy Metabolism).

If a fish that uses BCF locomotion is exposed to progressive incremental increases in swimming speed, they exhibit a linear increase in tail-beat frequency with swimming speed. If oxygen uptake is measured at each step, there is an exponential increase in oxygen demand by the working muscles because P_D increases with the cube of U (eqn (1)). The shape of the curvilinear relationship between swimming speed and oxygen uptake is shown in **Figure 3(a)**; it typically is a power function:

$$\dot{M}O_2 = aU^b \qquad (2)$$

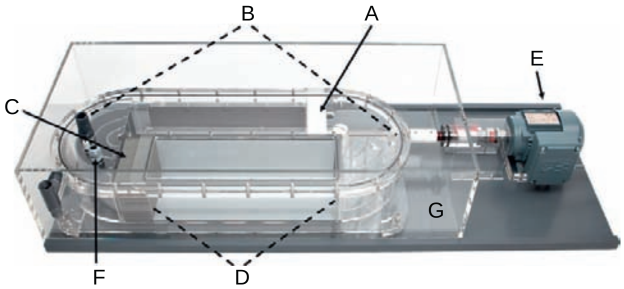

Figure 2 A photograph of a swim-tunnel respirometer. A propeller (not visible, (A)) generates a flow of water in an enclosed recirculating pathway (B), the flow is straightened with vanes and a honeycomb of tubing (C), so that it enters the swim chamber (D) with a uniform velocity profile. The fish swims spontaneously against the current in the swim chamber. The propeller is driven by a variable-speed electric motor (E), to obtain known current velocities and, therefore, swimming speeds. The whole recirculating pathway can be sealed, and oxygen uptake measured with an oxygen electrode (placed at F), from the decline in oxygen levels in the sealed chamber. The recirculating pathway is immersed in an outer chamber (G) and, at intervals, the system can be flushed, by a pump, with new aerated water from this outer reservoir, with water exiting through a chimney, to replace the oxygen consumed by the fish. A measurement of oxygen uptake can then be repeated. Photograph courtesy of Loligo Systems.

where $\dot{M}o_2$ is the rate of oxygen uptake, *a* and *b* are constants, and *U* is the swimming speed. The exponent *b* is always >1.

The capacity to swim aerobically depends on the ability of the fish to provide oxygen and substrates to the contracting muscle over and above their basal metabolic needs. Gill ventilation increases markedly with exercise, such that water flow over the gills is increased by up to tenfold. In some species, active ventilation of the gills ceases and they simply open the mouth and use their forward motion to create a current across the gills, (i.e., ram ventilation). The heart increases pumping activity, and cardiac output can go up by fivefold. There is also redistribution of blood, away from organs such as the liver and intestine, to preferentially perfuse the red muscle, brain, and heart. It has been estimated that blood flow to the red muscle can increase by up to 6 times when fish are at their maximum aerobic activity level (**see also Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming).

When fish swim aerobically, they can increase their $\dot{M}o_2$ by up to 10 times above their standard metabolic rate (SMR). This capacity to increase $\dot{M}o_2$ is known as aerobic metabolic scope, and the largest scopes are seen in larvae of coral reef species, which, for their size, are the champion swimmers of the fish world. The 10-fold increase in $\dot{M}o_2$ is, however, still less than some birds and athletic mammals, which can increase it by over 30 times when running or flying.

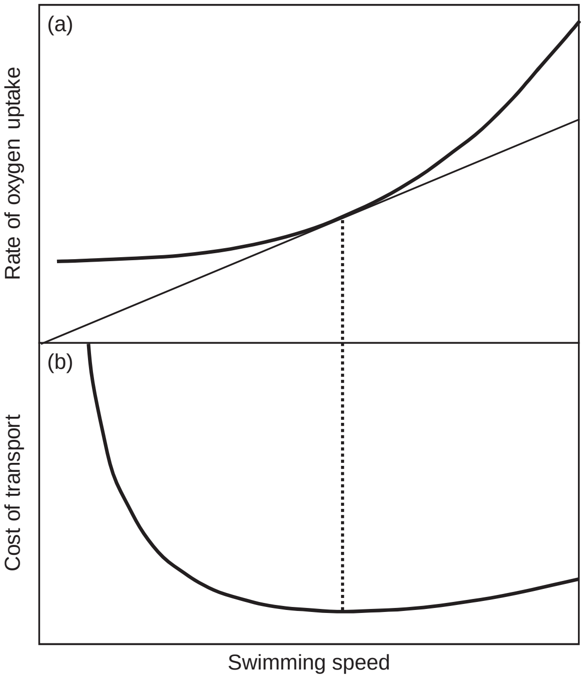

Figure 3 (a) The relationship between rate of oxygen uptake and swimming speed, where the tangent line intersects with this relationship, is the optimum swimming speed, at which the fish swims with the greatest energetic efficiency. (b) The cost of transport, as derived by dividing the rate of oxygen uptake by swimming speed. At the optimum swimming speed, the cost of transport (b) is minimal, as indicated by the vertical dotted line.

Most of the information about aerobic swimming energetics in fishes comes from studies on salmonids, especially of the genus *Oncorhynchus*, in particular the rainbow trout, *O. mykiss*. It is believed that salmonids reach their maximum possible rates of $\dot{M}o_2$ and, therefore, their maximum aerobic energetic flux, when they are exercising at their maximum sustainable aerobic swimming speed (as measured in a swim-tunnel respirometer), with their heart pumping at its maximum capacity. In other species, such as the European sea bass *Dicentrarchus labrax*, the maximum sustainable aerobic exercise does not evoke their entire aerobic metabolic scope, because they achieve higher maximum rates of $\dot{M}o_2$ if they are exercised when they are also digesting a meal (**see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation).

In **Figure 3(a)**, the point where the curve of $\dot{M}o_2$ versus *U* intersects with a tangent drawn from the origin indicates the speed at which there is the minimum cost of transport (COT). The COT is the energy required to transport a unit mass over a unit distance. If the COT is plotted against swimming speed, a U-shaped curve is created, with a distinct minimum (**Figure 3(b)**). The U-shape results from the high costs of SMR (relative to the net costs of swimming) at low speeds and the high costs due to the exponential rise in P_D at high speeds (eqn (1)). (Note that if the fish is not at its basal metabolism when inactive, switching off nonessential costs could contribute to this decrease at low-swimming speeds.) The minimum COT corresponds to the swimming speed at which the fish can travel the maximum distance for a given quantity of energy. It has been proposed that fish should, therefore, spontaneously swim at this speed in the wild, at least when performing long-term sustained aerobic swimming, such as during reproductive migrations (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance and **Fish Migrations**: Pacific Salmon Migration: Completing the Cycle). This idea is, however, still debated.

Relatively little is known about the energetic costs of labriform or balistiform locomotion, but these costs may be less than for BCF swimming, possibly because the body is held rigid while the fins beat, resulting in less average drag. These species will, however, transition to more expensive BCF locomotion to achieve very high swimming speeds.

In all studies using swim flumes, fish eventually reach a speed where they can swim no faster with aerobic red muscle alone. A gait transition occurs, and the fish supplement red muscle function with contraction of the powerful white muscles. This produces a burst of forward movement, a gait that is often called 'burst and glide' locomotion. The available evidence indicates a number of possibilities for the transition between gaits and each one acknowledges that it does not occur because the red muscle is exhausted or depleted of oxygen. One possibility is that the red muscle cannot contract at a faster rate to power faster tail beats (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops). Another is that oxidative phoshorylation cannot generate ATP fast enough for the highest tail beat frequencies (**see also Hypoxia**: Anaerobic Metabolism In Fish). Another possibility is that the skeletal muscles strip the blood of oxygen, leaving the heart starved of oxygen (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping). Fish have a single circulation; all blood leaves the heart and returns after it circulates through the gills and the body's systemic circulation. In many fishes, the heart gets most of its oxygen from this venous return. When fish exercise aerobically, their working red muscle extracts a great deal of oxygen from the blood so, as they swim faster and faster, there is less and less available for the heart. The fish may switch to white muscle with the red muscle extracting less oxygen from the blood, leaving just enough venous oxygen for the heart. This latter explanation appears to be particularly acute when fish swim at elevated temperatures (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature and **Temperature**: Effects of Climate Change).

The fact that red muscle is not fatigued when fish perform a gait transition in a swim-tunnel respirometer allows them to repeat maximum aerobic exercise many times, with virtually no recovery period between the tests.

Anaerobic White Muscle and High-Intensity Bursts of Activity

White muscle is composed primarily of 'fast glycolytic' (FG; type II) fibers, which produce the most power at high contraction frequencies and which rely almost exclusively upon endogenous intramuscular fuel stores to generate ATP anaerobically. This process is known as substrate-level phosphorylation, with the most dominant reaction being glycolysis, where glucose (stored as glycogen) is converted into pyruvate, and then lactate, to release only two ATP per glucosyl equivalent (**see also Hypoxia**: Anaerobic Metabolism In Fish). The fibers have little aerobic capacity and are much less-well vascularized than red muscle fibers with little to no myoglobin.

White muscle typically comprises most of the myotomal muscle mass (up to 90%; **Figure 1**) and is used for short bursts of high-speed swimming, such as predator–prey chases or to surmount velocity barriers during upriver migrations. The duration of burst swimming with white muscle is presumably limited by the availability of endogenous stores of high-energy phosphagens and glycogen. It may also be limited by accumulation of nonvolatile products of anaerobic metabolism (e.g., lactate or H^+). Anaerobic metabolism can reduce the pH of the muscle and the blood, raise the lactate and produce dramatic changes to cell organic phosphate pools and ion distributions. This may impair further muscle and, perhaps, nerve function.

When anaerobic exercise ceases, energetic costs must be repaid and metabolic equilibrium reestablished in the muscle and the whole animal. This is visible metabolically as excess post-exercise oxygen consumption, or EPOC. This used to be called the 'oxygen debt', a term that is still used today. The EPOC comprises the energetic costs of replenishing endogenous fuel stores, but also of reestablishing endocrine and other balances (e.g., the catecholamines, epinephrine, and norepinephrine, released during intense exercise), and of repairing any cell damage. Thus, attempts to directly relate the size of EPOC to the actual amount of ATP that was used to fuel anaerobic exercise may be futile. The energetic costs of EPOC have been measured most extensively using a protocol, whereby a fish is chased by the experimenter, who continually touches its tail until it can no longer make a rapid escape response. This might be equivalent to when a prey species is chased to exhaustion, for example, by a cormorant or a seal. At such exhaustion, white muscle stores of glycogen are profoundly depleted, and there is a severe drop in muscle and blood pH, associated with the production of lactate. The EPOC is then typically equivalent in magnitude to the maximum rate of $\dot{M}O_2$ observed during aerobic swimming, and persists for a number of hours. It can take up to 24 h to recover fully from such exhaustive exercise, depending on the water temperature. Thus, a major difference between maximal aerobic and anaerobic exercise is that fish can repeat maximal aerobic exercise immediately, whereas they cannot repeat maximal anaerobic exercise until they have replenished endogenous fuels and dealt with the end products.

Spontaneous Swimming Activity: What do Fish Actually do?

Laboratory studies of aerobic and anaerobic exercise have revealed much about the mechanisms that sustain swimming, and what sets the energetic limits for each type of activity. In the wild, it is unknown, however, to what extent fish might exploit their maximum aerobic or anaerobic performance. Recent research has allowed fish (smallmouth bass, *Micropterus dolomieu*) to swim spontaneously up a long channel in which they encountered different current speeds, and their swimming patterns were filmed to identify steady aerobic swimming versus bursts of anaerobic swimming. This revealed that the bass transitioned between muscle types, depending on the current speed, and often used bursts of anaerobic swimming to traverse areas of rapid flow even if, based on their swimming performance measured in a swim flume, they in fact could have negotiated that same current speed with aerobic swimming. Thus, they chose to cross the velocity barrier very quickly, rather than steadily, and they transitioned to anaerobic swimming before reaching their maximum capacity for aerobic exercise, even without knowledge of how long the section of rapid flow was. Furthermore, even when they used many bursts of anaerobic swimming in the channel, they showed virtually no EPOC or evidence of the white muscle metabolic imbalances that have been demonstrated in fish chased to exhaustion. Thus, fish transition dynamically between aerobic and anaerobic swimming. Also, they quite easily reestablish equilibrium in white muscle if it is not used too intensively and for a short duration, with little EPOC. Indeed, it has also been shown that steady aerobic exercise actually improves recovery from intense anaerobic exercise in some fishes. Thus, fish may use their maximum aerobic swimming performance only rarely (instead using bursts of anaerobic swimming interspersed with aerobic swimming), and they may never experience the large EPOC and extreme metabolic imbalances observed after prolonged chasing. This, of course, means that it may be very difficult to estimate actual energetic costs of swimming in wild fish at this level! In addition, the relative use of anaerobic versus aerobic swimming is an individual characteristic that varies substantially within a species. Costs of swimming have been estimated from energy store depletion in fish that are no longer eating, primarily migratory adult salmon and eels (**see also Fish Migrations**: Eel Migrations and Pacific Salmon Migration: Completing the Cycle).

Environmental Influences and the Fry Paradigm

Another reason why it is difficult to estimate energetic costs of swimming in wild fish is because their physiology is so profoundly influenced by physico-chemical (abiotic) conditions in their environment (**see also Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism). The first person to model how environmental conditions might influence aerobic swimming energetics was a Canadian scientist named F.E.J. Fry, in the 1940s. Fry reasoned that, if environmental factors influence either the magnitude of SMR or the maximum capacity for oxygen uptake in fish, they would then influence aerobic metabolic scope. Environmental parameters will, therefore, set the boundaries within which all energetic demands and activities are constrained. Fry modeled how major factors would influence metabolism and physiology to define aerobic metabolic scope, as shown in **Figure 4(a)**.

Temperature: A Controlling Factor

Fish body temperature is generally near that of the surrounding water (except for some scombrids and lamnid sharks (**see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks). Fry termed temperature a controlling factor, because it sets rates for all metabolic processes, and so controls physiology and energetics (**see also Temperature**: Membranes and Temperature: Homeoviscous Adaptation). The effects on aerobic metabolic scope are shown in **Figure 4(a)**. At low temperatures, all processes are depressed by the cold, so SMR is low but so is the capacity of the red muscles and heart to perform work. Thus, aerobic scope is small. As temperature increases, SMR rises but the warmth allows for greater red and cardiac muscle performance, so aerobic scope increases. As temperatures continue to rise, there is an inexorable rise in SMR, which eventually is so high that it is equivalent to the maximum capacity for $\dot{M}O_2$. Once again, therefore, aerobic scope is very small, and there is no oxygen available to allocate to swimming. The magnitude of aerobic metabolic scope therefore follows a bell-shaped curve with temperature (**Figure 4B**), with a clear optimum, and lower and upper limits (which may be lethal). Fish also show a bell-shaped curve for their aerobic swimming performance. Thus, overall energetics and

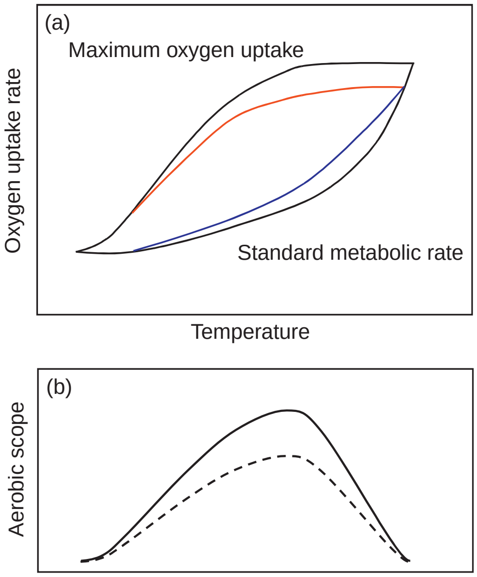

Figure 4 (a) The Fry paradigm, which models the effects of environmental factors on aerobic metabolic scope. Temperature is considered to be a controlling factor, which controls all metabolic processes. The solid black lines show how standard metabolic rate (SMR) and maximum oxygen uptake rate vary as a function of water temperature. The difference between these two rates is the aerobic metabolic scope, the capacity to provide oxygen for energetic fluxes such as swimming exercise. Note how the SMR shows an exponential increase with temperature. At low temperatures, maximum oxygen uptake is also low, because the cold inhibits all metabolic processes (including muscle performance). Therefore, scope is small. As temperatures rise, aerobic scope increases because the warming accelerates metabolic processes. Eventually, however, the effects of temperature on SMR make it rise to the point where it coincides with the fish's maximum oxygen uptake rate, so aerobic scope is again very small. The resultant aerobic metabolic scope is shown in (b), with a clear bell-shaped relationship and an optimum temperature range. In (a), the red line shows the effects of a limiting factor, such as oxygen, on maximum oxygen uptake rate. The blue line shows the effects of a loading factor, such as stress. These factors constrain aerobic scope, as shown by the dotted line in (b).

the capacity to allocate energy for swimming will depend on temperature, and it might be expected that fish will try to choose temperatures, if they can, which maximize their scope for aerobic activity.

Limiting Factors, in Particular, Availability of Dissolved Oxygen

Fry considered the availability of dissolved oxygen to be a limiting factor. Water has a low concentration of oxygen per unit volume and hypoxia, a decline in oxygen levels, can be a frequent occurrence in aquatic habitats (**see also Hypoxia**: The Expanding Hypoxic Environment). Of course, if there is less oxygen in the water, then, this will limit the maximum capacity for oxygen uptake, and therefore aerobic metabolic scope (**Figure 4(a)**). Other limiting factors may be pollutants or extreme turbidity, which may cause gill damage and therefore also limit $\dot{M}\mathrm{o}_2$ and aerobic scope.

Loading Factors

These are factors which cause a rise in SMR. Fry actually termed them 'masking factors', but loading factors is more explicit, because it makes clear that the effect is to place a load on the system by raising SMR and thereby constraining scope available for other activities such as swimming (**Figure 4(a)**). One major loading factor is an endocrine stress response, which can be biotic in nature (e.g., intraspecific aggression) or abiotic (e.g., exposure to salinity change or to pollutants). SDA is potentially another (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion and **Food Acquisition and Digestion**: Cost of Digestion and Assimilation)

Estimating the Costs of Swimming in Wild Fish

The energetic costs of swimming will, of course, depend on a species' lifestyle, but it has been estimated that swimming is a major component of energy expenditure for many fishes. Monitoring energetics of fish in their natural environment is a great technological challenge, because their physiology is so influenced by multiple environmental factors and they are so difficult to study and follow underwater. This challenge is now being addressed, with recent advances in techniques of biologging (measuring and storing biological information) and biotelemetry (measuring and transmitting information) that can provide relatively accurate information about swimming activity, and therefore energy expenditure, of fishes in the wild (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance). Biotelemetry is particularly useful because animals do not have to be recaptured to recover logged information, but the transmitter battery makes the sensors larger and heavier, therefore more likely to influence activity. In freshwater habitats, radio-telemetry is used whereas the high conductivity makes this impossible in seawater, where ultrasonic telemetry must be employed (**see also Fish Migrations**: Tracking Oceanic Fish).

Early radio-telemetry involved simply picking up signals about fish position in a water body, providing general information about distances swum in a given time interval, but no information about true activity levels or swimming speeds. Some studies have used externally attached speed-sensing devices, such as small paddle wheels, which trail behind the fish. These, however, can only be used on large animals, such as sharks, and tend to be relatively insensitive at low speeds and prone to damage or malfunction. More sophisticated techniques provide more precise data on metabolic costs of swimming by measuring and transmitting detailed information about biochemical or physiological correlates of oxygen uptake. These techniques all require that wild fish be captured, fitted with the transmitter, and then submitted to forced exercise in a respirometer, so that the relationships among the chosen physiological variable, swimming speed, and $\dot{M}O_2$ can be described. The animal is then released back into the wild.

It is possible, for example, to monitor heart rate as the electrocardiogram (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping and Action Potential of the Fish Heart), the electrical activity that accompanies cardiac contraction, using electrodes and a transmitter placed inside the peritoneal cavity. Using heart rate to predict metabolic rate is, however, subject to error because this requires that other physiological traits, such as cardiac stroke volume (the amount of blood pumped per beat), oxygen extraction at the gills, and oxygen-carrying capacity of the blood, are either constant or vary in direct proportion with heart rate. Some transmitters use a cuff around the ventral aorta to monitor cardiac output and total blood flow, using a Doppler technique. This is more useful information than just heart rate, but the relationship with metabolic rate will still be confounded by any variations in tissue oxygen extraction, arterial oxygen saturation, and blood-oxygen-carrying capacity. Furthermore, cardiac activity can, of course, be affected by activities other than swimming in fish, such as digestion of food, and by external conditions such as hypoxia. Thus, telemetry of cardiac performance may be most useful for estimating the total energy expenditure in wild fish. This is, in itself, an important goal in fish ecophysiology.

There are techniques that can, however, measure swimming muscle activity directly. One method is the measurement and transmission of information about electromyograms (EMGs), the electrical activity that accompanies contraction of swimming muscles. Each axial myotome contracts once per tail beat, so an EMG can be used to derive tail beat frequency. If the relationships among tail beat frequency, swimming speed, and M_{O2} are measured on the captive fish, then, energetic expenditure for swimming can be estimated for the individuals after they have been returned to the wild. The sensors and transmitters can be placed inside the body cavity, so they do not contribute to drag and raise costs of swimming in themselves. This technique has permitted some quite detailed activity budgets to be constructed for free-swimming fish. For example, the cost of swimming activity for rainbow trout in a small lake was less than half their costs for SMR over a period of a year, and activity showed a daily pattern being lowest just before dawn. The rainbow trout also used less than 20% of their available aerobic metabolic scope.

The differential pressure tag (DPT) measures pressure changes at the tail as it beats during swimming. The DPT, therefore, measures changes in tail beat amplitude and force, and provides information about swimming effort. They are applied externally and require surgery to place the sensor through the caudal peduncle (the portion of the body just anterior to the caudal fin). Thus, they may influence natural behaviors in wild fish, and may be most useful for aquaculture applications.

The EMG or DPT transmitters can only, however, provide estimates of energy expenditure associated with red muscle activity, as the costs of white muscle activity are only visible as EPOC. The EPOC should, however, be visible as changes in cardiac activity (cardiac output). Furthermore, changes in water temperature will have a profound effect on the actual energetic costs of swimming. The best sensors, therefore, are those that can simultaneously measure a number of variables, such as body temperature, ECG, and EMG.

Conclusions

Laboratory studies have provided a significant amount of information about the function of fish swimming muscles, the mechanistic bases of swimming energetics, and the physiological factors which limit maximum aerobic and anaerobic performance, and which elicit a transition from aerobic to anaerobic swimming. Studies on fish swimming spontaneously indicate that they alternate dynamically between aerobic and anaerobic swimming, and may rarely exploit their maximum aerobic performance. The Fry paradigm provides a framework within which to explain how environmental factors will influence aerobic swimming energetics. It is to be expected that we will learn a great deal more about swimming energetics of fish in the wild, with the development of biologging or biotelemetry sensors that measure multiple factors simultaneously.

Glossary

Adenosine triphosphate (ATP) An almost universal carrier of chemical bond potential energy; fish use ATP made from catabolism of foodstuff or body reserve molecules to fuel energy-dependent processes.

Creatine phosphate An energy store alternative to ATP. Also known as phosphocreatine.

Critical swimming speed (U_{crit}) The U_{crit} is determined in a swim tunnel where the fish are forced to swim against a current. The current velocity is increased in steps and each step is maintained for a specified time (usually 10 min to 1 h) or until the fish fatigues.

Fatigue Inability of the exercising fish to sustain a set swimming speed. Cellular mechanisms eliciting fatigue are under debate.

Gibb's free-energy change Equals the energy available from ATP under cellular conditions, depends on concentration ratios of ATP over those of ADP and Pi as well as cellular pH and Mg^{2+} levels.

Standard metabolic rate (SMR) The minimum metabolic rate of survival. Typically, SMR is measured on resting, unstressed adult animals in the post-absorptive state under normothermic conditions. For fish, normothermic is defined as a temperature well within the species tolerance limits for which the animals have had ample time to acclimate.

Introduction

Metabolic specialization and the level of energy turnover in teleost fish depend on the levels and variability of activity and on environmental factors. In the first place, fish are constrained to the vertebrate mode of metabolism, which, when compared to aquatic marine invertebrates, appears less flexible in terms of the pathways used, less reliant on the use of amino acids in metabolic pathways and osmoregulation and, possibly, less able to support survival under the most extreme environmental conditions. Nonetheless, teleost fish have conquered a wide range of freshwater and marine habitats, from streams to burrows in sediments to virtually all of the pelagic, deep, and shallow-water habitats. Examples of extreme adaptation do exist, exemplified by the extreme tolerance of crucian carp (*Carassius carassius*) to anoxia as well as by the specialization of Lake Magadi tilapia (*Alcolapia grahami*) to life in alkaline lakes, among others. These adaptive features not only require the expression of specialized processes providing tolerance (e.g., specialized mechanisms of energy production, of acid–base and ion regulation, or of antioxidant protection) but also require the expression of metabolic and regulatory features fueling those efforts and adjusting energy demand to the constraints frequently imposed by ambient extremes. For example, many previous efforts have investigated the capacities and regulation of metabolic pathways used in response to the environmental challenges of hypoxia and/or changing temperatures.

Global environmental change and its impacts on ecosystems have emphasized the need to interpret molecular, biochemical, and physiological findings in fish in an ecological context. Well-known metabolic features established earlier thus also need to be integrated into larger ecological frameworks. This re-interpretation with respect to ecological relevance should include an analysis of how metabolic features support or limit whole-organism functioning and survival at the ecosystem level, for example, under the influence of limited food availability or interactions with other species. Furthermore, integrative analyses of the interacting influences of abiotic and biotic stressors are required for a comprehensive understanding of species' response to environmental change. Individual metabolic pathways contribute to set the functional capacities of cells, organs, and whole organisms. Conversely, they also operate under constraints set by the capacity to supply the tissue with oxygen, which is challenged by environmental factors such as variable oxygen content, especially hypoxia, elevated CO_2 levels, fluctuating temperatures, or toxicants (e.g., hydrogen sulfide). These constraints thus are understood best from a whole-organism point of view.

The key role of all energy metabolism is to fuel energy-demanding processes in maintenance (e.g., protein turnover, anabolism, ion exchange and acid–base regulation, and cardiocirculatory activity) as well as whole-organism performances such as growth, reproduction, motor activity in foraging, migration, and escape (**see also Energetics**: General Energy Metabolism). Energy is gained from the hydrolysis of adenosine triphosphate (ATP), which is continuously re-phosphorylated from adenosine diphosphate (ADP) in oxidative or substrate-level phosphorylation in mitochondria, or anaerobic glycolysis. In a simplified view, the energy content of the adenylate system is adjusted high by maintaining free concentrations of ATP high over low ones of ADP and inorganic phosphate, that is, a high phosphorylation potential (wherein $[ATP]/[ADP]\ ^*\ [Pi]$ is generally on the order of 500). The energy content is quantified through evaluation of the Gibb's free-energy change of ATP hydrolysis ($\mathrm{d}G/\mathrm{d}\xi$, kJ mol^{-1}), a term influenced by intracellular pH, cellular magnesium levels, and the dissociation equilibria of inorganic phosphate as well as the kinetic constants of the enzymatic reactions involved (e.g., the creatine–kinase reaction):

$$\begin{aligned}\mathrm{d}G/\mathrm{d}\xi = {} & \Delta G'^{\circ} \\ & + RT\cdot\ln([\mathrm{Cr}]_{\mathrm{free,tot}}\cdot[P_{\mathrm{i}}]_{\mathrm{free/tot}}/[\mathrm{PCr}]_{\mathrm{free,tot}}\cdot[\mathrm{H}^{+}]\cdot K_{\mathrm{appCK}})\end{aligned}$$

where

$$\begin{aligned}K_{\mathrm{appCK}} &= [\mathrm{ATP}]_{\mathrm{tot}}\cdot[\mathrm{Cr}]_{\mathrm{tot}}/[\mathrm{ADP}]_{\mathrm{tot}}\cdot[\mathrm{PCr}]_{\mathrm{tot}}\cdot[\mathrm{H}^{+}] \\ &= K_{1,\mathrm{CK}}\cdot f_{\mathrm{ADP}}3\text{-}\ \cdot f_{\mathrm{PCr}}\text{-}/f_{\mathrm{ATP}}4\text{-}\end{aligned}$$

where the fractions *f* of ionized specimens of ADP, PCr, and ATP vary with pH and Mg^{2+} levels.

Aerobic Metabolic Pathways: Sustaining Functional Scope

Mitochondrial Functioning

The capacity and scope of aerobic energy metabolism has been identified as crucial in meeting long-term functional demands and in setting long-term tolerance to environmental parameters. It supports not only maintenance, but also crucial performances such as foraging, growth, and reproduction (**see also Energetics**: General Energy Metabolism). The capacity of aerobic metabolism supports the lifestyle of a species including its level of spontaneous or long-term activity. Such capacity is not only set by the capacity of the enzymes involved but is co-defined by the constraints imposed by the environmental abiotic regime. Constraints may be imposed, for example, by motor activity or by large temperature oscillations, when cool or warm temperature extremes cause the organism to exceed the limits of metabolic capacity. Constraints may also be imposed by ambient hypoxia, which reduces aerobic scope, or by elevated CO_2 levels, which may cause metabolic depression through disturbances in acid–base status. Shifted ion concentrations in ambient water (e.g., brackish vs. full-strength seawater) might enhance or reduce the costs for ion and acid–base regulation, thereby demanding a variable fraction of an organism's energy budget. Furthermore, acclimatization may occur and shift tolerance limits or windows, for example, when salmon or trout migrate between seawater and freshwater habitats or when temperate-zone fishes acclimatize, within limits, to a modified regime of ambient temperatures. The process of acclimatization may involve adjustments of metabolic capacities or shifts between metabolic pathways. For example, evolutionary adaptation to hypoxia involves improved mechanisms of oxygen uptake and a reduction in energy demand. In the cold, lipid metabolism tends to be emphasized more. In relation to climate zone and climate variability, temperature adaptation largely occurs by modulating metabolic capacities and thereby the level of standard metabolic rate and performance capacity.

Some generalizations are possible concerning how environmental and lifestyle constraints shape the level of aerobic scope available to an aquatic species. Oxygen limitations in hypoxic areas minimize aerobic scope for exercise. This reduction enables the organism to conserve available oxygen. As a trade-off, this reduction may still support successful competition by making room for the evolution of large-enough body sizes. Such trends may force all species of the hypoxic ecosystem into the slow lane. Such a phenomenon is also observed in polar oceans. Here it is hypothesized to be enforced by the obligatory exploitation of energy savings and stenothermy in the permanent cold. Conversely, aerobic scope might be maximized due to competition with other species at similar performance levels, up to the limits set to all competing species by environmental constraints, for example, hypoxia or permanently low temperature in cold oceans. As a trade-off between aerobic scope and body size, this may either limit aerobic scope or body size or both depending on environmental characteristics. Among a variety of possible patterns, body size is likely set to a maximum level in some species, associated with a reduction in aerobic scope (**see also Swimming and Other Activities**: Energetics of Fish Swimming).

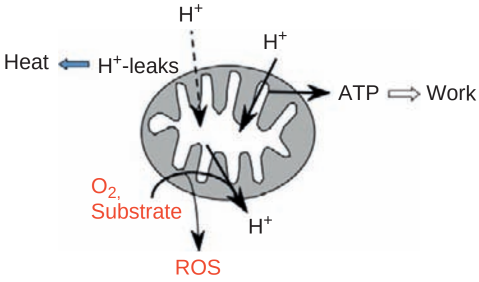

Figure 1 Scheme of main mitochondrial processes, which are associated with the capacities of ATP generation, including the oxidation of substrate through oxygen consumption, the buildup of mitochondrial membrane potential (proton motive force, $\Delta\psi$), and the rate of dissipative proton leakage as well as formation of oxygen radicals (ROS). All of these processes are subject to adaptive modification under the influence of environmental, functional, and lifestyle constraints.

Temperature adaptation involves the adjustment of aerobic scope of the whole organism (**see also Temperature**: Effects of Climate Change) and, as a precondition, of the scope of overall (per g tissue) mitochondrial capacities for substrate oxidation and ADP re-phosphorylation (**Figure 1**). First, mitochondrial capacities (per mg mitochondrial protein) fall upon cooling, following a simple Q_{10} relationship (the factorial drop in enzyme capacities with a 10° C drop in temperature) (**see also Temperature**: Effects of Temperature: An Introduction). Cold acclimatization or adaptation might involve an upregulation of mitochondrial capacity and/or of mitochondrial density to compensate for this Q_{10} effect. In liver, cold compensation is mainly accomplished by a rise in tissue mass, leaving mitochondrial protein per gram liver largely unchanged. Extremely high mitochondrial densities are found at low uncompensated functional capacities in red and cardiac muscle of Antarctic notothenioid fishes. Upregulation of enzyme capacities and mitochondrial respiratory capacity seems to be restricted to cold-exposed eurythermal fishes, for example, Northeast Arctic Atlantic cod (*Gadus morhua*). Some changes in the activities of membrane-bound enzymes are enabled by changes of membrane structure and enhanced membrane fluidity in cold-acclimatized fishes.

Conversely, warm acclimation should go hand in hand with reduced mitochondrial capacities as seen in temperate fish during summer, when citric synthase was reduced and cytochrome oxidase activities remained unchanged in white muscle of North Sea Atlantic cod. This response is not uniform, however, as seen in the Antarctic zoarcid (*Pachycara brachycephalum*) and the Antarctic notothenioid (*Pagothenia borchgrevinki*). Both species were shown to display some residual capacity to warm-acclimate, but their compensatory response differs from that in temperate fishes. In the polar species warm acclimation may reverse the strategy of energy savings in the cold resulting in elevated metabolic rates upon warm acclimation.

Cold-Induced Shifts to Lipid Metabolism

Development of enhanced mitochondrial density in the cold goes hand in hand with enhanced whole-body and intracellular storage of lipids and with the preferred use of lipids by mitochondria. Both trends are seen during cold acclimation in temperate fish (as in striped bass *Morone saxatilis* or rainbow trout *Oncorhynchus mykiss*) and, even more so, in cold-adapted polar fishes. It has been hypothesized that elevated mitochondrial contents provide tissues with a high capacity to maintain a high phosphorylation potential (see above). The low-energy turnover lifestyles in polar fishes would support a constantly high energy-status even further. Under these conditions, the glycolytic pathway is not cold-compensated, thereby favoring the use of noncarbohydrate substrates such as lipids. Interestingly, studies in plankton as well as in pelagic fishes show that elevated lipid levels are more typical of pelagic than benthic life forms. Their somewhat higher levels of motor activity would most likely be paralleled by somewhat higher rates of standard metabolism (SMR), as well as most likely higher mitochondrial densities and capacities. These trends would be stronger than in warm-water species as a consequence of mitochondrial proliferation at relatively low metabolic rates elicited by cold adaptation. High mitochondrial densities would lead to excess availability of mitochondrial intermediates such as citrate. Especially when costs are kept low during long periods of low to moderate activity levels in the cold and when phosphorylation potential is high, excess citrate is exported from the mitochondria into the cytosol where it fuels net fatty-acid synthesis. Energy savings are further supported by the gain of neutral buoyancy with elevated lipid levels.

Furthermore, elevated mitochondrial densities as seen in Antarctic fishes are paralleled by decreased myofibrillar volume fractions in the cell. The β-oxidation pathway located in the mitochondrial matrix is structurally favored in the cold over the glycogenolytic pathway, which is structurally associated with muscular fibrils. While both lipid synthesis and catabolism are favored in the cold in organisms at all levels of the food chain, the formation of high lipid stores will be supported even further at the upper end of the food chain, through the uptake of lipid-rich prey.

In summary, enhanced lipid accumulation and metabolism in the cold appear as by-products of increased mitochondrial densities and the associated shift to lipid metabolism. The enhanced cellular network of membranes associated with elevated mitochondrial densities has beneficial side effects by improving oxygen diffusion into the cell and to mitochondria. This helps in reducing the need for convective oxygen supply and thereby supports energy savings even further in the cold. Cost reductions are also involved, when muscle fibers are both fewer and larger, and capillary density is reduced as seen most clearly in Antarctic fish. This likely involves further energy savings due to reduced total surface area and ion-exchange activities of cellular membranes. These patterns of energy savings and reduced convective oxygen supply will, however, cause a narrowing of thermal windows in the cold, as a trade-off (**see also Temperature**: Effects of Climate Change).

Anaerobic Metabolic Pathways: Extending Limits to Function and Time

When ambient temperature approaches the upper or lower borders of the thermal window, oxygen deficiency generally may develop as a consequence of insufficient functional capacity. This deficit in functional capacity elicits transition to passive tolerance and associated systemic and cellular stress signals such as hormonal responses and oxidative stress. Importantly, passive tolerance also involves the use of anaerobic metabolic pathways and relies on sufficient anaerobic capacity. In fact, anaerobic metabolism may play an important role in setting the capacity of passive tolerance and accordingly, the length of this period. Here, the level of tolerance to temperature-induced hypoxemia benefits tolerance to ambient hypoxia and vice versa. Overall, mechanisms sustaining passive tolerance extend the capacity to survive under extreme conditions of temperature or hypoxia, but passive survival remains time-limited (**see also Temperature**: Effects of Climate Change).

While oxygen deficiency is reflected best by succinate accumulation in mitochondria, cytosolic anaerobic metabolism in fish muscle also responds to hypoxia. This anaerobic metabolism is always used when energy demand and metabolic rate exceed aerobic capacity, for example, during burst muscular activity for prey capture and predator avoidance (**see also Swimming and Other Activities**: Energetics of Fish Swimming). Reaching swimming velocities beyond a critical limit during short-term bursts depends on a large pool of high-energy phosphates, especially phosphocreatine, followed by the activation of anaerobic glycolysis and lactate formation, and finally adenylate degradation. Fully exploiting anaerobic capacity also depends on the capacity to first accumulate and then remove end products such as lactate and protons, including the ability to minimize and reverse associated pH disturbances. The increase in aerobic muscle design in the cold would explain why, as a trade-off, anaerobic capacity is reduced, especially in polar fish with their low-activity lifestyles. Accordingly, the contribution of anaerobic glycolysis during exercise is smaller in Antarctic notothenioids than in cold-acclimated temperate species. The contributions of the various pathways to supporting energy status (Gibb's free-energy change of ATP hydrolysis) during muscular exercise at various temperatures await further study. Recent comparative work in squid (*Lolliguncula brevis*) has shown that the various components of anaerobic metabolism are suitable to elevate the velocity reached during swimming, by buffering ATP levels and the Gibb's free energy of ATP hydrolysis and extending them above the limits required for ATPases to function. Such buffering occurs by the accumulation of free ADP and by glycolytic acidification. These principles would also apply to the time extension of passive tolerance during environmental extremes such as temperature or hypoxia, but on much longer timescales than during exercise (see below).

During cold acclimation, glycolytic enzyme activities increase in those temperate species that do not show large adjustments in aerobic metabolism (as in some salmonids). High mitochondrial densities constrain the space available for contractile proteins, glycogen stores, and glycolytic complexes. However, glycolytic capacity would decrease in species with a compensatory increase in oxidative capacity. Then, oxidative enzymes, creatine kinase, adenylate kinase, and AMP deaminase activities show cold compensation in Antarctic notothenioids, whereas glycolytic enzymes do not, at least in muscle. High mitochondrial densities constrain the space available for contractile proteins, glycogen stores, and glycolytic complexes.

Zoarcids are benthic sluggish fish with a low degree of spontaneous activity, such that the need for cold compensation in aerobic metabolism may be less than in more active species. This leaves some space for the compensation of anaerobic capacity. When cold-exposed (0° C), both cold-acclimated temperate (North Sea) and Antarctic zoarcids (*Zoarces viviparus* vs. *P. brachycephalum*) formed lactate in similar amounts during exercise, as seen in flounder (*Platichthys stellatus*), acclimated to 11° C. Accordingly, a similar degree of cold compensation of anaerobic pathways was possible in the temperate species as a result of cold acclimation and in the polar species, as a result of cold adaptation.

As a corollary, maximized aerobic cellular design in muscle of cold-acclimated or cold-adapted, slow-cruising pelagic fish is associated with minimized glycolytic capacity. By contrast, high-performance fish in tropical and temperate waters operate at lower mitochondrial densities but higher capacities than do polar fish. This allows them to maximize the use of both aerobic and anaerobic pathways and thereby swimming velocity. The pressure to enhance glycolytic capacity is likely alleviated in the

Antarctic and the deep sea where all ectothermic organisms, including both predators and prey, are tied to low-velocity largely aerobic lifestyles. Cellular space constraints and energy savings at cold temperatures are reflected in high mitochondrial densities, at the expense of myofibrillar density and, thus, contractile-force development.

These basic relationships are influenced by the change in body size during ontogeny of individual fishes. Baseline energy demand and, thus, SMR per unit fish and the need to maximize the aerobic machinery are reduced with increasing body size, thereby freeing cellular space for enhanced myofibril densities and, thus, force generation (**see also Energetics**: General Energy Metabolism). The reduction in mitochondrial density in larger fish opens cellular space for glycolytic components (glycogen granules, enzyme complexes, and buffer components), such that enhanced power generation during burst activity becomes possible.

In this context, an interesting observation is that maximum speed in Antarctic notothenioid fish seems more constrained by cold temperatures in larvae than in adults. Larval swimming velocity was 2–3 times below that of temperate and tropical larvae at their respective habitat temperatures. At first sight, this finding might either relate to the benthic origin of notothenioids or simply be due to the fact that high-performance predators do not exist for larval stages. However, both small body size and cold adaptation elicit similar adaptational traits in that mitochondrial densities are maximized. In adult (large) notothenioid fish, cold compensation led to mitochondrial densities close to cellular space limitations. The maximizing of aerobic capacity in small, including larval, fish therefore will likely reach an early limit in the cold. This may contribute to limited maximum swimming performance in larval notothenioid fish at cold temperatures (**Figure 2**). Energetic constraints on larval life are thus maximized in the cold, with the consequence that energy-saving strategies are maximized in larval, compared to adult, fish.

Extending Energetic Limits

There is a clear relationship between the use of carbohydrates and anaerobic pathways and the extension of exercise performance beyond aerobic limits. Similarly, this is true, also, for the capacity of passive perseverance under anoxia and thermal extremes. The onset of anaerobiosis beyond the critical swimming speed contributes to fatigue in muscle. A fall in pH affects the energy status of the muscle cells, quantified as the Gibb's free-energy change of ATP hydrolysis ($dG/d\xi$) and thereby the function of cellular ATPases (see above). At constant levels of the phosphates, a fall in pH initially causes a small

Figure 2 Schematic depiction of whole-organism aerobic and anaerobic capacities in groups displaying different lifestyles and associated levels of locomotor performance in various temperature regimes. The graph shows the temperature-specific consequences of cold adaptation (broken arrows), i.e., consequences are compared at the same temperature. The figure illustrates how on a continuum between low and high levels of performance, the expression of anaerobic metabolic capacity follows a parabolic function (in temperate to warm-water species). Use of anaerobic metabolism is maximized in sluggish benthic species, minimized in moderately active aerobic cruisers and enhanced again in high-performance fish (and squid) at warmer temperatures. Cold adaptation (broken arrows) elicits reduced performance levels at maximized aerobic design like in pelagic Antarctic notothenioids (blue vs. green lines), especially for cold-adapted larvae (see text). In Antarctic fish, cold adaptation of anaerobic capacity (magenta vs. red lines) occurs in benthic sit-and-wait predators, but not in moderately active Antarctic fish. Here, anaerobic capacity appears reduced, as a trade-off in the maximization of aerobic design. Note that the figure does not differentiate between cold-adapted stenotherms and eurytherms.

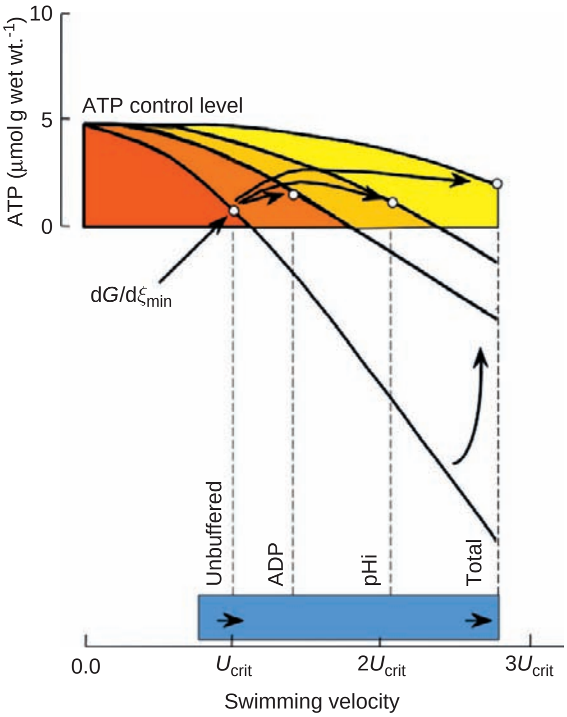

Figure 3 The role of the phosphagen system and anaerobic glycolysis in extending the period and velocity of swimming beyond the critical swimming speed U_{crit}. From a metabolic perspective this critical limit is best defined from the onset of supplementary anaerobic energy production. The figure adopts the respective patterns and model calculations as available for squid and extrapolates the principles into a general model to be tested in fishes. It illustrates how anaerobic metabolism provides power for time-limited swimming at supra-critical speeds. The buffering of ATP levels and Gibbs free-energy change of ATP hydrolysis is elicited by the combined effects of accumulation of free ADP levels and of intracellular acidification due to anaerobic glycolysis, both eliciting transphosphorylation from the phosphagen. Note that the present approach differs from the classical swimming protocols in fish physiology. The time protocol co-determines the swimming speed reached beyond U_{crit}. Maximum attainable velocity results higher as the swimming period beyond U_{crit} decreases.

reduction in standard and *in vivo* ATP free-energy change values by about 2 kJ mol^{-1} until a minimum is reached below pH 7.0. Further decrements follow the depletion of ATP and the phosphagen and the accumulation of ADP and inorganic phosphate (**Figure 3**).

The buffering of ATP levels leads to a buffering of ATP free-energy-change values, which are decreased initially by the accumulation of inorganic phosphate from net phosphagen depletion. Actually, this decrease can be considered advantageous, because both the acidosis and the accumulation of inorganic phosphate have some protective effect on ATP concentrations. As a consequence, the minimum level of ATP free energy is reached at higher ATP contents with the use of the phosphagen than without (**Figure 3**).

The accumulation of inorganic phosphate is very likely involved in limiting the degree of muscular activity or reducing the maximum swimming velocity. These processes are interpreted as early signs of fatigue. Inorganic phosphate may actually start to slow muscular performance at levels of ATP free energy higher than the minimum, limiting level. This may be beneficial when extending the time period during which anaerobic metabolism is to be used at low activity levels, for example, in hypoxic environments. At low performance levels, the rate of anaerobic glycolysis is low and the degree of free ADP accumulation small causing a delay in the depletion of the phosphagen and also less of a decrease in the Gibb's free-energy change of ATP hydrolysis over time. This reduced performance level keeps ATP free-energy change at higher levels. Reduced performance levels beyond the anaerobic threshold may be supported through the combined effects of low pH and elevated inorganic phosphate levels on muscular performance.

The anaerobic threshold is set low when oxygen availability is low, for example, due to ambient hypoxia. Reducing the energy requirements for locomotion in hypoxic environments delays the depletion of anaerobic resources including the phosphagen and also delays fatigue through a slower accumulation of inorganic phosphate. Development of an acidosis occurs unchanged and may support a reduction in performance prior to fatigue. Work in invertebrates shows in fact that intracellular pH falls more rapidly in hypoxia-tolerant species and may cause a protective decrease in performance before the energy status reaches a critically low level. A decrease in performance induced by acidosis is typically observed in many types of muscle tissue and may be protective during ischemia, long-term environmental stress, or extended periods of anaerobic exercise.

The acidosis also protects the levels of the adenylates and the Gibbs free-energy change of ATP hydrolysis. If metabolic expenditure is low, such as during hypoxia, effective lowering of pH$_i$ through ion exchange may contribute to a long-term use of anaerobic resources. The patterns of pH$_i$ regulation thus can strongly modulate the use of anaerobic resources. Progressive acidification first supports maximum levels of activity but then sets limits to the level of performance and, finally, the period of anaerobic exercise. These considerations can be extrapolated to strategies extending periods of passive tolerance to environmental extremes. Here the balanced use of anaerobic resources and energy stores also involves the downregulation of intra- and extracellular pH as seen in some animal models. In this case, the pH decrements elicit metabolic depression and thereby a time extension of passive tolerance.

As a corollary, aerobic scope sets and limits the capacity for long-term and long-distance cruising at high velocities. Similarly, the capacity for anaerobic performance sets the maximum energy turnover required for escape or attack on short timescales. In addition, it likely contributes to set the length of time when anaerobic metabolism is exploited under extreme environmental conditions, for example, during excursions into hypoxic environments linked to food uptake or during passive long-term sustenance under anoxia or thermal extremes.

Background

Any collection of articles on fish physiology would be incomplete without a thorough treatment of locomotion. Swimming, after all, is a unifying character of the vast majority of fishes. Locomotion determines a fish's ability to access habitats, defend territories, secure mates, capture prey, and escape from predators – it is clearly a fundamental aspect of the fitness of mobile organisms.

When we think of the physiology of locomotion, we are thinking about what fish are capable of doing: how biochemistry, muscle structure, innervation, circulation, and morphology all interact with the hydraulic environment to create opportunities for, and limits to, a fish's ability to move. On its own, physiology defines the limits to performance, and there are clear implications for fitness and adaptation. By association, this means there are also implications for management and conservation.

It is important to recognize, however, that physiological capacity is not tantamount to performance. It is what organisms do with their abilities – how they behave – that ultimately determines actual performance. Because of this, it is not possible to meaningfully review the conservation implications of physiology – or fitness implications generally – without integrating behavior into the discussion. This article considers performance to be the output of both physiology and behavior, and it is from this perspective that the ecological relevance of swimming performance can best be understood.

Threats to Fisheries Conservation at the Dawn of the Third Millennium

There has never been a time when environmental conservation and stewardship have been more important. When it comes to the conservation of fisheries, the consequences for humans are often dire. As human economies and populations grow, we turn increasingly to fisheries as a source of protein, and both commercial and artisanal fisheries are harvesting the oceans and waterways well beyond sustainable levels. In many commercial fisheries, most of what is captured is discarded as bycatch, creating a situation where fishing pressure affects not only target populations but nontarget ones as well.

Simultaneously, the by-products of industry and industrial agriculture put fisheries at unprecedented risk. Chemical pollution and eutrophication, sedimentation and turbidity, thermal pollution, and outright water withdrawals all act to reduce the resilience and productivity of the environments that we expect to support these fisheries.

In riverine environments, no single activity has posed a greater threat to fisheries than has the development of hydropower. This has been recognized for well over a century: The eighteenth and nineteenth centuries saw a proliferation of mill and logging dams built throughout Europe and eastern North America, leading to widespread losses of economically and ecologically important fish species (**Figure 1**). These losses were not limited to the riverine environment: many of the species affected by dams were diadromous migrants, species that routinely migrate between the marine and freshwater environments. These populations acted as vehicles conveying nutrients between ecosystems, and it long has been understood that, in many cases, losses of anadromous populations were also causing the depletion of coastal fisheries.

Dam development did not end with the Industrial Revolution. At the end of the nineteenth century, the invention of the electric dynamo provided the technological basis for the hydroturbine. This created an economic incentive for development of more and much larger dams, leading to further increases in the rate of dam development (**Figures 2** and **3**). Hydropower development slowed in North America and Europe by the late twentieth century. In recent years, however, developing economies in China, Brazil, and elsewhere have driven a global expansion in the number and scale of dam construction. Today, economic development coupled with concerns of global climate change mean that the value of hydropower, and hence, the scale of hydropower development, will continue to increase.

The effects of dams on riverine ecosystems are multifold. First, they alter habitat, converting lotic environments characterized by high velocities and turbulence (and thus high values of total kinetic energy) into a series of lentic pools with reduced kinetic energy and increased

thermal stratification. This fundamentally alters habitat character, allowing for sediment deposition in riverbeds, raising or lowering temperatures, and otherwise creating environments that may be incompatible with native species, but that may promote non-native predators and other invasive species. In addition, behavioral cues used to navigate waterways may no longer be appropriate for traversing reservoirs, creating a situation in which traits such as swimming performance and navigation that evolved in lotic environments are no longer adaptive.

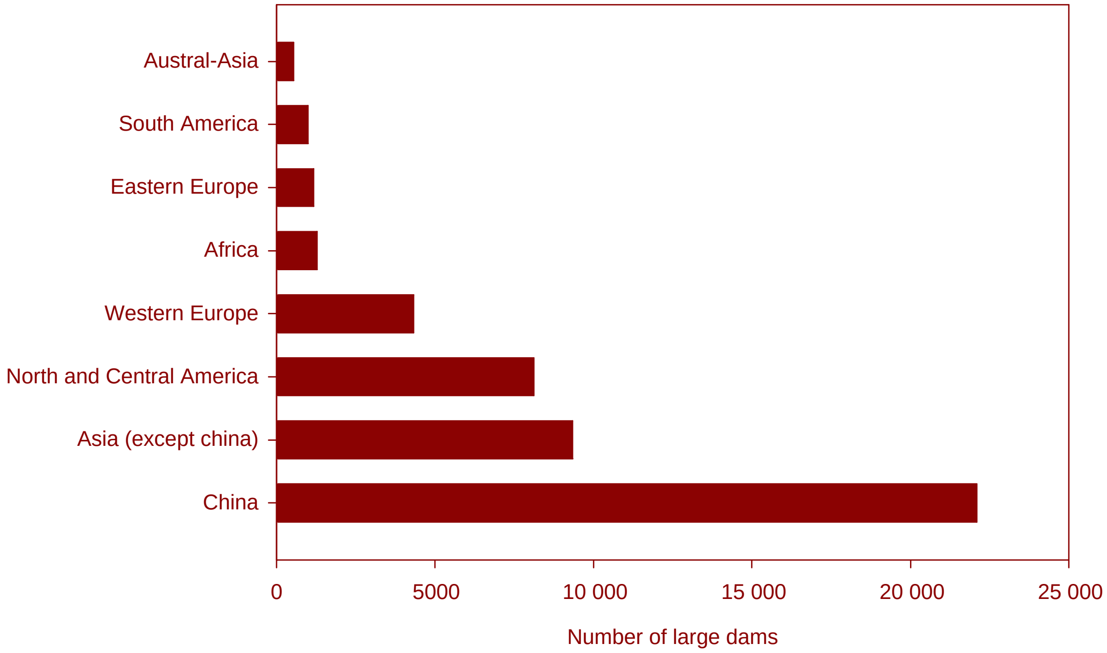

Figure 3 Large dam construction by geographical region. Note the massive construction in China, nearly all of which has occurred during the last 60 years. From World Commission on Dams (2000) *Dams and Development: A New Framework for Decision-Making*. London: Earthscan Publications.

Perhaps even more important than altering habitat, dams create barriers to movement. This is obviously important for philopatric (homing) anadromous species such as salmon – without access to their natal habitat, these populations can quickly go extinct. Downstream migrating juveniles, as well as adults of iteroparous and catadromous species, are also faced with the difficulty of finding passage routes around the dams and avoiding passage through turbines (**Figure 4**).

Barriers degrade habitat for nonmigratory species as well, reducing gene flow among resident populations and restricting access to important habitats. The development and application of telemetry technology in recent years has shown that movement along river and stream corridors is a much more ubiquitous and important trait than was thought previously, and even partial barriers to movement can cause subtle and chronic reductions to habitat quality. Importantly, the ability to traverse barriers is closely tied to swimming performance and behaviors. This means that development of mitigation measures to counter these dam effects will require a strong and holistic understanding of fish locomotion.

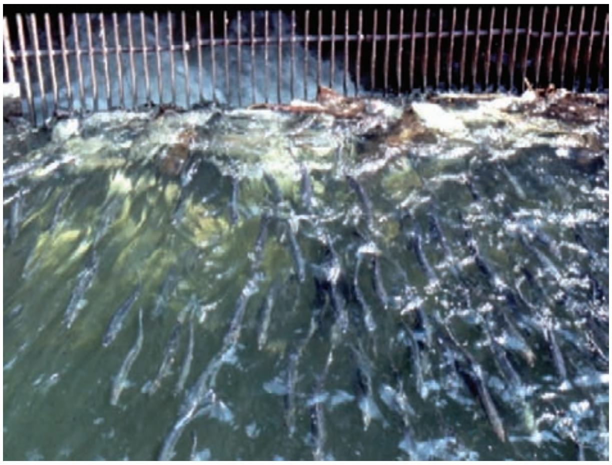

Figure 4 Adult American shad being impinged on powerplant intakes. Photo courtesy of Boyd Kynard.

In addition to dams, water withdrawals create situations in which large numbers of fish are killed. Withdrawals serve a number of functions, including cooling water for power plants, municipal water supplies, and agriculture. Rates of water withdrawal vary greatly around the world, with developed countries using far more per capita than do developing countries. As global economies develop, demand for water will continue to grow, with individual facilities often processing large proportions of local water bodies. Fish that are entrained at these facilities suffer very high mortality rates – designing intake structures to avoid entraining fish has become an important challenge.

Industrial and municipal withdrawals are often coupled with heated discharge. This is a major source of elevated temperatures in many water bodies, and compounds the ongoing effects of habitat destruction and climate change. As a result, temperatures of freshwater systems around the world are increasing at rates even greater than those that would be predicted from climate change alone.

Swimming performance has important implications for each of the conservation issues summarized above. Swimming ability can determine whether, and to what extent, a given population is susceptible to overfishing. Likewise, engineering criteria for providing fish passage at dams and exclusion from water withdrawals rely on swimming performance data. Finally, chemical and thermal alterations to habitat, whether from industrial effluent or from climate change are well known to affect swimming capacity, behavior, and energetics. Because of this, a good understanding of swimming ability, founded on appropriate and reliable data, is essential to the development of sound management practices, as well as solutions to mitigate for human activities.

Swimming Performance Data – Where Does It Come from?

Much of what we know about fish swimming performance reflects the historical context of social values and perceived needs. Some of this interest has stemmed from applications that have little to do with fish. For example, the salmonid body form influenced the development of hydrofoils in the eighteenth century, and the processes by and efficiency with which fish produce thrust continue to influence nautical engineering today.

Despite these interesting applications, conservation issues have consistently influenced the scope of scientific investigations. By the late nineteenth century, fisheries managers had become aware of the threats posed by milldams, and the resulting population declines of commercially important fishes in Europe and North America were viewed as one of the most important challenges confronting fisheries managers at the time. Several fishways – structures designed to provide routes of passage around dams for migrating fish – were developed during this period, but these structures were almost universally ineffective. Coincidentally, the field of fluid mechanics was undergoing rapid advances – contributions by Osborne Reynolds and others permitted the merger of the fields of biomechanics and hydraulic engineering. The first half of the twentieth century saw concerted efforts by hydraulic engineers to apply these new fields to fishway design in Europe, Great Britain, and North America. Although reliable methods for quantifying swimming performance were lacking, the importance of the topic was recognized, and engineers began testing their designs in laboratories using live fish (**Figure 5**).

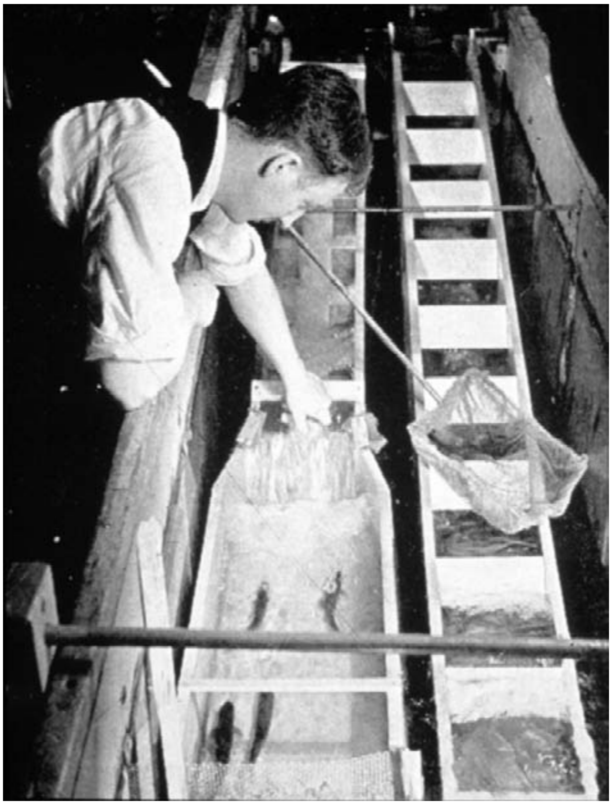

Figure 5 Fishway designs being tested at the University of Iowa hydraulics laboratory during the 1930s. Engineers at the time recognized the importance of empirical testing with live fish to verify performance. From McLeod AM and Nemenyi P (1940) *An Investigation of Fishways*. Iowa City: State University of Iowa.

During this period, biologists became interested in fish locomotion from the perspective of the nascent fields of ecology and evolutionary biology. Swimming performance and biomechanics developed into an area of basic research pursued independent of management and conservation concerns. Nevertheless, two areas of study arose from these efforts that have substantial conservation implications today. The first is the field of functional morphology – specifically the classification of different body forms and locomotor modes, which have substantial implications for swimming ability and behaviors as well as designs for protective devices (**see also Buoyancy, Locomotion, and Movement in Fishes**: Maneuverability). The second is the field of bioenergetics, whereby the energy consumed during locomotion and other activities can be related to ecology and trophic interactions (**see also Energetic Models**: Bioenergetics in Ecosystems).

Interest in bioenergetics led to the development of respirometers for quantifying swimming energetics. Several designs were developed, with the most popular being designs by Brett (**Figure 6**) and Blazka (**Figure 7**). These became important tools for a variety of applications and are still in widespread use today.

Although Brett was perhaps best known for his work on swimming energetics, he also developed two measures of swimming performance that have been widely used by

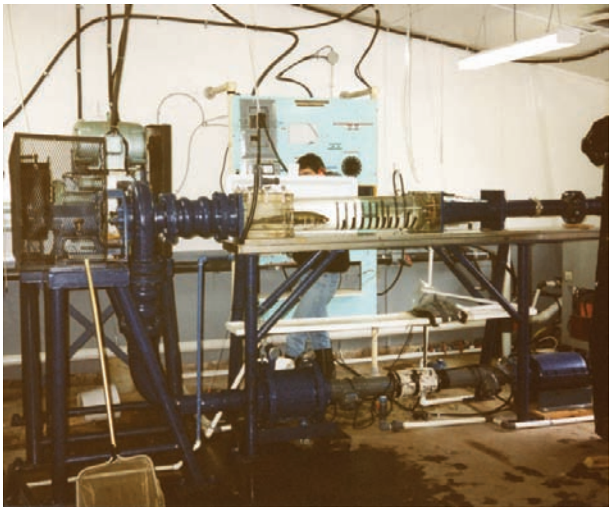

Figure 6 Photo showing the Brett respirometer. Fish are confined in an acrylic chamber and flow is regulated using a centrifugal pump. Note the long straight section on the upstream end: this helps establish uniform flow characteristics throughout the cross section of the swim chamber. Photo courtesy of Scott Hinch.

both researchers and managers. The first and most frequently replicated measure he called U_{crit}, or critical swimming speed. During the course of his early work, Brett noticed that salmon were able to sustain slow swimming speeds more or less indefinitely without fatiguing. This had an obvious application for salmon smolts that encountered hydroelectric dams as they migrated to the ocean. Brett assumed that if intake velocities were kept below the maximum sustainable swim speeds, then fish should never become entrained into turbine intakes, thus making it possible for them to seek and use safer alternate routes. Toward this end, Brett developed a standardized protocol whereby fish were placed in a swim chamber and subjected to incremental increases in flow velocity. Each increment was nominally set to one-half body length per second for a 60-min increment (subsequent researchers have used a range of velocity and time increments). U_{crit} is calculated as the final flow velocity, adjusted downward by the proportion of time remaining in the final time increment (**Figure 8**).

The velocity threshold below which swimming can be sustained indefinitely is ultimately governed by the physiology of the fish, that is, by its aerobic scope. This is largely a function of the quantity and distribution of mitochondria-rich musculature, and as such, varies with body size and species (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional Properties of Skeletal Muscle: Work Loops). Most fish are ectotherms, meaning they are unable to regulate body temperature. Because of this, performance is typically reduced at temperatures both below and above what fish typically encounter, with optimum performance occurring over a relatively narrow range of temperatures. At low temperatures, their metabolism, and hence aerobic scope, is reduced. At high temperatures, the maintenance metabolic costs increase at a greater rate than the associated benefits, and eventually metabolism itself begins to fail. The range of thermal optima varies by species and represents a combination of physical limits and evolution; for example, cold-water-adapted species have lower thermal optima than warm-water-adapted species. For tropical

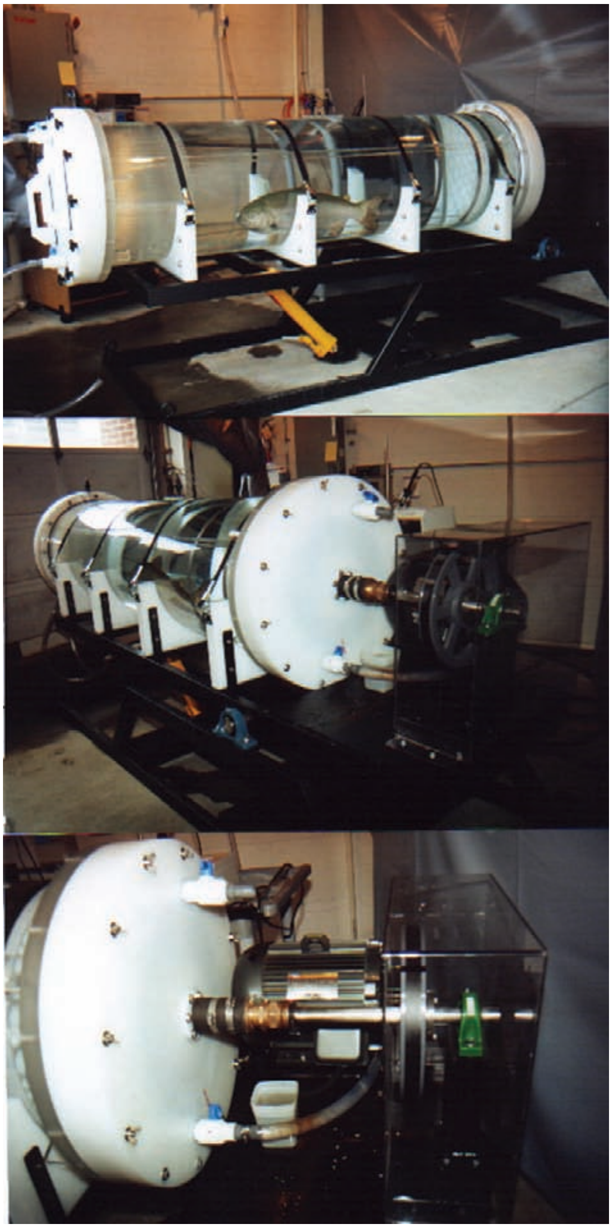

Figure 7 Images of a Blazka-type respirometer. The design incorporates two coaxial tubes. Fish are housed in a swim chamber in the internal tube, and an axial pump drives flow through the enveloping tube. These respirometers typically have a lower volume than Brett-type respirometers (**Figure 6**). Photo courtesy of Matthew Mesa.

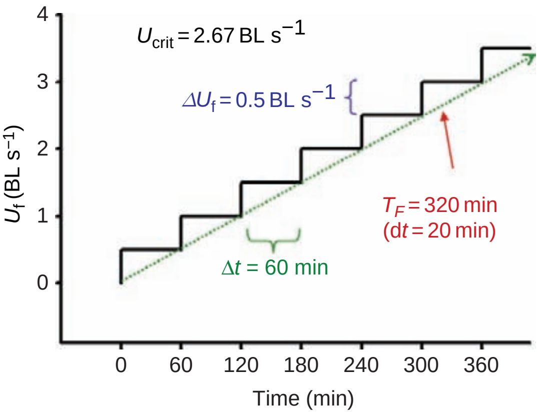

Figure 8 Schematic of U_{crit} protocol showing increments of velocity (ΔU_{f}) and time (Δt). Note that swim speed equals flow speed, and that U_{crit} interpolates the maximum speed that can be maintained for the interval duration, Δt.

migratory species (**Figure 9**), this may be advantageous. If these species' scopes for activity are greater, fish-passage solutions may be possible at the many new dams being built in the tropics that would not be possible in temperate regions.

The second important swimming performance metric that Brett helped develop was the relationship between swim speed and fatigue time (SSFT) for fish that are swimming at speeds greater than their maximum sustained swim speed (**Figure 10**). During the course of his studies, Brett noticed (and many subsequent authors have confirmed) the existence of two distinct modes of nonsustainable swimming. Once speeds exceed sustained levels, fish begin to recruit anaerobic musculature to power swimming. Often, this is noticeable by the onset of the so-called burst-and-coast swimming, a kinematic shift whereby fish use both aerobic and anaerobic

Figure 9 Freshwater Riches of the Amazon, by Ray Troll (www. trollart.com). The faunal diversity shown here is typical of the Amazon and other tropical rivers. Thousands of species inhabit these rivers, but little is known about swimming abilities or migratory habits. Extensive damming projects in development will likely impede movements of many of these species.

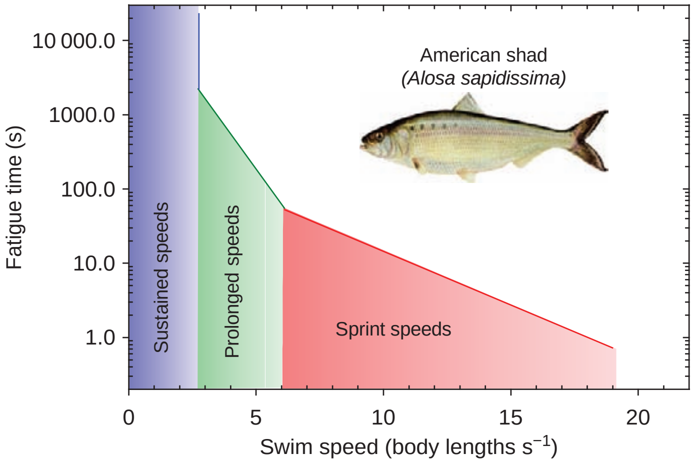

Figure 10 Swim speed–fatigue time relationship of American shad (mean body length = 45.5 cm). Similar relationships exist for many teleosts, although scope, scale, and slope can vary considerably by species and morphology.

physiology to power locomotion. This is typically called the ‘prolonged mode’, and Brett found that, for salmon, this mode characterized speeds that resulted in fatigue in more than 20 s. At some point, however, it is no longer possible to power locomotion with aerobic musculature, and fish enter a pure burst, or sprint mode. These two modes have distinct swim speed–fatigue time relationships, typically being much steeper in prolonged mode than in sprint mode.

Thus, sprinting comprises the broadest range of swim speeds, although endurance is necessarily shortened in its duration compared with prolonged mode. The relationship between swim speed and fatigue time has broad ecological relevance, (e.g., governing prey capture and predator avoidance). It also has important implications for fisheries and can influence capture of fish by mobile trawls and other common fishing gear (**Figures 11** and **12**). Because of this, researchers interested in bycatch reduction and gear efficiency have conducted many studies that have greatly contributed to our knowledge of swimming abilities of marine species.

As mentioned above, swimming performance is not fixed by species or even individual. An individual’s size can have dramatic effects on swimming ability, as can environmental conditions. The effect of size on swimming ability is largely a function of mechanics: larger fish typically have more propulsive area and a larger muscle mass, and so are able to move at greater absolute speeds. Because of this size effect on absolute swimming speed, swim speeds are often normalized by dividing by body length, and are reported in body lengths per second. Over a relatively small range of body sizes, this is a reasonable and effective approach. The danger of the approach, however, is that it assumes that

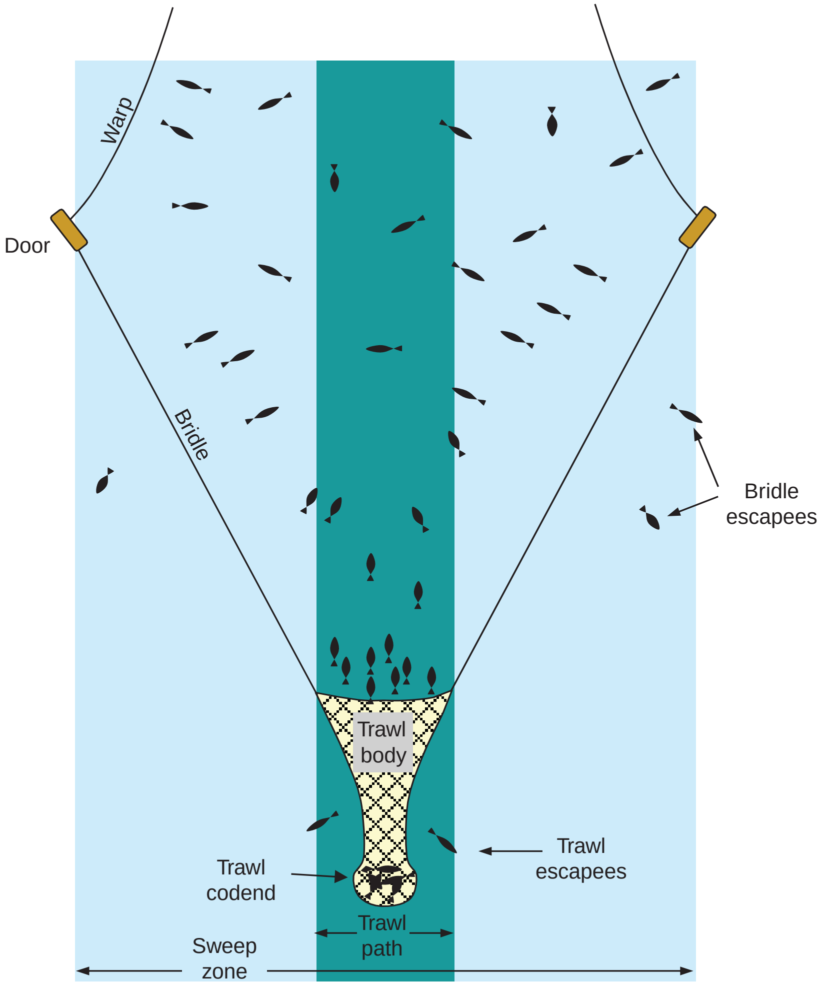

Figure 11 Schematic showing path of a typical otter trawl. Ability to escape depends on both swimming ability and behavior. Fish that are corralled by the bridle sweeps are more likely to be captured than those that swim across the sweeps. Capture likelihood is also affected by escape distance, speed of trawl, and mesh size. Redrawn from Castro-Santos T and Haro A (2006) Biomechanics and fisheries conservation. In: Shadwick RE and Lauder GV (eds.) *Fish Physiology Volume 23: Fish Biomechanics*, pp. 469–523 New York: Academic Press.

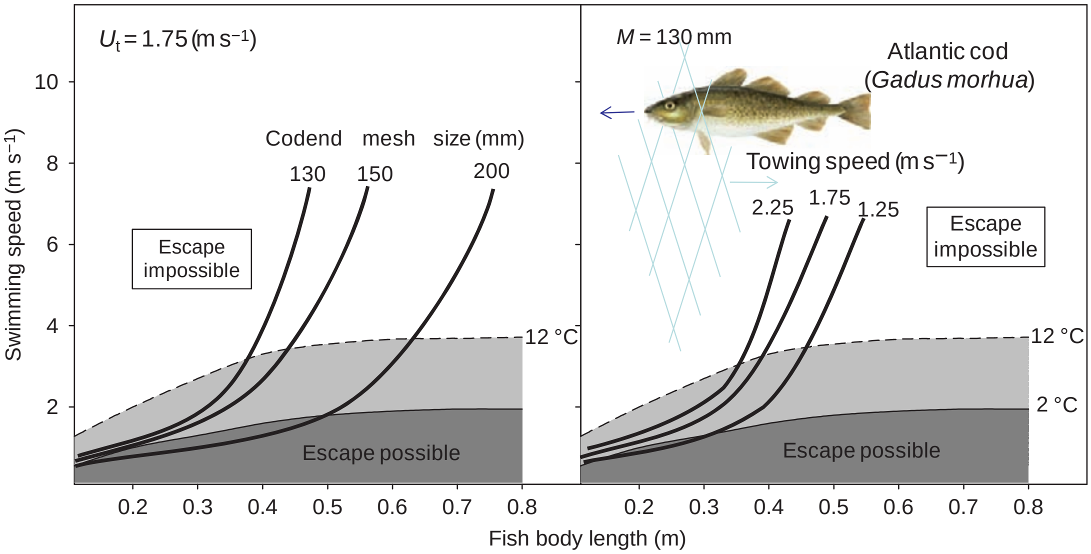

Figure 12 Effect of swimming ability, trawl speed, and mesh size on escape potential for Atlantic cod from the codend of an otter trawl. Shaded areas indicate zone in which escape is possible at 2 °C and 12 °C. Solid curves represent swimming speed required to escape through meshes (M) of different sizes (left panel) and through a fixed sized codend mesh at a range of tow speeds (U_t right panel). A vertical line drawn from the body size of the fish that intersects the solid curves within a shaded area indicates that it is possible for the fish to escape through the codend mesh at a given temperature. This type of analysis holds the potential for identifying gear design and fishing strategies that can target specific size classes and species. The information could be used to protect nontarget species and life stages as well as to improve fishing efficiency. He P (2010) Swimming capacity of marine fishes and it role in capture by fishing gears. In: Domenici P and Kapoor BG (eds.) *Fish Locomotion, an Eco-Ethological Perspective*, pp. 484–512. Enfield, NH: Science Publishers.

swimming performance is isometric, that is, it changes uniformly with size. In fact, this is not the case: smaller individuals of a given species tend to have a greater relative performance than larger individuals, that is, swimming performance is allometric. This arises for several reasons, including allometry in morphology and physiology (**see also Swimming and Other Activities**: Energetics of Fish Swimming and **Energetics**: Physiological Functions that Scale to Body Mass in Fish). One consequence of this is that, in the absence of appropriate data, managers sometimes set velocity criteria for fishways and water withdrawals based on relative flow velocities, using data from very different-sized animals than those that they are trying to protect. Resolution of scaling effects on locomotion remains an area of active research and is of substantial interest to both managers and researchers.

Limitations of Available Data

The ease with which U_{crit} and SSFT can be measured (particularly the former) has made these valuable tools for laboratory studies. Because of this, there has been a proliferation of studies reporting U_{crit} for a large number of species under a range of conditions. The availability of this information and its apparent relevance to fish passage and protection have led to its ubiquitous application in fish-conservation measures.

However, just because data are available does not mean that they are applied appropriately or that they are even applicable to conservation efforts. Unfortunately, many examples exist of such inappropriate applications of swimming performance data. The reason so many studies have used the U_{crit} and related protocols is that these techniques are readily performed in a laboratory setting, where fish are confined to small chambers under very controlled conditions. These conditions may not exist in the field, however, and the apparatus used to collect the data prevents fish from exhibiting the full range of behaviors that are available to free-swimming fish. This means that performance in these chambers consistently underestimates natural capabilities. Moreover, no method has been developed using these structures that quantifies the willingness of fish to volitionally swim at a given speed, or against a particular current velocity. This is particularly important for upstream-migrating fish. Many of these migrants are strongly rheotactic, adapted to seek out zones of high-velocity flow used as cues for orientation and navigation.

This has important implications for design of fishways and other obstacles such as culverts at road crossings. Fish often show a reluctance to enter such structures; in the absence of a strong velocity jet, the resulting low entry rate leads to poor passage, regardless

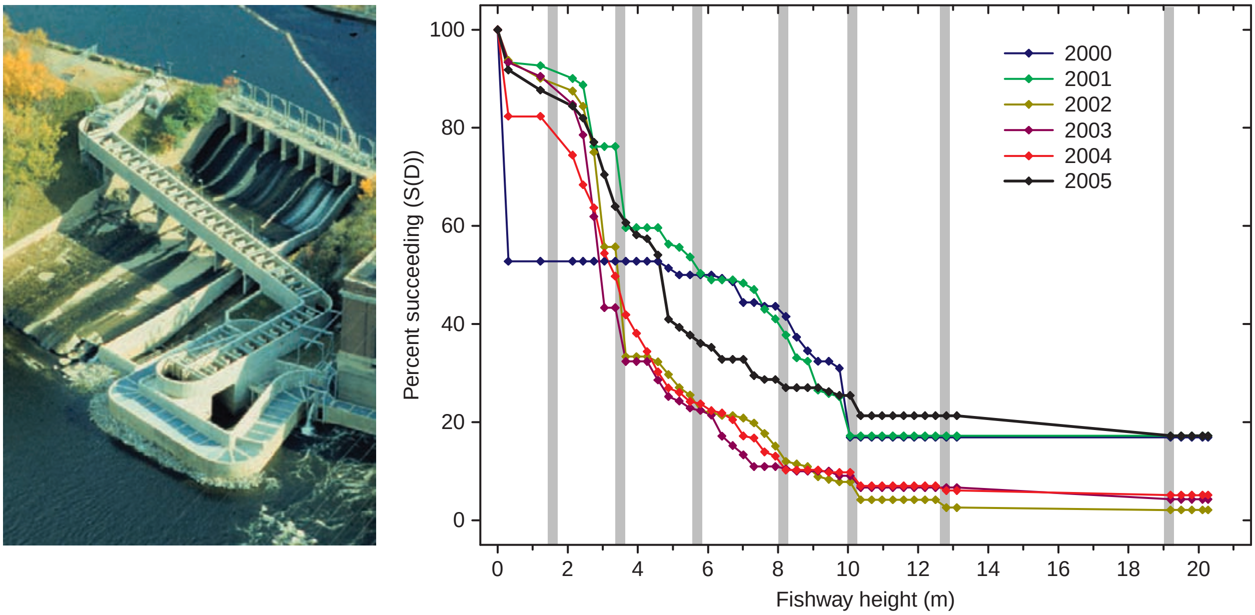

Figure 13 A fishway designed to pass Atlantic salmon and American shad. Although both species are sufficiently strong swimmers to pass this structure, their behaviors and tolerances are different: salmon pass the structure with ease, but only about 10% of American shad that enter pass successfully (right panel). Developments in telemetry technology have greatly improved the ability of researchers and managers to evaluate structures like this, but fewer than 1% of fishways have ever been rigorously evaluated.

of structure design. Because of the data limitations described above, management recommendations systematically underestimate the ability of fish to traverse these barriers, and, in their efforts to avoid creating velocity barriers, they err in the opposite direction and fail to provide sufficient stimulus for the fish to enter. In this way, management solutions intended to eliminate barriers can be ineffective (**Figure 13**), potentially causing more harm than benefit.

The limitations of existing swimming data – as well as potential solutions – have been made evident by a series of recent studies using open-channel flumes and volitionally swimming fish. Hydraulics in these flumes can be controlled to produce a broad range of velocities, and fish are provided a low-velocity zone or staging area downstream of the channel from which they are able to enter the channel at will (**Figures 14** and **15**). This method has been used by Stephen Peake and his

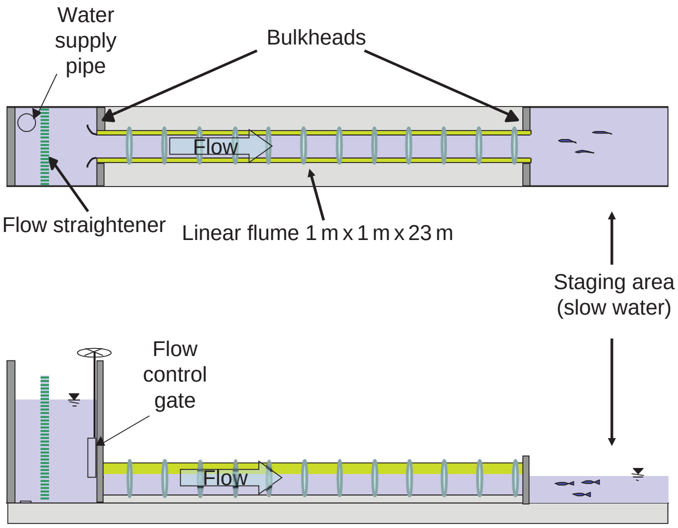

Figure 14 Open-channel flume used for volitional swimming studies. Velocities within these flumes are regulated by the control gate and flow source; the staging area downstream of the flume provides fish with a low-velocity zone from which they enter the flume volitionally. Progress up the flume can be monitored with video, or using telemetry arrays (indicated by ellipses).

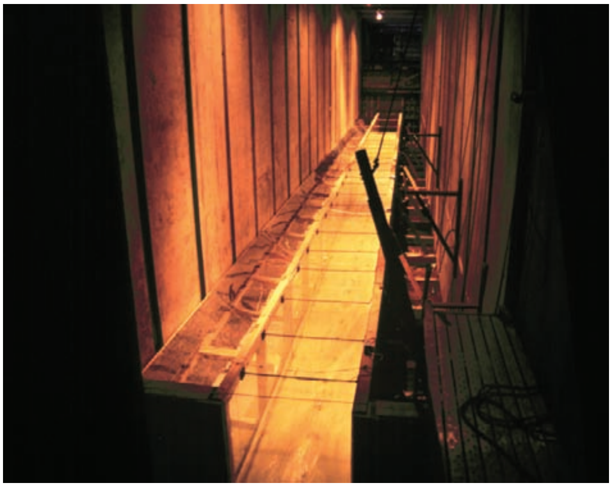

Figure 15 Open-channel flume prototype at the S.O. Conte Anadromous Fish Research Center, a large-scale facility designed to test full-scale prototypes of fishways and related structures. Fish have been tested in this flume against velocities of 0.5–5.0 $\mathrm{m\,s^{-1}}$.

colleagues to estimate sustained swimming speeds. The author and his co-workers have developed a similar approach that provides estimates of swim-speed versus fatigue-time relationships, as well as the extent to which a given velocity motivates fish to enter. Because of these structures' considerable length, it is also possible to measure directly the ability of fish to swim a given distance against a range of velocities, eliminating the need for (in fact, challenging) many of the assumptions about swimming performance that underlie current fishway designs.

Another advantage of studying volitional swimming performance is that it provides empirical evidence for not only what fish are capable of doing, but also what they are actually willing to do, and how well they do it. For example, for any flow velocity there exists an optimum swim speed that maximizes the distance a fish is able to traverse (**Figures 16–18**). Fish that swim too fast or too slow fatigue at shorter distances. The ability of fish to approximate their distance-maximizing optimum appears to be under selective control: anadromous species that must traverse high-velocity zones tend to do a better job

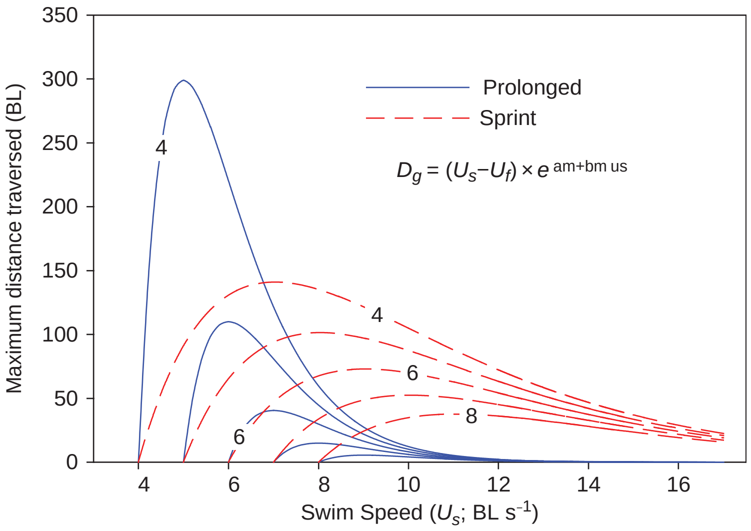

Figure 16 Maximum possible distance traversed (D_g) by American shad against a range of flow velocities (U_f), given the swim speed–fatigue time relationship for prolonged (blue) and sprint modes (red) shown in **Figure 10** (U_s = swim speed; a_m and b_m are intercept and slope terms for each mode). Curves represent flow velocities from 4–8 body lengths per second. Note that fish that swim at the speed of flow make no upstream progress, but swimming too fast also reduces range. Thus, distance maximization is a function of both the swim speed–fatigue time relationship and the ability of the fish to select the optimum swim speed (**Figure 17**). Modified from Castro-Santos T and Haro A (2010) Fish guidance and passage at barriers. In: Domenici P and Kapoor BG (eds.) *Fish Locomotion: An Eco-Ethological Perspective*, pp. 62–89. Enfield, NH: Science Publishers.

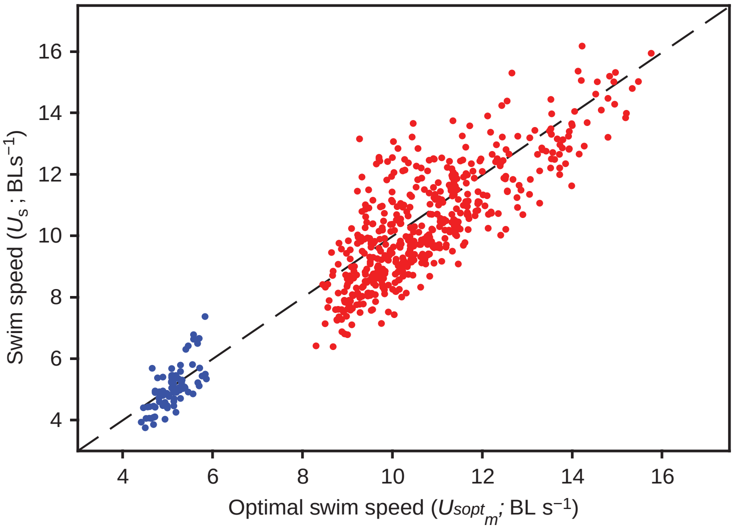

Figure 17 Swim speed optimization by American shad swimming in prolonged (blue) and sprint mode (red). The dashed line represents the optimal swim speed for maximizing distance, given the flow velocity (**Figure 16**), points above the line indicate fish that swam too fast and points below the line indicate fish that swam to slowly. Although on average American shad approximate the distance maximizing behavior, the magnitude of error limits actual distance traversed (**Figure 18**). Modified from Castro-Santos T and Haro A (2010) Fish guidance and passage at barriers. In: Domenici P and Kapoor BG (eds.) *Fish Locomotion: An Eco-Ethological Perspective*, pp. 62–89. Enfield, NH: Science Publishers.

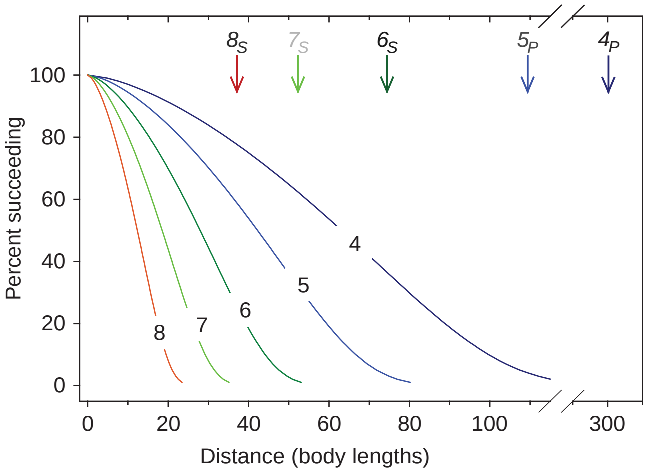

Figure 18 Consequences of the failure of American shad to select optimal swim speeds. Arrows indicate theoretical maximum distance of ascent against each flow velocity (4–8 body lengths per second). Curves represent models of distance of ascent based on empirical data. Note that individuals can never achieve their theoretical maximum potential – the extent to which they fall short is a result of behavior and varies by species. Estimates of performance that ignore either capacity or behavior are often inaccurate and intrinsically imprecise. Modified from Castro-Santos T and Haro A (2010) Fish guidance and passage at barriers. In: Domenici P and Kapoor BG (eds.) *Fish Locomotion: An Eco-Ethological Perspective*, pp. 62–89. Enfield, NH: Science Publishers.

of picking the optimal swim speeds than resident species. Once again, this points to the importance of observing natural behaviors in field-like settings in order to gauge the ideal conditions for optimizing passage.

The lack of good information on free-swimming fish is not surprising when one considers the difficulty of observing them under controlled conditions. Behavioral data have been particularly difficult to acquire. Part of the reason for this is that behaviors are often quantitatively elusive: How should we identify and quantify relevant performance variables? Ideally, quantities should be derived from known or assumed fitness or applied relevance. When scientists are able to explicitly describe the assumed relevance of a given behavior, it becomes easier to determine appropriate metrics with which to quantify it.

The above caveats notwithstanding, laboratory studies have provided valuable information on swimming performance with important conservation implications. Swimming performance has repeatedly been shown to be affected by temperature and by exposure to pollutants, and to vary by life stage. In addition, the energetic costs of locomotion have been extensively studied. Migratory energetics can have important implications for spawning success and survival. This, in turn, drives the viability of populations as well as the size and resilience of fisheries. Barriers to movement, even if ultimately traversed, incur energetic costs that can counteract conservation efforts.

Ongoing efforts to study fish-swimming performance would do well to consider the important conservation challenges facing fisheries managers. Recognizing both the limitations and benefits of various approaches to studying swimming performance should help guide future research and resolve some pressing questions. In a world where humans and fish compete for ever-more limited resources, the importance of this knowledge will only increase.

Glossary

Abiotic The chemical and physical (nonbiological, physical) variables of the environment (e.g., temperature).

Absorption Passage of nutrients across the gut and into the blood; uptake of fluid and solutes by cells and tissues.

Alkaloids A large group (*c.* 6000 are known) of toxic, basic nitrogenous compounds found in plants. The term alkaloid has not been precisely defined, but the group encompasses heterocyclic nitrogen bases derived from the amino acids – ornithine, lysine, phenylalanine, tyrosine, and tryptophan.

Amino acids Molecules with an amine group, a carboxylic group, and one of 20 R groups that are the building blocks of proteins.

Ammonotelic Excreting nitrogen mainly as ammonia (i.e., NH_3 or the ammonium ion, NH_4^+), as in most teleost fish and aquatic invertebrates. Total ammonia nitrogen (TAN) is the sum of the ammonia–nitrogen found in the unionized (NH_3) and ionized (NH_4^+) form.

Anti-nutritional factor (ANF) A substance that reduces the value of a feed or feedstuff, primarily via interference with the digestion, absorption, or metabolism of nutrients.

Ash The mineral residues remaining after combustion of feeds, feedstuffs, or plant and animal tissues at 450–500 °C.

Bioavailability (biological availability) Describes the proportion of a nutrient in a feed or feedstuff that may be utilized by an animal. Bioavailability of a nutrient can be subdivided into three constituent phases: availability in the intestine for absorption, absorption and/or retention in the body, and utilization. Bioavailability is studied to evaluate the quality of feeds and feedstuffs, and to provide data for establishing nutritional requirements.

Biotic factors Biological factors such as availability of food, numbers of conspecifics and competitors, and predators, etc., that affect the abundance, distribution, and life histories of individuals and species.

Carbohydrates Compounds containing carbon, oxygen, and hydrogen, and having the general formula $C_x(H_2O)_Y$ (although some compounds classifed as carbohydrates do not comply with this general definition). The group includes simple sugars (monosaccharides) and their derivatives, oligosaccharides and polysaccharides, such as starch and cellulose.

Carnivore Generally applied to animals that feed upon other animals, although there are also carnivorous (flesh-eating) plants that trap and digest insects and other small animals.

Crude fiber The insoluble carbohydrates remaining after boiling a feed or feedstuff in acid and alkali; this fraction represents the carbohydrates that are not readily available to, and are poorly utilized by most animals.

Crude protein The content of nitrogen in a feed, feedstuff, plant, or animal tissue multiplied by a factor (usually 6.25, since most proteins contain about 16% N) to provide an estimate of the protein content; this only gives a crude estimate of protein content because variable amounts of nonprotein nitrogen will be present in analyzed samples.

Digestion The process of solubilization and hydrolysis of ingested nutrients in the gastrointestinal canal into constituent molecules and elements suitable for transport across the intestinal wall.

Ectotherm (adj. ectothermic) An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Endocrine Mode of secretion in which a chemical is released by a cell into extracellular fluid then enters the blood.

Endotherm An animal that uses its own metabolism as the major source of heat to maintain its body temperature greater than that of the surrounding environment.

Energy budget The balance of energy input and use in a biological system, expressed in terms of consumption (intake or ingestion), production (growth), respiration, fecal losses, and excretory losses.

Ether extract The portion of a feed, feedstuff, or tissue that is soluble in ethyl ether and is removed by extraction in this solvent; it represents the majority of the lipid fraction of a feed.

Excretion The elimination of waste materials from the body; specifically the elimination of waste materials produced by metabolism, for example, nitrogenous excretion refers to the elimination of nitrogenous compounds (ammonia, urea, uric acid, etc.) resulting, primarily, from the metabolism of proteins and nucleic acids.

Feces The undigested feed residues, plus some endogenous digestive secretions, sloughed cells of the intestinal lining, and bile metabolites that are expelled from the gut via the anus.

Feed efficiency Wet weight gain per unit feed consumed; it often calculated as gain divided by the amount of feed provided, thereby including an error relating to unconsumed feed waste; it may also be termed feed conversion efficiency or feed utilization (cf. feed:gain ratio).

Feed:gain ratio The term used in commercial aquaculture to express the quantity of feed required to produce a given weight gain; it is the reciprocal of feed efficiency.

Heat of combustion The heat produced when organic material is completely oxidized in an oxygen atmosphere to yield carbon dioxide, water, and oxides of nitrogen and sulfur; it is usually measured using a bomb calorimeter, and referred to as the gross energy of a feed or feedstuff.

Herbivore An animal that feeds exclusively on plants.

Homeotherm An animal that maintains a more or less constant body temperature regardless of external temperature variations; it is generally endothermic, being able to generate its own body heat.

Lipids Group of naturally occurring hydrophobic compounds including fats, oils, waxes, phospholipids, and others.

Macronutrients Substances required in relatively large amounts for normal growth and development; the macronutrients present in animal feeds are the proteins, lipids, and carbohydrates.

Maintenance requirement The amounts of food, or specific nutrients, needed to meet metabolic requirements, without any gain or loss of body weight; it is the level of intake that provides for the continuation of life processes but allows for no increase in biomass.

Metabolic rate A measure of the rate of metabolic activity within an organism; it is the rate at which an organism uses energy to sustain life processes. It is most usually measured as heat production or oxygen consumption (sometimes together with carbon dioxide production), but the latter only gives an estimate of the contribution of aerobic metabolism.

Metabolism An integrated network of biochemical reactions that occurs in living organisms; the biochemical processes by which the absorbed nutrients are transformed and stored (anabolism), broken down and energy made available for the performance of work (catabolism).

Micronutrient Nutrients needed in very small amounts.

Nitrogen-free extract (NFE): One of the six fractions in the system of proximate analysis; it is calculated by difference when the sum of the percentages of moisture, crude protein, ether extract, ash, and crude fiber is subtracted from 100. NFE is a complex mixture of compounds that may include cellulose, hemicelluloses, lignin, sugars, starch and pectins, organic acids, resins and tannins, pigments, and water-soluble vitamins.

Nutrient A substance used by an organism for maintenance, growth, and reproduction; it is designated as macronutrients (proteins, lipids, and carbohydrates) and micronutrients (vitamins and trace elements), depending upon the amounts required.

Nutrient requirement Minimum amount of a nutrient that is needed for the maintenance of growth, health, and reproduction, with no safety margin.

Omnivore An animal that feeds upon a mixed diet comprising both plants and animals.

Phytate Hexaphosphoinositol, the phosphate derivative of the sugar alcohol inositol, is found in plant seeds as the main storage form of phosphorus; fish are unable to digest phytate so the phosphorus is not bioavailable; phytate can inhibit the action of digestive enzymes, and can chelate with di- and trivalent metal ions, thereby reducing their biological availability; it is considered an important anti-nutritional factor (ANF) in plants used to manufacture fish feeds.

Poikilotherm An organism that cannot regulate body temperature except through behavioral means. An animal whose body temperature fluctuates with that of the environment.

Protease inhibitor A substance, often a protein (such as the trypsin inhibitors), that inhibits the actions of proteolytic enzymes, thereby reducing the efficacy with which an animal can digest protein.

Protein An organic molecule consisting of chains of amino acids, and containing chiefly C, H, O, N, and S. One or more polypeptide chain may comprise it, and such chains may also be associated with nonprotein components (prosthetic groups). It is essential in living organisms as enzymes and structural constituents of tissues.

Secondary metabolites (compounds) Compounds produced by microbes, plants, and some animals (e.g., antibiotics, alkaloids, and tannins) that are usually not essential to the growth of the organism, but may have other functions, for example, in chemical defense.

Spectroscopy Encompasses a range of techniques for acquiring information about atomic and molecular structure via the study of patterns of absorption or emission of electromagnetic radiation. Near-infrared spectroscopy is a technique that is used for the rapid analysis of the chemical composition of feeds and feedstuffs, and instruments that measure either reflectance (NIRS) or transmission (NIT) have been developed.

Tannins These are complex, soluble, phenolic secondary metabolites that play a prominent role in the general defense strategies of plants. They are believed to be by-products of the metabolism of the aromatic amino acid phenylalanine.

Vitamins These are organic compounds required by animals in small amounts for the maintenance of a variety of metabolic functions; these are classified as lipid soluble (vitamins A, D, E, and K) or water soluble (ascorbic acid, myo-inositol, choline, and the vitamin B complex). Vitamins are essential nutrients that must be obtained via the diet, and a lack of a vitamin will lead to the development of a deficiency disease.

Animal Bioenergetics

Experiments in bioenergetics were first carried out during the eighteenth century, and eventually the discipline matured to the stage where it was applied to solve problems within human and animal nutrition. This role for bioenergetics was initiated early in the twentieth century. Bioenergetics has been widely applied in animal science, where one of the major aims is to produce edible muscle. Interactions between farmed animals and their environments are often stressed, with research focusing on:

- the relationships between gas exchange and heat production;
- examination of the causes of energy expenditure, and the costs associated with the performance of various activities; and
- the establishment of a basis for the evaluation of feed ingredients and compound feeds in relation to energy requirements and expenditures.

The results of these various lines of research have been used to estimate the energy requirements of farmed animals, to predict the growth of animals on different feeding regimes and to assist in the development of compound feeds for terrestrial livestock and farmed aquatic animals. A major goal of aquaculture is the effective production of edible fillet (myotomal muscle), so it is important to know about the interactions of environmental and nutritional factors on muscle development and growth (**Figure 1**). Modern bioenergetics studies can increase this understanding.

Defining Bioenergetics: Energy Flow and Partitioning

Bioenergetics is the quantitative study of energy partitioning induced by the metabolic processes that occur in organisms for them to stay alive, grow, and reproduce; it includes events taking place at the

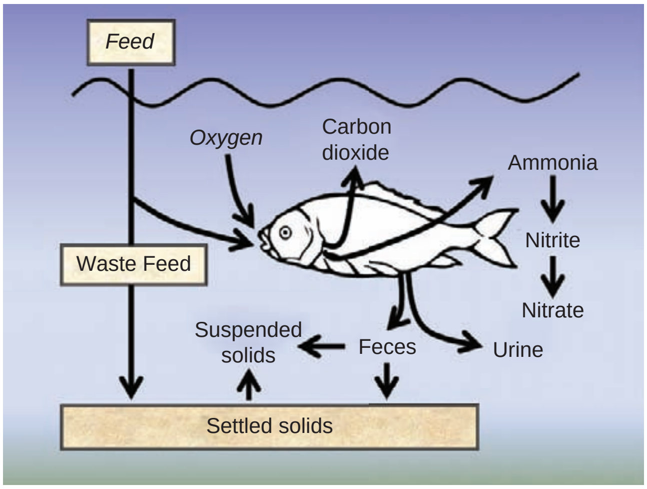

Figure 1 Two-way interactions between farmed fish and the environment may have marked influences upon the characteristics of the water (i.e., water quality) in which they are held. Adapted from Le Francois et al. (eds.) (2010) *Finfish Aquaculture Diversification.* Wallingford: CABI.

molecular and cellular level, as well as those that can be studied in whole organisms, populations, or ecosystems. In the broadest sense, a descriptive factorial scheme (**Figure 2**) can depict the fate of energy intake, and mathematical modeling or graphical representation can be used to investigate thef interrelationships among energy intake, metabolism, and energy retention.

Animals expend energy in the performance of physical activity, but even when resting animals may expend a considerable amount of energy to maintain the metabolic integrity of their body functions. For example, there is transport of substrates and metabolites in and out of cells, and chemical work is needed for tissue renewal and repair; the latter involves the turnover of proteins and the biosynthesis of lipids and carbohydrates (**see also Energetics**: General Energy Metabolism).

Retained Energy
PRODUCTION (P) Somatic growth Fat reserves Gametes (reproduction)

Figure 2 Flow diagram illustrating the factorial scheme of energy partitioning and dissipation in the study of animal energetics.

How much energy animals are required to expend, and how much of their energy intake they retain as production is under the influence of a wide range of environmental factors (**Figure 3**; **see also Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism). The environmental factors can be broadly divided into two main types, abiotic and biotic. Abiotic factors are those that relate to the nonliving, physical environment. For fish, and other aquatic animals, the abiotic factors include temperature, light intensity and day-length

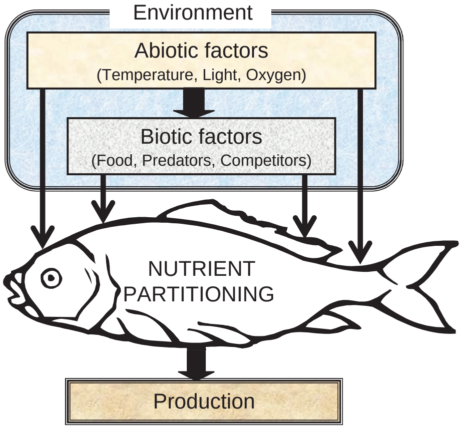

Figure 3 A wide variety of biotic and abiotic environmental factors influence energy partitioning and production of fish.

(photoperiod), oxygen concentration, water flow and currents, salinity, and other chemical properties of the water in which the animals live. The biotic factors, on the other hand, relate directly to the effects that organisms sharing habitats have on each other; biotic factors include the prey, predators, competitors, and parasites of the fish.

A Simple Model of Energy Partitioning

Food energy (C) is gross intake, usually expressed as a daily rate, but not all of this is available to the fish. Some is voided in the feces (F), and there are also losses as urinary excretion (U) and via diffusion from the body surface, including the gills of fish. From this, two quantities can be defined: digested and absorbed energy (D_E) and metabolizable energy (M_E) (**Figure 2**). D_E is the difference between food energy and fecal losses (i.e., $D_E = C - F$). M_E is the difference between food energy and the sum of losses in the feces, urine, and across the body surface, so $M_E = C - (F + U)$. In other words, M_E is the energy available for meeting the demands for staying alive, and for growing and reproducing.

The metabolic expenditure by an animal is often measured as the amount of heat produced (**see also Energetics**: General Energy Metabolism); this is usually called respiration (R). The difference between M_E and R is retained energy, usually termed production (P): $M_E - R = P$. When an animal is deprived of food ($C = 0$), body tissues are catabolized in order to support R, P is negative, and the animal loses body mass. On the other hand, if an animal eats some food but energy retention is zero over time (i.e., $P = 0$), there is an equilibrium and the animal is meeting its maintenance requirement (**Figure 4**).

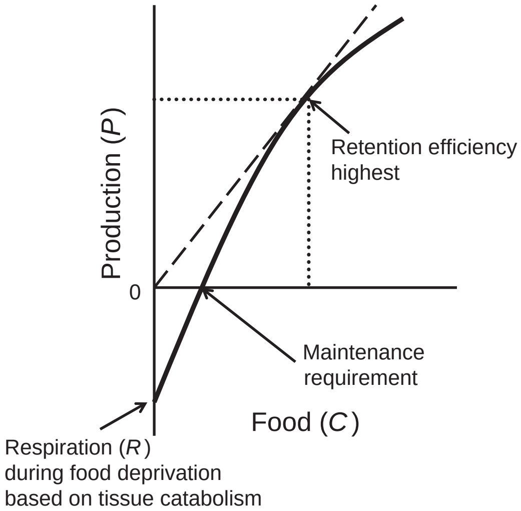

Figure 4 The relation between production and food intake, illustrating key points relating to energy retention.

As C increases so does R; R is greater at maintenance than it is in animals that are deprived of food, and as C increases above maintenance, R continues to increase. In a growing animal, an increase in C results in a proportion (r) of M_E being retained as P and a proportion $(1 - r)$ being lost in respiration (R). In other words, r is a measure of the efficiency with which energy is retained as production, or the energy utilization efficiency. Energy utilization efficiency is not constant but varies with the amount of food consumed. If the relationship between P and C is nonlinear, retention efficiency is highest at the point where a line drawn through the origin intersects with the plotted line that depicts the relationship between P and C (**Figure 4**). The efficiency with which C is retained as P is usually expressed as a percentage, the food conversion efficiency. In farming practice, the reciprocal of food conversion efficiency is sometimes used, that is, the amount of food required to produce a given unit of production or gain, the feed:gain ratio.

Units of Measurement

Bioenergetics is the study of biochemical transformations using units of energy as the common currency. In common parlance, for example, when we are undergoing weight reduction regimens we will often say that we are watching, or counting, our calories; the calorie is a unit used to measure energy, but the joule (J), an SI unit, has replaced the calorie in the scientific literature. The joule is named after James Prescott Joule, who was the first to demonstrate the equivalence of heat, work, and the various forms of chemical energy. The kilojoule ($1\ \text{kJ} = 10^3\ \text{J}$), rather than the joule, is most often the unit of choice in studies of animal energetics ($1\ \text{kJ} = 0.239\ \text{kcal}$; $1\ \text{kcal} = 4.186\ \text{kJ}$).

Bioenergetics involves the examination of biological rates, and power units (the watt in the SI system) are the appropriate ones to use when referring to such rates. The convention, however, is to retain the kilojoule and express rates in direct relation to periods of time. For example, food consumption is generally expressed as kilojoules per day (kJ d^{-1}) and energy expended on activity as kilojoules per hour (kJ h^{-1}).

Although bioenergetics relies upon energy units as common currency, it must be borne in mind that animals eat, digest, absorb, and metabolize food that is made up of chemicals. Animals have a requirement for, transform, and store macronutrients (proteins, lipids, and carbohydrates) and micronutrients (vitamins, minerals, and trace elements). As such, nutritional energetics revolves around the investigation of the absorption, biochemical transformation, and partitioning of nutrients. In the study of fish bioenergetics, the focus is most often on the fluxes and fates of energy, proteins, and lipids (**see also Energetics**: General Energy Metabolism).

Chemical Analyses and Energy Determination

Assessments of the chemical composition and energy value of feedstuffs, feeds, and animals are central to the study of the energetics and nutrition of farmed animals, including fish. The major energy sources in feeds are the organic macronutrients: lipids, proteins, and carbohydrates. These can be completely oxidized in a bomb calorimeter to yield carbon dioxide, water, oxides of nitrogen and sulfur, and heat. The three macronutrients yield different amounts of heat energy when completely oxidized: approximately 39 $\mathrm{kJ\,g^{-1}}$, 23.5 $\mathrm{kJ\,g^{-1}}$, and 17 $\mathrm{kJ\,g^{-1}}$ for lipids, proteins, and carbohydrates, respectively.

Chemical composition is measured using a variety of techniques. Some methods enable determinations to be made of individual amino acids, fatty acids, vitamins, and mineral elements, but the chemical analyses undertaken are not usually so comprehensive. Chemical composition is most frequently given as proximate composition in which six major fractions are recognized: moisture, crude protein, ether extract, ash, crude fiber, and nitrogen-free extract. Proximate analysis is time consuming and expensive, large samples are required, and the analyses are destructive. Alternatives can provide quick, nondestructive, quantitative assessments of the constituents of biological materials. These include X-ray computed tomography, total body electrical conductivity, near-infrared reflectance spectroscopy (NIRS), and near-infrared transmittance. NIRS has attained popularity because it is rapid and nondestructive, equipment costs are relatively low and the equipment is quite easy to use. NIR spectra can give information about physical and chemical properties, and NIRS is being used for assaying the chemical composition (protein, moisture and oil/fat) of feed ingredients, feeds and animal tissues, for species identification and for food authentication purposes.

Energy Budgets: Growth Trials and the Biological Evaluation of Compound Feeds

Chemical analyses provide a great deal of information about the nutritional properties of feeds, but biological trials are required to reveal the full value of feeds and their ingredients. For example, studies of digestion and absorption are required for the assessment of the bioavailabilities of nutrients to fish. Moreover, growth trials are fundamental for feed assessment, and for the determination of nutrient requirements. When conducting growth trials for feed assessment, it is seldom that data relating to all components of the energy balance equation are collected. Emphasis is usually placed upon the monitoring of food intake (C), fecal losses (F), and the energy and nutrients retained as production (P). Practical problems relating to the measurement of respiration (R) and excretion (U) over prolonged periods of time often preclude their inclusion in the assessment (**see also Energetics**: General Energy Metabolism).

Although neither R nor U is usually monitored in growth trials, their importance in determining the outcome of trials is recognized. For example, mammals and birds are homeothermic endotherms, whereas fish are poikilothermic ectotherms; these animals differ in metabolic characteristics and rates of energy expenditure. Homeothermic endotherms generate body heat and maintain a body temperature that differs from that of the environment. They have high metabolic rates and their maintenance requirements are high; if deprived of food, they lose body mass rapidly, and they have low starvation resistance (**Table 1**). Given that mammals and birds have relatively high maintenance requirements, the proportion of feed nutrients directed toward production may be low and so these animals are generally characterized as having relatively low retention efficiencies. Fish, being poikilothermic ectotherms, have a body temperature that changes as environmental temperature changes, and the main source of their body heat is the environment. Fish have lower metabolic rates than mammals and birds of similar size, and the maintenance requirements of fish are accordingly low. Fish are relatively efficient at converting food to body tissue, and have higher retention efficiencies than do mammals and birds of similar size.

Table 1 Comparison of metabolic characteristics and growth efficiencies of fish (poikilothermic ectotherms) and mammals (endothermic homeotherms)

	Fish	*Mammals*
Metabolic rate	Low	High
Starvation resistance	High	Low
Maintenance food requirement	Low	High
Food use for growth	High efficiency	Low efficiency

This comparison between mammals, birds, and fish can be extended to include generalizations about nutritional requirements and feed compositions. Most farmed mammals and birds are either herbivorous or omnivorous, and they are capable of digesting and metabolizing feeds that contain high concentrations of complex plant carbohydrates. Feeds formulated for these animals, such as poultry and pigs, usually have high carbohydrate content and relatively low protein and lipid contents (**Table 2**). Carbohydrates are an abundant and inexpensive energy source, so poultry and pig feeds are largely comprised of relatively cheap feed ingredients. In contrast to terrestrial farmed animals, many of the high-value, intensively farmed fish species are carnivorous. They are unable to digest and metabolize large amounts of dietary carbohydrate. These carnivorous fish rely upon feeds that contain relatively high proportions of proteins and lipids. Feed ingredients that contain these nutrients are more expensive than those that are rich in carbohydrate. Consequently, fish feeds are typically more expensive than those prepared for terrestrial livestock.

Monitoring Feed Intake

Effective feeding of farmed fish poses several problems not encountered when feeding terrestrial livestock. The feeds are exposed to water prior to being ingested, so they must be water stable with minimal loss of nutrients. Disintegration of feed will make it unavailable, and leads to undesirable water fouling. In addition, feeds should have physical and chemical characteristics that make them easy to detect and capture. As such, attempts are usually made to manufacture feeds that float at the water surface, or sink through the water column at prescribed rates that suit the fish's feeding preferences. A large proportion of the cost of aquaculture production is related to feeds and feeding, so feeds must be correctly formulated, and the quantities given to the fish should meet demand, without excessive wastage.

There are numerous factors that interact to influence feeding (**Figure 5**). Therefore, it is extremely difficult to predict when and how much a fish will eat. On intensive fish farms, feeding is usually highly automated, and several types of feeding systems have been developed. On-demand feeders are designed to circumvent problems arising from the unpredictability of feeding responses. The purpose of using on-demand feeders is to feed the fish effectively by presenting feed at the correct time and in sufficient quantity. On-demand feeders operate on the principle that both the timing and quantities of feed released are controlled by the fish: on-demand feeders are either self-feeders or interactive feeding systems.

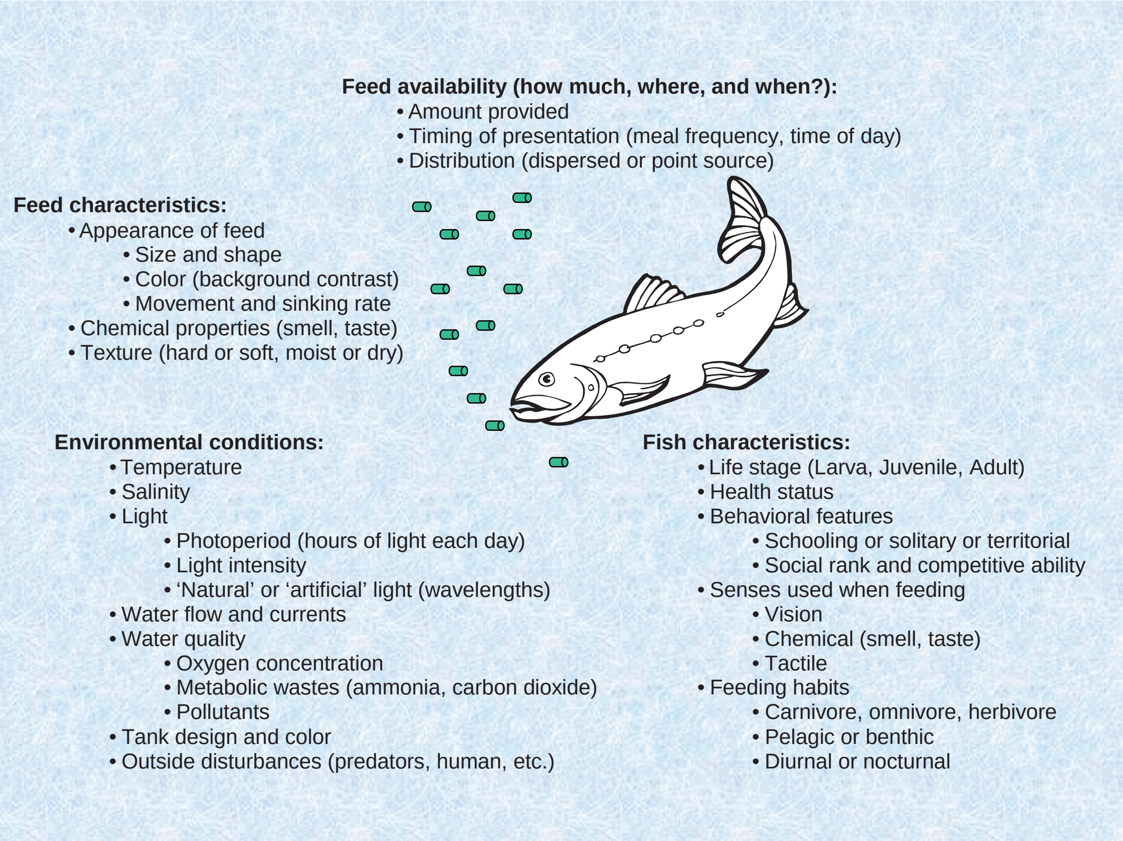
When self-feeding, the fish control the delivery of feed by activating a trigger system. The trigger is activated either by the fish biting on, or displacing, the tip of a rod, or by pulling on a small bead or pellet-shaped object attached to a string. When the fish activates the triggering system, a portion of feed is released from a hopper.

Interactive feeding systems usually rely upon the detection of waste feed to control the amount delivered. The fish are provided with feed at regular intervals and registration is made as to whether or not the feed is consumed. This may be done by direct observation of the feeding responses of the fish, by following the fate of feed pellets using video recording, or by using special optical (infrared) or hydroacoustic (sonar or Doppler) sensors to monitor the distributions of the fish or detect uneaten pellets. Feed delivery is stopped or modified according to feedback signals from the sensor system, so the delivery of feed is controlled in relation to the willingness of the fish to eat.

When feed assessment studies are conducted, it is important to collect accurate information about food intake. Measurements are usually made by combining automatic feeding with the collection of waste feed to get information about the amount of food eaten by a

Table 2 Comparisons of feeding habits and feed compositions of selected terrestrial livestock species and farmed fish

	Terrestrial livestock (pigs and chickens)	*Carps and tilapias*	*Salmonids and sea basses*
Feeding habits	Omnivorous	Herbivorous Omnivorous	Carnivorous
Metabolic substrates	Carbohydrates Fats	Carbohydrates Fats	Fats Proteins
Feed components (nutrient composition)	High carbohydrate Low protein (*c*. 20%) Low fat (*c* 10%)	High carbohydrate Medium protein (*c*. 30%) Low fat (*c*. 10%)	Low carbohydrate (up to *c* 20%) High protein (38+%) Medium-to-high fat (up to *c* 35%)
Feed costs (per kg feed)	Low Cheap ingredients with high carbohydrate content	Low-to-medium	High Expensive protein-rich ingredients



Feed availability (how much, where, and when?):
• Amount provided
• Timing of presentation (meal frequency, time of day)
• Distribution (dispersed or point source)
Feed characteristics:
• Appearance of feed
• Size and shape
• Color (background contrast)
• Movement and sinking rate
• Chemical properties (smell, taste)
• Texture (hard or soft, moist or dry)
Environmental conditions:
• Temperature
• Salinity
• Light
• Photoperiod (hours of light each day)
• Light intensity
• 'Natural' or 'artificial' light (wavelengths)
• Water flow and currents
• Water quality
• Oxygen concentration
• Metabolic wastes (ammonia, carbon dioxide)
• Pollutants
• Tank design and color
• Outside disturbances (predators, human, etc.)
Fish characteristics:
• Life stage (Larva, Juvenile, Adult)
• Health status
• Behavioral features
• Schooling or solitary or territorial
• Social rank and competitive ability
• Senses used when feeding
• Vision
• Chemical (smell, taste)
• Tactile
• Feeding habits
• Carnivore, omnivore, herbivore
• Pelagic or benthic
• Diurnal or nocturnal

Figure 5 The wide variety of factors that influence feeding in fish make prediction of food intake extremely difficult. From Le Francois et al. (eds.) (2010) *Finfish Aquaculture Diversification.* Wallingford: CABI.

group of fish. Techniques are also available that enable the food intake of individual fish to be monitored.

Assessment of Nutrient Bioavailability

Realistic assessments of feeds require that information is collected about the digestion and absorption of nutrients, that is, measurement of nutrient bioavilability is an important aspect of feed evaluation. In principle, $D_E = C - F$, so information about both C and F is required for the calculation of D_E. It is difficult to collect accurate information about food consumption and it is virtually impossible to collect all of the feces produced by fish during a growth trial. This means that D_E cannot be measured directly, and alternative indirect marker methods must be used for the estimation of nutrient bioavailability.

Many ingredients are used for preparing fish feeds. Some feed ingredients are now in short supply and are being replaced by alternatives. In particular, there is increased replacement of animal proteins, such as fish meal, with terrestrial plant proteins. The replacement of animal proteins with plant proteins presents several problems, particularly in feeds for carnivorous fish. Feeds given to carnivorous fish usually contain at least 38% protein, limiting the use of ingredients that contain moderate amounts of protein; plant protein sources usually have less protein than do animal products. Consequently, fractionation of plant materials is often carried out to increase the protein concentration in the feed ingredient.

In addition to their low protein concentration, many plants contain secondary compounds that reduce their value as feed ingredients. These compounds act as antinutritional factors (ANFs) by suppressing feeding or by interfering with the digestion, absorption, and utilization of nutrients. ANFs may interfere with protein digestion and absorption, bind to minerals and reduce their bioavailability, act as anti-vitamins, interfere with metabolic pathways, or disrupt endocrine signaling. The ANFs include protease inhibitors, alkaloids, tannins, phytate, and plant fibers. Some ANFs are heat labile, so thermal processing may be used to destroy them. ANFs present in the outer hulls or seed coats of plants may be removed and deactivated using de-hulling and heat treatment. Other ANFs are more resistant, and their removal or destruction may require treatment of plant materials with organic solvents or enzymes. Thus, a range of processing and fractionation technologies, including dehulling, heat treatment, enzyme treatments, aqueous or organic solvent extraction, and protein purification, may be applied to plant products to increase their value as feed ingredients.

Metabolic Rates: Energy Expenditure and Rates of Nitrogenous Excretion

There are many biotic and abiotic factors that influence energy expenditure and rates of excretion of poikilothermic ectotherms; temperature, oxygen availability, activity, and feeding are among the most important (**see also Energetics**: General Energy Metabolism and **Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism). For example, an increase in environmental temperature results in an increase in energy expenditure that is reflected in an increase in oxygen consumption. Aquatic hypoxia is a state of reduced oxygen availability. In fish farming, attempts are made to minimize exposure of fish to hypoxic conditions to avoid the negative effects this has on feeding, energy expenditure, and growth.

Increases in swimming speed result in increases in rates of energy expenditure (**see also Swimming and Other Activities**: Energetics of Fish Swimming). Given the high energetic cost of activity, it is surprising that fish of some species grow faster and more efficiently when swimming against a modest water current than they do when reared in tanks with less pronounced water flows. This is most probably related to behavioral changes that result from exposure of fish to flowing water. The fish often form schools, and do not spend as much time and energy on exploratory activities and aggressive behaviors when engaged in directed swimming activity.

Energy expenditures of fed fish are higher than those of fish deprived of food; fed fish may be more active than unfed fish and this may contribute to their elevated metabolic rates. Food search and capture may lead to some increase in energy expenditure, but metabolic rates are elevated whenever there is food in the gut; metabolic rates are usually highest a few hours after feeding has ceased. As such, the increase in energy expenditure that follows feeding may largely result from the energy requirements for

- physical processing of food, digestion, and the absorption of nutrients;
- biosynthesis, turnover, and deposition of tissue macromolecules; and
- deamination of amino acids and synthesis of excretory products.

Following the ingestion of food there is an increase in motor activity of the gut, and digestion and absorption involve the synthesis and secretion of digestive enzymes and transport of nutrients across the gut wall; all result in increased energy expenditure. Tissue constituents are in a dynamic state; quite a large proportion of the energy expenditure associated with the ingestion of food is related to turnover, synthesis, and deposition of macromolecules (primarily protein, but also lipids and carbohydrates; **Figure 6**; **see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation. Rates of nitrogenous excretion also increase following feeding, so amino acid deamination and the synthesis of nitrogenous excretory products contribute to energy expenditure. Fish excrete most of their waste nitrogen as ammonia, that is, they are ammonotelic. Ammonia excretion increases following feeding and protein-rich feeds induce greater ammonia excretion than feeds of lower protein content. Although fish mostly excrete ammonia, they also excrete some urea, amino acids, uric acid, creatine, and creatinine; the amounts of the different nitrogenous compounds excreted vary with species and life-history stage, feeding conditions, feed composition, and environmental factors (**see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation).

Growth and Nutrient Retention Efficiency

Feeds are evaluated according to whether or not they are utilized effectively to sustain production. Information is collected on feed composition, amounts eaten, and animal production, and used to calculate how efficiently nutrients are retained. The calculation of an efficiency requires that there is both a numerator and a denominator, and it is imperative that the terms and units in which both are expressed are clear. The numerator is production and the denominator is feed consumption, but expressions of retention efficiency differ in sophistication and complexity. The crudest expression of retention efficiency sets the weight gain of the animal as the numerator and the weight of feed consumed as the denominator. This is an unsatisfactory estimate because it takes no account of possible differences in energy concentrations and chemical compositions between the feeds and the animals that consume them.

If the aim is to express retention efficiency in terms of energy or a specific nutrient, such as protein, it is essential to have information on the chemical compositions of each feed and of the animals at the beginning and end of a growth trial. Once information on chemical composition has been obtained, the numerator is either the energy or amount of nutrient accrued as production, and the denominator is feed consumption expressed in appropriate terms. The units expressing feed consumption can be the weight of a given nutrient that has been eaten, the total amount of gross feed energy consumed, consumption expressed in terms of digested and absorbed nutrients or energy, or the amount of metabolizable energy consumed by the animal.

Figure 6 Food nutrients induce changes in gene activation and transcription, protein synthesis and turnover and nutrient metabolism. Transcriptomic (gene expression profiling), proteomic (protein expression analysis), and metabolomic (metabolite composition analysis) monitoring provide holistic assessments of these changes.

Many expressions are used to describe the efficiency of animal production. This can cause confusion, and it also means that care must be exercised when comparing results among studies to ensure that the metrics and estimates are equivalent and comparable.

Past and Future

The biochemical transformations that sustain life and support production are a form of combustion, and this is the basis of bioenergetics. This discovery paved the way for experiments that combined the study of food digestion and absorption with measurements of heat loss, energy expenditure, production, and energy retention. These studies contributed to the development of schemes used to predict animal performance and food requirements, and provided guidelines for use in feed formulation. As such, bioenergetics is established as an important area of applied animal sciences.

On the negative side, the focus on energy as the common currency may overshadow the facts that nutrients have different fates within the animal body, and that energy partitioning is governed by how the different nutrients are transformed during their progress through metabolic pathways. In-depth understanding requires knowledge about the roles of specific nutrients and their metabolism, but such knowledge is fragmentary for the nutritional energetics of fish. This type of information must be obtained if dynamic response models are to be updated and improved in the face of new challenges. These challenges include concerns about the environmental impacts of farming systems, shortfalls in supplies of some traditional feed ingredients, an increased focus on product quality, and the pressure to develop production systems that are sustainable in the long term.

The applied animal sciences have now entered the '-omics' era: genomics, transcriptomics, proteomics, and metabolomics (**Figure 6**). The techniques developed in support of these disciplines provide powerful tools for the examination of the biochemical networks involved in metabolic regulation. These '-omics' disciplines integrate to provide a holostic overview of the information stored in the genes, the biochemical transformations resulting from enzymatic activity and the actions of metabolic hormones, and compositional changes that accrue from the retention and elimination of metabolites. This integration provides new insights into the factors that control the need for, and use of, nutrients and energy that are a prerequisite for the advance of nutritional energetics. For example, '-omics' techniques make it possible to study the effects of abiotic factors and nutrients on the activation or suppression of genes that code for metabolic enzymes, examine effects on protein translation, and discern rates of nutrient fluxes through metabolic pathways. Metabolomics allows mapping of the fates of nutrients via global monitoring of the metabolites present within cells and tissues. Such studies may lead to the identification of biomarkers that could have utility in growth trials, and the identification of specific nutrients that exert strong biological effects. Further, the large data sets generated by the '-omics' technologies, together with bioinformatics (analysis of metabolic pathways using a systems biology approach), are expected to instigate development of mathematical models to describe and predict the cellular responses to nutrients. This, in turn, should allow progress toward solving several of the problems facing the animal production industries.

Respiration The metabolic process by which an organism assimilates oxygen and releases carbon dioxide and other products of oxidation.

Fish Bioenergetics Modeling in Ecosystems: An Overview

The laws of thermodynamics apply to the energy budgets of fishes (**see also Energetics**: General Energy Metabolism). Because energy is conserved, the amount of energy ingested by a fish should equal the sum of the total energy expenditures by the fish, the fish's growth, and waste heat production. The components of the fish's energy budget can be measured independently. Laboratory studies have played an important role in quantifying the various energy expenditures of fish (**see also Energetics**: General Energy Metabolism). Of all of the components in the fish's energy budget, fish growth is typically the component most easily measured. For fish populations in aquatic ecosystems, growth trajectories can be determined by sampling fish from the aquatic ecosystem and then weighing and aging these sampled fish.

Consumption of food by fish is not measured easily in the field (i.e., in lakes, rivers, and oceans). The traditional approach for estimating food consumption in the field is to examine and weigh stomach contents of fish caught in the field, and then to apply knowledge of gastric evacuation rates to estimate food consumption rate. The amount of food found in a fish's stomach can be highly variable within a given fish population, and therefore a substantial amount of sampling is usually required to obtain representative estimates of food consumption rates. In addition, food consumption rates may change over time. Moreover, use of gastric evacuation rates to estimate consumption rate also represents a modeling step, and this modeling step may involve several assumptions as well. For example, evacuation rates vary as a function of fish temperature, which is generally variable and unknown. An alternative approach toward estimation of food consumption in the field is to apply a fish bioenergetics model.

Use of bioenergetics models to estimate food consumption by fish in aquatic ecosystems has provided insights into fish ecology, food-web ecology, and contaminant biology of fishes, as well as facilitated sound management of fisheries. The ability to estimate food consumption via bioenergetics modeling has enabled fishery scientists to identify important factors regulating fish growth and consumption in aquatic ecosystems. Estimation of food consumption, based on bioenergetics modeling, has also allowed ecologists to assess the role of fish in cycling nutrients such as nitrogen and phosphorus in aquatic ecosystems. The availability of nutrients influences the rate of primary production, which serves as the base of the food web. In addition, estimation of food consumption via bioenergetics modeling has aided toxicologists in evaluating the importance of various factors affecting accumulation of contaminants, such as polychlorinated biphenyls (PCBs) and mercury (Hg), in fish (**see also Toxicology**: The Toxicology of Metals in Fishes, and The Toxicology of Organics in Fishes). Estimation of food consumption by fish populations via bioenergetics modeling has allowed scientists to quantify the trophic link between predator and prey populations within the aquatic ecosystem, and this type of bioenergetics model application has had important implications for managing valuable fisheries.

---

[1] This article is Contribution 1616 of the US Geological Survey Great Lakes Science Center.

Fish bioenergetics models may also be applied to aquatic ecosystems to predict fish growth for a given rate of food consumption. Although this type of bioenergetics model application is not as common as using the bioenergetics model to estimate food consumption by fish, predicting fish growth for a given rate of food consumption has been used to better understand factors affecting growth of fish in lakes, rivers, and oceans (**see also Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism).

A Simple Energy Budget for Fish

A simple energy budget for fish can be written as

$$G = C - R - F - U - S \tag{1}$$

where G is the growth, C the consumption, R the respiration, F the egestion, U the excretion, and S the release of gametes (typically at spawning; **see also Energetics**: Energetics: An Introduction) (**Figure 1**). A fish takes in energy through food consumption (C). The fish expends energy via respiration (R), which is defined as the metabolic process by which an organism assimilates oxygen and releases carbon dioxide and other products of oxidation. The fish also loses energy through egestion (F), which is the expulsion of feces. Energy is also lost through excretion (U), which is the discharge of urine. When a fish matures, energy is also lost through the release of milt or eggs at the time of spawning (S). Subtracting all of the energy losses (R, F, U, and S) from the energy taken in via consumption yields the energy incorporated into fish growth (G). Using algebra, eqn (1) can be rewritten as

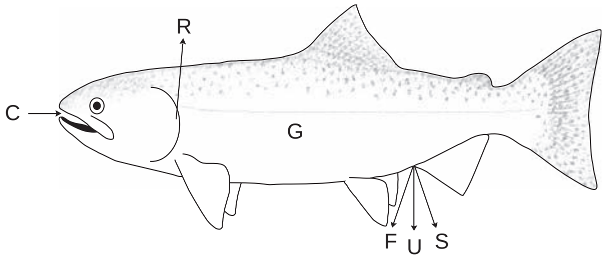

Figure 1 Diagram illustrating the energy budget for a fish. C, consumption; G, growth; R, respiration; F, egestion; U, excretion; and S, release of gametes at spawning.

$$C = G + R + F + U + S \tag{2}$$

where all of the terms are defined as in eqn (1). Summing the energy incorporated into fish growth with the various energy expenditure components yields consumption.

Wisconsin Bioenergetics Models for Fish

Beginning in the 1970s, researchers associated with the University of Wisconsin (UW) Center for Limnology (CFL) in Madison, Wisconsin (USA) have developed a suite of bioenergetics models for fish, and these models are generally called 'Wisconsin bioenergetics models'. A computer software package, prepared by a UW Center for Limnology research team, is available to the public. This software package includes bioenergetics models for a large variety of fishes: alewife (*Alosa pseudoharengus*), Atlantic herring (*Clupea harengus*), bloater (*Coregonus hoyi*), bluegill (*Lepomis macrochirus*), bluefish (*Pomatomus saltatrix*), burbot (*Lota lota*), coho salmon (*Oncorhynchus kisutch*), Chinook salmon (*Oncorhynchus tshawytscha*), dace (*Chrosomus* spp.), fishes of the family Coregonidae, lake trout (*Salvelinus namaycush*), largemouth bass (*Micropterus salmoides*), muskellunge (*Esox masquinogy*), Nile perch (*Lates niloticus*), northern pike (*Esox lucius*), pink salmon (*Oncorhynchus gorbuscha*), rainbow smelt (*Osmerus mordax*), sea lamprey (*Petromyzon marinus*), smallmouth bass (*Micropterus dolomieu*), sockeye salmon (*Oncorhynchus nerka*), steelhead (*Oncorhynchus mykiss*), striped bass (*Morone saxatilis*), tilapia (*Sarotheradon* spp.), walleye (*Sander vitreus*), walleye pollock (*Theragra chalcogramma*), weakfish (*Cynoscion regalis*), and yellow perch (*Perca flavescens*).

Typically, respiration is modeled as a function of fish weight and water temperature in these Wisconsin bioenergetics models. In some of these models, swimming speed is specifically included in the respiration component of the model, whereas an activity multiplier is included in the respiration component of other fish bioenergetics models. Egestion is modeled either as a function of consumption or as a function of both consumption and water temperature. Excretion is modeled as a function of consumption and egestion or as a function of consumption, egestion, and water temperature. Release of gametes is simulated by a fish losing a percentage of its body weight on the day of spawning. The time step for the Wisconsin bioenergetics models is typically 1 day.

To apply a Wisconsin fish bioenergetics model, four sets of information are required:

- water temperature regime experienced by the fish,
- diet composition of the fish,
- energy density of the fish's prey, and
- energy density of the fish.

These energy densities are used to determine the amount of energy contained in a given weight of the fish and its prey. The bioenergetics model is based on an energy balance (see eqns (1) and (2)), and therefore these energy densities are required for model application.

Each Wisconsin fish bioenergetics model can be applied in two different modes of operation:

- input fish growth to estimate consumption and
- input consumption rate to estimate fish growth.

In most cases, researchers are interested in estimating consumption, given a known amount of fish growth. However, in some instances, the researcher may be interested in predicting fish growth given a known consumption rate. Each Wisconsin fish bioenergetics model can be used to estimate consumption by a single fish or to estimate consumption by a population of fish. To apply the bioenergetics model to a population of fish, information on the population size and population mortality rate must be provided. Typically, when the bioenergetics model is applied to a single fish, the growth of the fish is chosen to be representative of an average fish within the fish population.

An Example of Fish Bioenergetics Modeling Guiding Fisheries Management

The classic example of fish bioenergetics modeling having an effect on fisheries management is the case of the stocking of salmonines (salmon and trout) into Lake Michigan (USA). The original top two native piscine predators in Lake Michigan were the lake trout and the burbot. Lake trout were extirpated from Lake Michigan during the 1950s, due to overfishing and sea lamprey predation. The sea lamprey, an invader from the Atlantic Ocean via the Welland Canal, also preyed on burbot, and this predation was responsible for the collapse of the burbot population during the 1950s. The alewife, a clupeid from the Atlantic Ocean, invaded Lake Michigan during the late 1940s. With a minimal amount of predator biomass in the lake, alewife abundance in Lake Michigan increased dramatically during the late 1950s and early 1960s, and peaked in 1966. Through lampricide treatments in tributary streams, sea lamprey abundance in Lake Michigan was greatly reduced during the early 1960s. A major salmonine stocking program for Lake Michigan was launched in 1965, with millions of Chinook salmon, lake trout, coho salmon, steelhead, and brown trout (*Salmo trutta*) stocked each year. Stocking of salmon and trout continues through today (2010) (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development, Lampreys: Environmental Physiology).

During the 1970s and early 1980s, researchers at the UW CFL developed bioenergetics models for salmon and trout, and then applied these models to populations in Lake Michigan. The results from these bioenergetics model applications revealed that estimates of annual consumption of alewives by salmon and trout populations in Lake Michigan increased from about 5000 metric tons in 1967 to over 50 000 metric tons by 1981. According to the modeling results, Chinook salmon were responsible for most of the annual consumption of alewives by Lake Michigan salmonines. The UW researchers then compared their estimates of annual consumption of alewives by salmon and trout in Lake Michigan with estimates of annual production of alewife biomass in Lake Michigan. From this comparison, these researchers estimated that Lake Michigan salmon and trout consumed as much as 33% of the annual alewife production in Lake Michigan in some years.

Based on the bioenergetics model results, the Center for Limnology researchers concluded that eventually the salmon and trout consumption would be sufficiently great to cause a substantial reduction in alewife abundance in Lake Michigan. These researchers warned managers of the recreational fisheries for Lake Michigan salmonines that the alewife population was headed for a collapse due to intense predation by the salmonines on alewives. Fishery managers from three of the four states surrounding Lake Michigan (Wisconsin, Illinois, and Indiana) responded to these warnings by reducing their stocking rates of Chinook salmon into Lake Michigan during the 1980s. Several additional Chinook salmon-stocking-rate reductions, with compliance from all four states (including Michigan), have been transacted during the 1990s and 2000s. Although alewife abundance in Lake Michigan has remained at relatively low levels during 1982–2008, when compared with abundances during the 1960s and early 1970s, the alewife population did not suffer a complete collapse during the 1990s or 2000s. The recreational fishery for Chinook salmon in Lake Michigan has remained an economically important fishery through the 2000s. Thus, from the standpoint of perpetuating the Chinook salmon fishery in Lake Michigan, these decisions to reduce Chinook salmon-stocking rates were effective decisions and were based on the results of bioenergetics modeling. The case of salmonine stocking in Lake Michigan clearly illustrates the utility of bioenergetics modeling in guiding fishery management decisions. Modeling studies on the dynamics of the

Lake Michigan alewife population and on Chinook salmon–alewife predator–prey interactions in Lake Michigan conducted during the 1990s and 2000s have corroborated the contention that Lake Michigan salmonines were exerting a strong predatory effect. Hence, the conclusion reached by UW Center for Limnology researchers in the 1980s concerning the strength of the trophic link between alewives and salmonines in Lake Michigan has been validated by subsequent studies.

Estimating the Strength of the Predator–Prey Trophic Link: Other Examples

Bioenergetics models have been used to estimate the strength of the predator–prey trophic link to quantify the predatory effect of introduced or invading fish populations on native fish populations. For example, bioenergetics modeling has been applied to the exotic Nile perch (*L. niloticus*) population in Africa's Lake Victoria to estimate annual consumption of endemic fishes by Nile perch. The Nile perch was introduced into Lake Victoria, where this piscivore fed on a variety of fishes, including the endemic haplochromine cichlids. Using bioenergetics modeling, researchers were able to estimate the degree of predation on haplochromines under various amounts of fishing mortality imposed on Nile perch. Consequently, this modeling exercise was useful in exploring various management strategies to reduce the predatory effect of Nile perch on the endemic haplochromines. In another example, bioenergetics modeling was used to estimate the annual consumption of native cutthroat trout (*Oncorhynchus clarki*) by the introduced lake trout in Yellowstone Lake (Wyoming, USA) and to evaluate the effectiveness of a lake trout-control program.

Bioenergetics models have also been used to quantify the predatory effect of native fish on invader populations. For example, dreissenid mussels invaded Lake Michigan (USA) and Lake Huron (Canada and USA) during the 1990s. A native benthivorous fish, the lake whitefish (*Coregonus clupeaformis*), has fed upon the dreissenid mussels in these two lakes. Bioenergetics modeling was applied to the lake whitefish populations in both lakes to determine the extent to which the lake whitefish populations were capable of reducing the population growth rate of dreissenid mussels. In another example, bioenergetics modeling has been applied to the burbot population in eastern Lake Erie (Canada and USA) to estimate its predatory effect on the round goby (*Neogobius melanostomus*), a benthic fish which invaded Lake Erie during the 1990s. The native burbot began to feed heavily on round gobies in eastern Lake Erie during the 2000s. Bioenergetics model results indicated that the burbot was the major contributor toward the predatory control of round gobies in the offshore waters of eastern Lake Erie.

Use of Bioenergetics Modeling to Better Understand Fish Growth and Consumption

Bioenergetics modeling can be applied to the average fish from a fish population to assess the effects of environmental factors on fish growth and consumption in aquatic ecosystems. For example, bioenergetics modeling has revealed that the faster growth of yellow perch in the central basin of Lake Erie compared with the western basin of Lake Erie was not due to a difference in water temperature between the two basins. Rather, the faster growth was attributable to greater availability of larger benthic invertebrate prey in central Lake Erie. In another study, bioenergetics modeling was used to determine if the relatively cold water temperature regime experienced by lake trout on Sheboygan Reef, a deep offshore reef in Lake Michigan (USA), was the primary factor for the slower growth of lake trout on Sheboygan Reef compared with lake trout from nearshore regions of Lake Michigan. Bioenergetics modeling results indicated that lake trout growth was not constrained by cold water temperatures on Sheboygan Reef. Rather, the low availability of small prey fish limited the growth of juvenile lake trout on Sheboygan Reef. A similar type of bioenergetics model application has shown that in most areas of the North Atlantic, growth of Atlantic cod (*Gadus morhua*) is not limited by cold water temperatures.

Bioenergetics modeling is well suited to address the effects of climate change on fish growth, because water temperature regime is an input to the bioenergetics model. Climate-change models can be used to predict future changes in water temperature. These predictions of water-temperature regimes can be used as an input to fish-bioenergetics models to generate predictions of changes in fish growth under various climate-change scenarios. For example, results from a modeling study indicated that growth rate of yearling largemouth bass in Lake Erie would increase by nearly of factor of 6 under a climate-warming scenario corresponding to the doubling of carbon dioxide in the Earth's atmosphere, provided that prey availability increased in accord with the increase in water temperature.

Bioenergetics modeling can also be used to estimate changes in fish-consumption rates due to changes in food supply. For example, the dreissenid-mussel invasions of Lake Michigan and Lake Huron are associated with declines in the abundance of a native amphipod *Diporeia*. Growth and condition of both alewife and lake whitefish have decreased in response to lower abundance of *Diporeia*, because this amphipod was an important component of the diet of both fishes. Bioenergetics modeling revealed that the overall feeding rate of alewives decreased during the dreissenid mussel invasion, whereas lake whitefish-feeding rate actually increased during the dreissenid mussel invasion. In addition, the bioenergetics modeling indicated that alewives did not compensate for lower *Diporeia* abundance by increasing their feeding rate on zooplankton. In contrast, lake whitefish fed on dreissenid mussels during the invasion at a rate higher than the rate at which lake whitefish fed on *Diporeia* before the mussel invasion.

Role of Fish in Cycling Nutrients in Aquatic Ecosystems: Bioenergetics Model Applications

Fish excrete nitrogen and phosphorus, two nutrients essential for the growth of phytoplankton and other aquatic plants. Phosphorus has been identified as the limiting nutrient for primary production in most freshwater ecosystems, whereas nitrogen is the limiting nutrient in many marine ecosystems. The phosphorus budget for a fish can be written as

$$P_U = P_C - P_G - P_F - P_S \quad (3)$$

where P_U is the phosphorus excreted, P_C the phosphorus consumed, P_G the phosphorus allocated to growth, P_F the phosphorus lost through egestion, and P_S the phosphorus lost through release of gametes at spawning. Knowing the phosphorus content in the urine of the fish, in the feces of the fish, in the somatic tissue of the fish, in the gonadal tissue of fish, and in the food of the fish, fish bioenergetics modeling can then be used to estimate the amount of phosphorus excreted by a population of fish within an aquatic ecosystem. In an analogous manner, fish bioenergetics modeling can also be used to estimate the amount of nitrogen excreted by a population of fish within an aquatic ecosystem. In addition, bioenergetics modeling can be used to estimate the degree to which a fish population can serve as a sink for phosphorus or nitrogen within an aquatic ecosystem.

Fish-bioenergetics-model applications have shown that certain fish populations play an important role in cycling nutrients within some aquatic ecosystems, while other fish populations have little effect on nutrient cycling within the ecosystem. For example, via bioenergetics modeling, excretion and egestion of phosphorus by the alewife population in Lake Michigan during the mid-1970s was estimated to be equivalent to the phosphorus regeneration by Lake Michigan zooplankton. Thus, alewives played an important role in phosphorus recycling within the Lake Michigan ecosystem during the mid-1970s. In another example, bioenergetics modeling revealed that populations of trout introduced into mountain lakes of the Sierra Nevada of California (USA) were regenerating phosphorus within the lakes at a rate approximately equal to the rate of atmospheric deposition of phosphorus into these lakes. Consequently, trout introductions into these mountain lakes had a substantial effect on the cycling of phosphorus within these lake ecosystems. In contrast, the round goby population in central Lake Erie was estimated to excrete less than 1% of the phosphorus needed by the benthic community for primary production. Thus, the bioenergetics modeling results indicated that the round goby invasion of central Lake Erie had very little influence on phosphorus cycling within the central Lake Erie ecosystem.

Contaminant Accumulation in Fish: Bioenergetics Model Applications

Bioenergetics modeling has been invaluable in identifying the major factors regulating contaminant accumulation in fish in aquatic ecosystems. For example, direct uptake of PCBs from the water into fish via the gills was once believed to be the major pathway of PCBs into fish living in lakes, rivers, and oceans. However, application of a bioenergetics model to Lake Michigan lake trout revealed that nearly all of the PCBs in adults entered the lake trout via food consumption. In addition, bioenergetics modeling has been used to quantify the effects of fish growth on rates of contaminant accumulation in fish. For example, female walleyes grow considerably faster than male walleyes, with mean weight at age for mature females ranging from 20% to 50% higher than that for mature males. Despite the substantially higher growth rate for females, bioenergetics modeling has shown that this higher growth rate for females will only account for roughly a 15% higher PCB concentration in males compared with same-aged females. This growth dilution effect is the phenomenon of faster-growing fish having lower contaminant concentrations than slower-growing fish, under equivalent conditions. Thus, bioenergetics modeling has shown that growth dilution typically accounts for only a modest proportion of the observed differences in fish contaminant concentrations.

Limitations to Fish Bioenergetics Model Applications

All mathematical models have limitations and caveats associated with their use, and fish bioenergetics models are no exception to this rule. Several problems with fish-bioenergetics-model applications have been identified. For example, values of several of the model parameters for a particular fish species may have been borrowed from the bioenergetics model for another fish species, and these borrowed values may not be appropriate for model application. In addition, fish activity may vary from one aquatic ecosystem to another, and therefore the preset fish activity level included in the bioenergetics model for a particular fish species may not be appropriate for every model application. Also, if fish are not properly acclimated to the respiration chamber in the laboratory, then their respiration rates may be elevated compared with normal conditions in the aquatic ecosystem (**see also Energetics**: General Energy Metabolism). If these elevated respiration rates are then incorporated into the fish bioenergetics model, then the bioenergetics model will overestimate consumption when applied to fish in aquatic ecosystems. Fish bioenergetics models should be evaluated in both the laboratory and the field to determine their reliability in estimating consumption and growth.

Glossary

Alphastat regulation Regulating the pH of blood and intracellular fluids in a manner that conserves the fractional dissociation state ($\text{alpha}_{\text{imid}}$) of the imidazole side-chains of histidyl residues of proteins.

Homeophasic adaptation Modification of the lipid composition of cellular membranes, notably in the head groups of phospholipids, to achieve conservation of the ability to form nonlamellar phases, which may be critical for endocytosis and exocytosis.

Homeoviscous adaptation Modification of the lipid composition of cellular membranes that achieves stability in the static order (fluidity) of the bilayer. Counteracts temperature-dependent changes in membrane fluidity (viscosity) mainly by changes in saturation level of fatty acids.

Noncovalent chemical bonds A diverse set of bonding interactions that do not involve sharing of electrons, but instead are based on polar effects, ionic interactions, hydrogen bonds, van der Waals interactions, and the hydrophobic effect. Noncovalent (weak) chemical bonds are primarily responsible for the higher orders of structure of large molecules – proteins, nucleic acids, and lipids. Noncovalent bonds have bond energies similar to the thermal energy of cells; so, they break and reform continually, giving proteins, lipids, and nucleic acids their intrinsic capacities to undergo conformational changes needed for function. The marginally stable structures established by reliance on weak bonds also make proteins, lipids, and nucleic acids highly sensitive to perturbation by temperature, hydrostatic pressure, pH, and the osmotic composition and concentration of biological fluids.

Orthologs Homologous genes (i.e., sharing a common evolutionary ancestor) that are found in different species.

Osmolyte A low-molecular-weight constituent of cells, including small organic molecules (amino acids, polyhydric alcohols, urea, and methylammonium compounds) whose concentrations are adjusted during osmoregulation to maintain cellular volume and establish an intracellular milieu compatible with optimal protein function.

Introduction

The diverse physiological capacities of fishes – including energy metabolism, locomotion, differentiation, growth, active transport, nerve-impulse conduction, and reproduction – are based on a set of biochemical processes and structures that are highly sensitive to perturbation by the environment, notably to conditions of temperature, hydrostatic pressure, osmotic composition and concentration, and pH. The success with which fishes have managed to sustain these biochemical capacities, while colonizing a vast range of habitats that differ in their physical and chemical properties, thus, is a reflection of pervasive adaptation at the biochemical level.

The purpose of this article is to present some general principles of adaptation that explain how these diverse biochemical systems succeed in functioning under widely different environmental conditions, thereby helping to support the remarkable diversification we find among the 25 000 or so species of fishes. The analysis is constructed around two distinct and complementary issues. First, the discussion is on how alterations in the abiotic (physical and chemical) environment perturb biochemical systems, thereby shifting key structural and functional properties of the systems into suboptimal ranges, where physiological function is compromised. Second, some general mechanisms of adaptation that account for the abilities of organisms to restore these perturbed systems to optimal states of structure and function are sketched out.

In developing this analysis, it will be necessary to define as rigorously as possible what is meant by ‘optimal’ values of structural and functional properties of diverse biochemical systems. Although this analysis might seem destined to head us into choppy philosophical waters, in fact, comparative biochemical studies during the past few decades have provided a basis for a sound, quantitative understanding of what ‘optimal’ means for a variety of biochemical systems. Studies of a taxonomically diverse suite of fishes and other animals from widely different habitat conditions have revealed striking patterns of conservation in the values of environmentally sensitive biochemical traits. These conserved values, which are examined in several systems and in a variety of stress-related contexts, serve as quantitative indices of how closely a biochemical system is poised to its optimal range of values, those at which physiological systems work best. These optimal values can be viewed, then, as the targets of the processes that underlie adaptation to environmental stresses.

Noncovalent Bonding as a Basis for Environmental Stress

All biochemical systems have higher-order structures stabilized by noncovalent bonds. These bonds are sometimes referred to as weak chemical bonds to indicate that their bond energies are of the same order of magnitude as the thermal energy of the system. Thus, these weak bonds continually form and break at biological temperatures. Despite their labile nature, noncovalent bonds are responsible for the formation and stabilization of the membrane bilayer, the conformations and assembly states of proteins, the binding of ligands to proteins and nucleic acids, and the capacities of nucleic acids to support closely regulated transcription of genes and translation of the resulting messenger RNA (mRNA) into proteins.

To one not familiar with the linkages between structure and function in these diverse molecular systems, it might seem puzzling as to why evolution has led to such a profound dependence on biochemical structures and reactions that are so intrinsically sensitive to perturbation by the physical (temperature and hydrostatic pressure) and chemical (ionic composition and pH) features of the environment and the cell. The most general explanation of this reliance on noncovalent bonds is based on the critical role that changes in molecular shape and organization have in most aspects of biochemical activity. The precision and sensitivity of all biochemical processes are based in large measure on reversible changes in the three-dimensional shape (conformation) and organizational state (e.g., assembly of different proteins linked to a common function) of lipids, proteins, and nucleic acids. Thus, all organisms face a common problem in coping with changes in the abiotic features of their environments: the properties of biochemical systems that give these systems their remarkable abilities to form the structures and drive the processes essential to life also render them highly sensitive to environmental change.

Optimal Values for Biochemical Systems: The Conservative Side of Adaptation

It follows from this analysis that the core, weak-bond-dependent biochemical systems responsible for cellular structure and function must adapt their properties to offset perturbation from the environment, so as to maintain these diverse systems in an optimal range for function. **Figure 1** presents a general model of what this conservative type of adaptive response achieves. Shown are the responses of homologous systems of a variety of species evolutionarily adapted to different values (low, medium, and high) of the environmental variable in question, to an acute change in this environmental factor. The responses could also be viewed in the context of acclimatization to environmental changes occurring during an individual organism’s lifetime. Even though each system exhibits a sharp response to an acute change in the environmental factor, at the normal range of environmental conditions

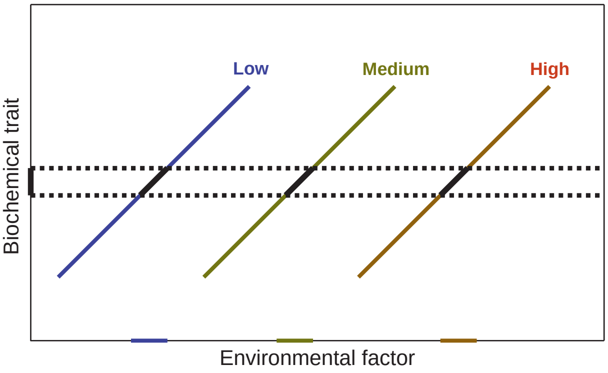

Figure 1 A model showing how an environmentally sensitive trait, such as one based on noncovalent bonds, in species adapted to different values of an environmental factor such as temperature is influenced by acute changes in this factor and by evolutionary adaptation or acclimatization. The three species (or three acclimatization states) illustrated, low, medium, and high, have highly conserved values for the trait in question at their respective adaptation or acclimatization conditions (thick line segments in response functions and on the abscissa). The conserved range is shown by dashed lines. These conserved ranges for traits are defined as optimal values for the trait.

experienced by the organism, either during its evolutionary history (genetic adaptation) or at the season in question (acclimatization), the value of the system is strongly conserved. Empirically, these conserved values are defined as optimal. What makes them optimal in terms of function and mechanism is discussed next in the context of each major class of large molecular systems.

Conservation of Protein Structure and Function

Proteins provide excellent illustrations of the conservative nature of biochemical adaptation portrayed abstractly in **Figure 1**. They likewise present fascinating examples of the complementary roles played by adaptive changes in a large molecule – here, in amino acid sequence – and in the milieu in which large molecules carry out their activities. As proteins are so strongly affected by changes in temperature, enzyme–temperature interactions, notably those involving binding reactions, provide a good starting point for this analysis (**see also Temperature**: Proteins and Temperature).

The initial step in an enzymatic reaction is the binding of ligands (substrates and cofactors) to the enzyme's catalytic site(s). Binding ability is usually quantified by determining the Michaelis–Menten constant (K_m) of the ligand, which is measured in units of substrate concentration (e.g., mmol L^{-1}) and equals the concentration of substrate or cofactor that is sufficient to cause the reaction to proceed at half-maximal velocity (V_{max}). Strong binding is indicated by a low value of K_m. For most enzymes, acute increases in temperature cause a loss of binding ability (increase in K_m) as shown in **Figure 2** for a glycolytic pathway enzyme, lactate dehydrogenase-A (LDH-A). Loss of binding ability with rising temperature is thought to be largely due to temperature-dependent changes in the three-dimensional configuration of the regions of the protein involved in ligand recognition. However, despite the acute effects of temperature change on binding, when comparisons of orthologs from differently temperature-adapted species are compared, a high degree of conservation of K_m is observed at the normal body temperatures of the species. These values of K_m can be regarded as optimal values for binding ability. (**see also Temperature**: Proteins and Temperature).

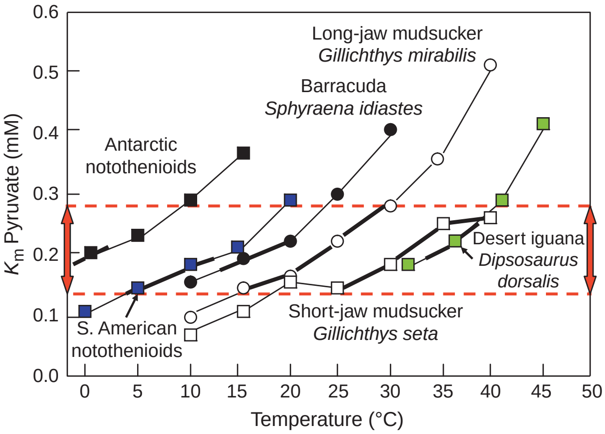

Figure 2 The effects of adaptation temperature and acute shifts in measurement temperature on binding of the substrate pyruvate (indexed by K_m^{pyruvate}) by orthologs of lactate dehydrogenase-A. Dark line segments illustrate K_m^{pyruvate} values at the physiological temperature ranges of the different species. The dashed lines and vertical thick arrows on the ordinates show the conserved range of K_m^{pyruvate} values for the species. Conservation of an Appropriate Internal Milieu

Organic Osmolytes

The osmolyte composition and concentration and the proton activity (pH) of intra- and extracellular fluids have strong effects on proteins. To a large degree, the changes in osmolyte composition and concentration that are observed during osmotic regulation and the fine-scale adjustments of pH made during acid–base regulation, and in response to shifts in body temperature, reflect the importance of conserving critical properties of proteins such as K_m. Discovery of the key roles of organic osmolytes in establishing an appropriate milieu for protein function and structure was an important achievement of comparative biochemistry over the past three decades. Although most of these studies have involved osmotically conforming marine and estuarine invertebrates, species that display wide variation in osmolyte composition and concentration in response to changes in external osmolality, the conclusions drawn from these studies apply to fishes as well, notably to osmoconforming marine elasmobranchs and hagfishes whose body fluids have osmolalities close to that of the surrounding medium.

Cells of osmoconforming marine invertebrates and hagfishes contain a suite of small organic molecules that individually have little or no effect on protein structure or function at physiologically relevant concentrations. These osmolytes thus are termed compatible osmolytes. In marine elasmobranchs and the coelacanth, a different strategy is found, the counteracting-solute strategy. Here, a mixture of urea, a protein denaturant, and methylammonium solutes such as trimethylammonium N-oxide (TMAO) and glycine betaine, which are potent stabilizers of proteins, is employed. When the appropriate ratio of urea to methylammonium solutes is present, there is no net effect on protein stability or function: the destabilization caused by urea is fully offset by the stabilization achieved by methylammonium solutes such as TMAO. Thus, the conservation of critical protein characteristics, such as ligand-binding ability and an optimal balance between protein stability and flexibility, can be achieved through accumulating either a suite of organic osmolytes that are inherently nonperturbing at physiologically relevant concentrations or a set of two or more types of osmolytes that have offsetting effects on protein stability and function.

The use of protein-stabilizing osmolytes, such as TMAO, is not restricted to the context of osmotic adaptation. Recently, Paul Yancey, the discoverer of the counteracting-solute mechanism, and colleagues showed that depth-related changes in osmolyte composition and concentration offset the effects of elevated hydrostatic pressure on proteins. TMAO not only can offset perturbation caused by a chemical, urea, it also offsets disruption of protein structure and function by a physical factor, hydrostatic pressure. Comparisons of the tissue-fluid compositions of bony fish collected at different depths revealed that the concentration of TMAO increased in a regular manner with increasing depth of occurrence (**Figure 3**). The effect of depth of occurrence on [TMAO] was seen among conspecifics collected from different depths as well as between species with different depths of occurrence, suggesting active depth-related regulation of TMAO. Other studies by Yancey and colleagues showed a similar trend in a variety of marine invertebrates collected at different depths. Elasmobranch fishes, too, showed an interesting trend: shallow-living species contained the canonical 2:1 ratio of urea to methylammonium compounds long noted in comparative studies of elasmobranches living in shallow habitats. However, with increasing depth of capture, the ratio shifted toward a more stabilizing mixture, that is, a lower [urea]:[TMAO] ratio. In species from the greatest depths sampled, the concentration of TMAO exceeded that of urea.

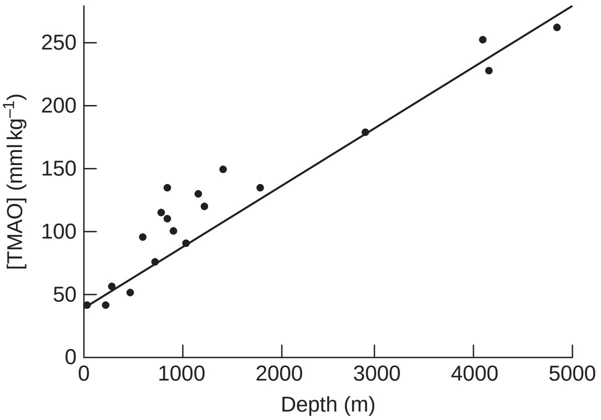

Figure 3 The relationship between depth of capture (m) and concentration (mmol kg^{-1}) of trimethylamine-N-oxide (TMAO) in a variety of marine bony fishes. The depth-related trend in concentration of TMAO is found among conspecifics collected at different depths as well as among different species of fish. Modified from Samerotte AL, Drazen JC, Brand GL, Seibel BA, and Yancey PH (2007) Correlation of trimethylamine oxide and habitat depth within and among species of teleost fish: An analysis of causation. *Physiological and Biochemical Zoology* 80: 197–208, Figure 2.

pH

The hydrogen ion also plays an important role in conserving protein function and structure. At physiological pH values, only a single amino-acid side-chain, the imidazole ring of the amino acid histidine, can be titrated by changes in pH (**Figure 4**). For a wide range of physiological processes, it is important to retain this titration capacity, to ensure that biochemical reactions can respond appropriately to the acid–base status of the cell and blood. Largely for this reason, regulatory processes function to conserve the charge states of imidazole residues. As the dissociation of the imidazole side-chain is temperature-dependent – the pK of the reaction exhibits a shift of approximately –0.018 pH unit per degree Celsius increase in temperature (however, the response is not quite linear with temperature over the biological temperature range (**Figure 4**, left panel)) – increases in body temperature drive dissociation of the proton from the imidazole ring. Thus, unless counterbalanced through acid–base regulation, changes in cell temperature can disrupt processes dependent on an appropriate charge state of imidazole side-chains. To avoid this type of thermal perturbation, a pH regulatory strategy termed 'alphastat regulation' is observed in almost all cells, under almost all circumstances. 'Alpha$_{\text{imid}}$' refers to the fractional charge state of imidazole side-chains (**Figure 4**), and alphastat regulation denotes regulatory processes that function to maintain this stable charge state. Alphastat regulation maintains the stability of protein function, including ligand-binding ability and subunit aggregation state, two common pH-sensitive characteristics of proteins. Thus, the adaptive changes in proteins that result from evolutionary shifts in amino-acid composition are defended in the context of acute fluctuations in pH through alphastat regulation. For enzymes that employ an imidazole residue in the active site, for instance, lactate dehydrogenase, for which binding of pyruvate requires a protonated imidazole ring (**Figure 4**, right panel), alphastat regulation is a vital component of the overall capacity of the system to retain stable ligand binding in the face of temperature change. When pH is maintained constant across all temperatures (pHstat conditions), K_m^{pyruvate} values for LDH-A orthologs vary over a much wider range than those under the alphastat conditions that pertain in the cell (**Figure 4**, right panel). Conservation of optimal

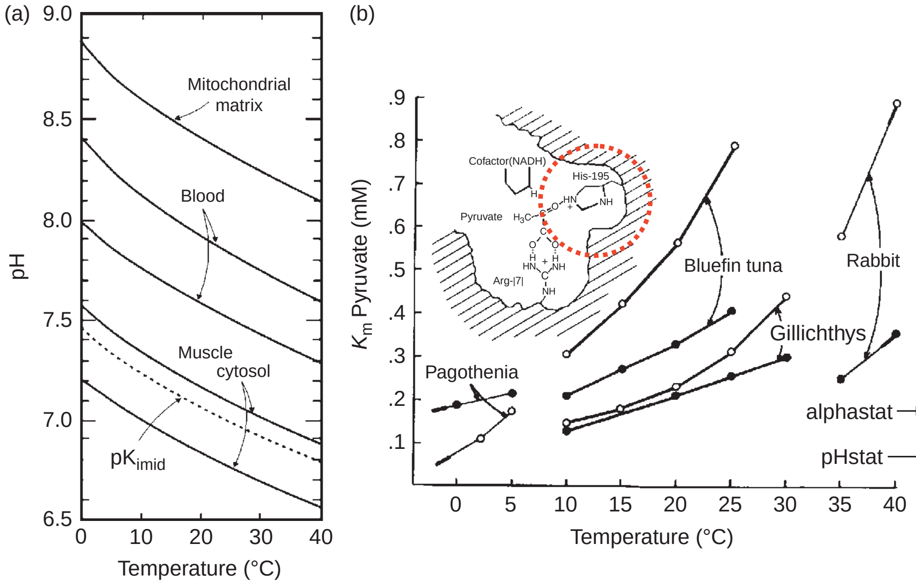

Figure 4 The effects of measurement pH on orthologous LDH-As of different species of vertebrates. Left panel: the observed variation in extracellular (blood)-, intracellular (muscle cytosol)-, and mitochondrial matrix pH as a function of temperature. Note that the temperature-dependence of pH follows that of the dissociation constant of the imidazole side-chain of histidine, pK$_{imid}$. Right panel: the effect of a biologically realistic assay pH (alphastat regulation) and temperature-independent pH (pHstat regulation) on the $K_m{}^{pyruvate}$ of LDH-A orthologs. Alpha$_{imid}$ = [imid–H$^+$]/{[imid] + [imid–H$^+$]}. Modified from Hochachka PW and Somero GN (2002) *Biochemical Adaptation*. New York: Oxford University Press, Figure 7.16.

conditions for proteins thus involves close regulation of the pH of the milieu. Optimal pH values in the cytoplasm are essentially those at which the charge states of imidazole side-chains are conserved, as shown in **Figure 4**.

Conservation of Membrane Function: Homeoviscous and Homeophasic Adaptation

The principles of conservation of optimal values of key structural and functional traits outlined for proteins apply for cellular membranes as well, which are composed of approximately equal masses of proteins and lipids. Changes in temperature exert complex effects on membranes due, as in the case of protein-based structures, to influences on noncovalent bonds. Temperature-sensitive noncovalent bonds, such as those mediated by van der Waals interactions among the aliphatic chains of membrane phospholipids, largely establish the physical state of the bilayer. The expression 'physical state' encompasses a number of membrane properties, including the static order (fluidity) of the bilayer and the propensity of the membrane to form nonlamellar structures. To maintain the optimal physical state of the membrane, that is, to support the membrane's critical functions as a barrier, a site of transport (including exo- and endocytosis) and, in the mitochondrion, a locus of ATP production, the lipid composition of the bilayer must be regulated to compensate for the effects of temperature and, in deep water habitats, those of pressure.

Two different aspects of conservation of physical state have been examined in detail in fishes. Homeoviscous adaptation, the conservation of the static order of the membrane bilayer, is noted in comparisons of species evolutionarily adapted to different temperatures and in conspecifics acclimated (or acclimatized) to different temperatures. **Figure 5** illustrates these relationships for brain synaptosomal membranes from vertebrates adapted to temperatures between −1.9 °C (Antarctic notothenioid fish) and approximately 39 °C (birds and small mammals).

The regulatory responses that lead to homeoviscous adaptation involve modification in the acyl-chain composition (chain length and degree of saturation (double-bond content)) and head-group composition of phospholipids. Increases in double-bond content of acyl chains typically increase membrane fluidity. Thus, decreases in saturation with falling adaptation or acclimation temperature are normally observed in fishes and other ectotherms. Shifts between classes of head group can also modulate the static order of the bilayer.

Changes in head group, for example, shifts between choline and ethanolamine, are also instrumental in establishing homeophasic adaptation, the retention of the appropriate propensity for generating the nonlamellar, hexagonal-phase membrane states required for endocytosis and exocytosis.

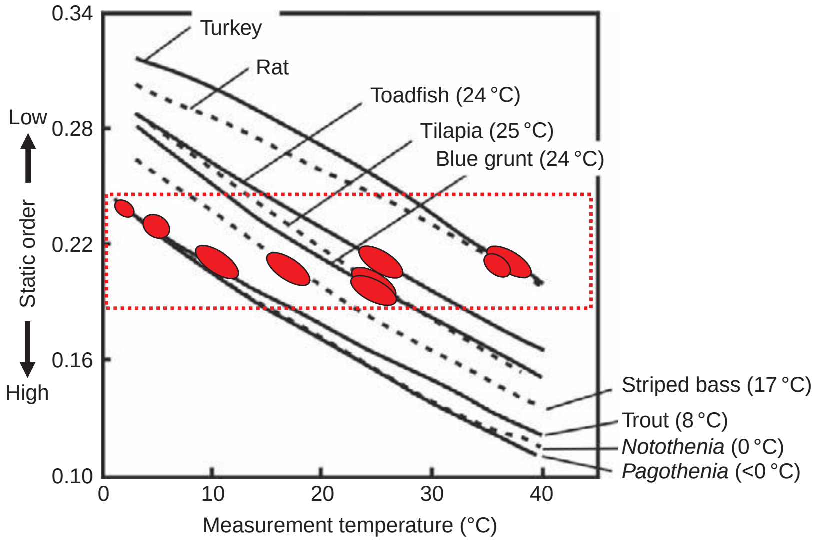

Figure 5 Homeoviscous adaptation of brain synaptosomal membranes. The effect of measurement temperature on membrane static order (measured as fluorescence anisotropy of the probe 1,6-diphenyl-1,3,5-hexatrience (DPH)). Filled ovals indicate the static order at the different species' temperatures of adaptation. Modified from Logue JA, DeVries AL, Fodor E, and Cossins AR (2000) Lipid compositional correlates of temperature-adaptive interspecific differences in membrane physical structure. *Journal of Experimental Biology* 203: 2105–2115, Figure 1.

Optimal properties of membranes can be regulated quite rapidly by substituting different acyl chains on phospholipids or modifying the phospholipid's head groups. Changes in cholesterol content have also been observed in thermal acclimation, with rising temperatures promoting higher cholesterol levels. By conserving optimal physical states for membrane lipids, optimal functional states for membrane-localized proteins are conserved.

Conservation of Gene Regulatory Ability

Adapting to an acute environmental stress frequently involves modulating gene expression in appropriate manners. Thus, sustaining optimal capacities for tightly regulated gene expression is a vital component of an organism's repertoire of responses for dealing with environmental perturbations of the biochemical machinery of the cell.

Due to the roles of noncovalent bonding in DNA and RNA secondary structures and in the interactions among nucleic acids and gene-regulatory proteins, such as transcription factors, abiotic stress would be predicted to have major impacts on the regulation of gene expression. Currently, much less comparative information is available on the effects of abiotic factors, such as temperature, hydrostatic pressure, and osmolality, on DNA and RNA structure and function than in the case of proteins and lipids. Nonetheless, even at this relatively early stage of comparative investigation of adaptation to stress in transcription and translation, adaptive patterns are emerging that resemble in many ways those discussed above for proteins and membranes. Here, we consider but one example of the types of adaptive responses that cells might use in maintaining an optimal state of DNA secondary structure for supporting transcription. While still somewhat conjectural, this illustration of temperature–DNA interactions may reflect a broad suite of adaptive processes that involve effectors of optimal nucleic-acid secondary structure.

DNA secondary structure is highly temperature dependent because of its reliance on hydrogen bonding between the two DNA strands. Yet, to be active in transcription, DNA must have a secondary structure that is sufficiently open to allow the complex transcriptional machinery, which comprises transcription factors and RNA polymerases, to function correctly. There is evidence from several studies, including one of fish acclimated to different steady-state temperatures as well as to an environmentally realistic regimen of diurnal variation in temperature, that DNA structure is closely regulated in a manner that conserves transcriptional ability. The extremely eurythermal killifish, *Austrofundulus limnaeus*, which experiences daily temperature fluctuations between approximately 24 °C and 38 °C, showed a strong temperature dependence in expression of a gene encoding a protein named high-mobility-group-B1 (HMGB1). This gene-regulatory protein is important in establishing the openness – and, thereby, the transcriptional potential – of DNA in a global manner. HMGB1 proteins are not specific transcription factors; rather, they modulate the openness of DNA throughout much of the chromosome, thus allowing specific transcriptional regulators to exert their effects on their target genes. Upregulation of the gene encoding HMGB1 occurred in steady-state cold-acclimated *A. limnaeus* and during the cold phase of a diurnally cycling temperature regimen. If the changes in mRNA for HMHG1 protein are reflective of changes in this rapidly turning-over protein, then an important form of temperature compensation of transcriptional activity could result. Thus, because DNA's double-helical structure is stabilized by reduced temperature, introducing higher concentrations of a protein that opens up DNA structure could offset the effect of cold on transcriptional capacity. Likewise, at high temperatures when DNA's structure may fluctuate into too open a configuration, reduction in concentrations of HMGB1 protein could offset this effect of heat on regulatory competence. Although the importance of this putative temperature-compensatory shift in DNA structural stability remains to be documented, it would appear that the concept of conserving an optimal structural state, as discussed for proteins and membranes, applies for DNA as well in the context of transcriptional potential.

Summary

The thrust of the above analysis has been to illustrate the conservative nature of biochemical adaptations that function in the face of abiotic stress to sustain the structural and functional characteristics of protein-, lipid- and nucleic-acid-based biochemical systems. Through adaptive changes in structures of the large molecules themselves and through compensatory shifts in osmolyte systems, pH, and other large molecules (e.g., HMGB1 proteins) that affect these biochemical systems, critical physiological processes such as enzymatic function, membrane transport, and signal transduction and transcription of DNA are sustained in the face of shifts in the abiotic environment. In all cases, we find that these conservative adaptations lead to the retention of optimal values for critical properties of the biochemical systems that underlie the physiological activities that are required for life, piscine or otherwise, across a wide range of environments.

Glossary

Abiotic factors Nonliving chemical and physical factors in the environment (e.g., temperature and salinity).

Activation energy The minimum amount of energy required to initiate a chemical reaction.

Arrhenius breakpoint temperature (ABT) The temperature at which the activation energy of a biological reaction changes abruptly. ABT is correlated with maximum habitat temperature for some species.

Arrhenius equation An equation describing the effects of temperature on reaction rates due to the increase in kinetic energy of molecules, which causes more molecules to exceed the activation energy of the reaction.

Arrhenius plot A graph showing the relationship between the natural logarithm (ln) of a measured reaction rate on the ordinate (*x*-axis) plotted against the inverse of temperature (1/*T*) in kelvin on the abscissa (*y*-axis) that is used to show the effects of temperature on the rate of a reaction.

Ectotherm (adj. ectothermic) An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Endotherm An animal that uses its own metabolism as the major source of heat to maintain its body temperature greater than that of the surrounding environment.

Eurytherm An ectotherm able to survive over a broad range of environmental temperature.

Heat Form of energy resulting from random molecular movements that flows between objects at different temperatures.

Heterotherm Organisms that have both homeothermic and poikilothermic characteristic (see regional heterotherm and temporal heterotherm).

Homeotherm Organisms that maintain their body temperature within a relatively narrow range despite changes in environmental temperature.

Kinetic energy Energy due to motion.

Maxwell–Boltzmann distribution A probability function describing the distribution of kinetic energy of particles in a sample of an ideal gas. The shape of this distribution changes with temperature, with a larger proportion of particles with higher energies as temperature increases.

Poikilotherm An organism that cannot regulate body temperature except through behavioral means. An animal whose body temperature fluctuates with that of the environment.

Q_{10} Factoral change in the rate of a biochemical reaction or process with a 10 °C increase in temperature.

Regional heterotherm An organism that maintains a relatively constant temperature in some parts of the body, while allowing temperature in other parts of the body to vary with environmental temperature (e.g., tunas).

Temporal heterotherm An organism that maintains a relatively constant body temperature through generation of metabolic heat at some times of day or during some seasons, while allowing body temperature to vary with external temperature at other times of day or during some seasons (e.g., hibernators and organisms that undergo daily torpor).

Thermal energy Total energy of a system as a result of kinetic energy of the translational, rotational, and vibrational movement of molecules and potential energy of atomic interactions such as hydrogen bonds.

Temperature Measurement of the average kinetic energy or heat content within a substance or system.

Stenotherm An ectotherm able to survive only within a narrow range of environmental temperatures.

Introduction

Temperature has profound effects on biological systems at all levels of organization from the molecule to ecosystems through its effects on the rates of biological reactions, and on the formation and stabilization of weak intermolecular interactions. Consequently, understanding the fundamental effects of temperature is central to a core understanding of how all organisms, including fish, interact with their environment.

Temperature's effects are so profound that organisms have evolved a variety of strategies for either avoiding or compensating for the effects of temperature. These thermal strategies can be described using two sets of terms. The terms 'poikilotherm' and 'homeotherm' distinguish organisms based on the constancy of their body temperature. Poikilotherms have a body temperature that varies with the temperature of the environment, whereas homeotherms have a relatively constant body temperature. The terms 'endotherm' and 'ectotherm' distinguish animals based on the source of heat that affects body temperature. For endotherms, the majority of body heat is generated internally as a consequence of metabolic processes, and many endotherms have specialized physiological mechanisms for heat generation. For ecotherms, the majority of body heat is derived from the external environment. Most mammals and birds are homeothermic endotherms that maintain a relatively constant body temperature as a result of metabolic heat generation. Most fishes are poikilothermic ecotherms whose body temperature varies as a result of changes in environmental temperature. However, some fishes can be considered to be homeothermic ecotherms because they live in a very thermally stable environment, or use behavioral mechanisms to seek out microhabitats with a specific temperature.

Although all ecotherms generate heat as a result of standard metabolic processes (see also **Tissue Respiration**: Cellular Respiration and Mitochondrial Respiration, the low metabolic rate of most ectotherms does not generate sufficient internal heat to balance heat loss to the environment. For fishes, an additional challenge is the rapid loss of internally generated heat to the aquatic environment as the blood passes through the gills. Some fishes, such as tuna and marlin, have evolved a variety of strategies for reducing the loss of this heat to the environment, as well as for generating additional body heat (see also **Design and Physiology of Arteries and Veins**: The Retia, **Pelagic Fishes**: Physiology of Tuna, and Endothermy in Tunas, Billfishes, and Sharks). However, even these fishes are unable to maintain their entire body at a constant temperature in the face of environmental temperature variation. Instead, only certain parts of their body are maintained at a relatively constant temperature, while temperature in other regions of the body varies with the environment. Animals that employ the strategy of selectively defending the temperature of only some parts of the body are termed regional heterotherms. Temporal heterotherms allow their body temperature to track environmental temperatures at some times, while maintaining a relatively constant body temperature at other times.

Because most fishes are ectotherms, temperature plays a particularly critical role in determining their distribution and abundance. Temperature sets both the absolute limits at which fishes can live and influences their ability to function within those limits. For example, fishes can be found living actively only within a temperature range from a few degrees below 0 °C up to about 45 °C, and only a very few species of fish can even survive at all of temperatures across this range, with most species specializing to live at a much narrower range of temperatures. Fishes that can live across a wide range of temperatures are termed 'eurytherms', whereas fishes that specialize to live only at a narrow temperature range (and who cannot survive outside this range) are termed 'stenotherms'. The thermal sensitivity of an animal such as a fish is often summarized using a tolerance or performance curve, which relates the value of some parameter of tolerance (such as lethality, ability to maintain equilibrium, or sensitivity to touch) or performance (such as fecundity, growth, metabolic rate, or swimming performance) to temperature (**Figure 1**). These curves provide information on several parameters, including: (1) the optimal temperature for performance (T_{opt}); (2) the thermal breadth (or window), which defines the range of temperatures over which performance meets some specified threshold; and (3) the maximum and minimum tolerated temperatures for short-term survival (see also **Temperature**: Measures of Thermal Tolerance).

In order to understand the factors shaping performance curves and why temperature is so important for the lives of fishes, it is necessary to have a strong understanding of the effects of temperature on living systems. To do so, we must first define what is meant by the word temperature and distinguish this concept from the related words thermal energy and heat.

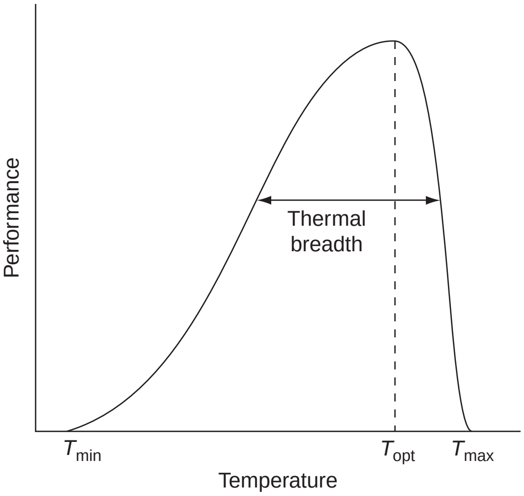

Figure 1 Thermal performance curve. This curve shows a hypothetical relationship between a performance parameter such as growth, swimming speed, or enzyme reaction rate and temperature. T_{opt} is the optimal temperature for performance. T_{max} is the maximum temperature at which performance is greater than 0. T_{min} is the minimum temperature at which performance is greater than 0. The thermal breadth (or thermal window): the temperature range over which performance exceeds some predetermined level. It is also possible to define an upper and lower T_{p} (pejus temperature) at which performance is statistically significantly lower than the performance at T_{opt}.

Temperature and Its Measurement

Temperature can be defined as a measure of the average translational kinetic energy (E_{k}) associated with the movement of a group of molecules. Translational kinetic energy (E_{k}) can be calculated as $E_{\mathrm{k}} = (1/2)mv^2$ (where m is the mass of the molecules and v their velocity). Thus, a group of fast-moving molecules will have a higher average kinetic energy and thus a higher temperature than a group of molecules that are moving more slowly, provided the molecules are of the same mass. But because molecules of greater mass have more kinetic energy at the same speed as molecules with lower mass, the molecules in a lead ball move more slowly than the molecules in an aluminum ball when the two balls are at the same temperature.

Temperature is measured on a variety of arbitrary scales, the most scientifically relevant of which are the Kelvin and Celsius scales. The kelvin (K) is the SI base unit of temperature. Note that temperatures reported in kelvin do not have a degree symbol, and the unit kelvin is not capitalized (although the symbol for the kelvin is a capital K, and the K is capitalized when we refer to the Kelvin scale). The Kelvin scale is designed so that 0 K is at absolute zero, a hypothetical temperature at which all molecular movement stops. The other major reference point on the Kelvin scale is the triple point of water (the temperature at which the solid, liquid, and gaseous phases of water are in equilibrium). The triple point of water is set as exactly 273.16 K. This number seems as if it is entirely arbitrary, but in fact it is a historical artifact of the development of the Kelvin scale from the existing Celsius scale. The Celsius scale was originally defined such that 0 °C was at the freezing point of water, and that 100 °C was at the boiling point of water. Each unit on the Kelvin scale (K) was set as the same as the degree Celsius (°C). In 1954 the Celsius scale was redefined such that absolute zero is at – 273.15 °C, and 0.01 °C is at the triple point of water. This definition sets both the degree Celsius and the kelvin as 1 part in 273.16 parts, which is the difference between absolute zero and the triple point of water. The Kelvin scale and the Celsius scale are thus readily interconvertible: 0 °C is exactly 273.15 K. To convert degrees Celsius into kelvin, one can simply add 273.15 to the temperature in °C.

Temperature, Thermal Energy, and Heat

Temperature, thermal energy, and heat are related concepts, but they are not the same. As discussed above, temperature can be operationally defined as a measure of the average kinetic energy of the molecules in a system. Thermal energy, in contrast, is the total energy contained in a system and depends not just on the kinetic energy from the translational movement of the molecules in the system, but also on the energy from the rotational and vibrational movement of the molecules, on their electrical interactions, and on the total number of molecules in the system. A milliliter of water contains much less thermal energy than does a liter of water at the same temperature. Likewise, a liter of air contains less thermal energy than does a liter of water at the same temperature, because water contains more molecules per unit volume than does air.

Heat is a word used to describe the transfer of energy from a system at higher temperature to a system at lower temperature. The word heat is also sometimes (incorrectly) used to describe the total thermal energy possessed by a system, but the word heat is more properly confined to describing the process of transfer of thermal energy from one system to another. This confusion arises, in part, because the amount of heat necessary to raise a given mass of a substance by a specific unit of temperature is termed the specific heat (or specific heat capacity). Given that heat is readily lost from blood to either water or air across a respiratory structure (gills or lungs, respectively), and that water can store more thermal energy than air, it becomes obvious why fishes have more difficulty retaining metabolic heat than do terrestrial animals.

There is a strong relationship between temperature and thermal energy. When we add thermal energy to a system, the temperature of the system generally increases. When we remove thermal energy from a system, the temperature of the system generally decreases. Note, however, that adding or removing energy does not always cause a change in temperature. It can also cause a change in state. For example, when thermal energy is removed from a liter of water, the water may freeze without changing temperature. Similarly, ice can melt when thermal energy is added, again without changing temperature. This change in state means that the average kinetic energy of the ice molecules in the moment before the ice melts is the same as the average kinetic energy of the water molecules in the moment after melting. Thermal energy is absorbed by the process of melting, but it does not result in a change in kinetic energy. Instead, the addition of thermal energy results in a change in weak bond formation between the molecules, which affects their potential (not their kinetic) energy. From this brief discussion, we can see that thermal energy has important effects both on the formation of weak bonds among molecules and on the movement of these molecules. As we discuss below, both of these processes are critically important factors when assessing the effects of temperature (or more correctly, thermal energy) on fish.

Effects of Temperature on Rate Processes

Increasing the temperature of a system increases the thermal energy of the system, which then causes an increase in the rates of most chemical reactions. The increase in the rate of chemical reactions is, in part, due to an increase in the number collisions between molecules per unit time. In order for two molecules to undergo a chemical reaction, they must first come into contact. Thus, increasing the number of collisions between molecules increases the number of contacts that can lead to a chemical reaction. However, this factor can only account for a very small proportion of the observed increase in reaction rate with temperature. For example, at biologically relevant temperatures, reaction rates roughly double (i.e., increase by 100%) with a 10 °C increase in temperature. We can approximate the frequency of collisions between particles as proportional to the square root of the temperature in kelvin. If the temperature of a system were increased from 10 to 20 °C (from 283.15 to 293.15 K), the frequency of the collisions would increase by a factor of 1.018-fold (or 1.8%), which is far lower than the observed ~100% increase in reaction rate. Thus, other factors must be involved in the increase in reaction rates with temperature.

Far more important for increasing the rates of reactions with temperature is an increase in the energy with which molecular collisions occur. Chemical reactions occur only when the energy of the molecular collision exceeds the activation energy (E_a) of the reaction (**Figure 2**). The Maxwell–Boltzmann distribution (**Figure 3**) can be used to describe the fraction of molecules with different kinetic energies in a population of molecules at a specified temperature, and allows

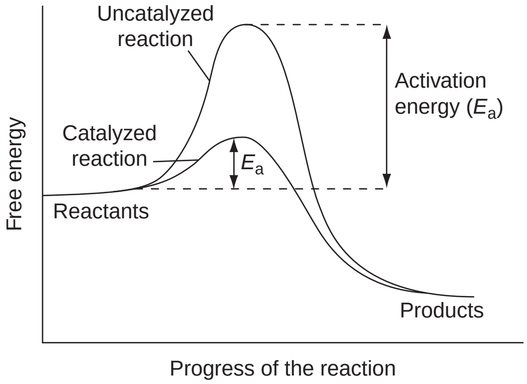

Figure 2 Free energy diagram for a spontaneous (exergonic) reaction. Chemical reactions occur through the formation of a high-energy transition state (the activated complex). The energy needed to form this transition state is called the activation energy (E_a) and is the difference between the energy of the reactants and the transition state. Catalysts such as enzymes reduce the activation energy of a reaction relative to that of the uncatalyzed reaction.

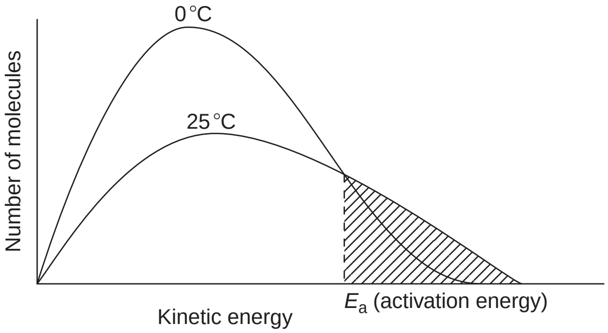

Figure 3 Effects of temperature on the Maxwell–Boltzmann distribution. The Maxwell–Boltzmann distribution is a probability distribution that shows the number of molecules with a given kinetic energy as a function of kinetic energy. In order for a reaction to proceed, the molecules involved must have kinetic energy equal to or greater than the activation energy (E_a). The number of molecules that exceed the activation energy is shown by the area under the curve in the shaded area of the diagram. As temperature increases, the Maxwell–Boltzmann distribution shifts down and to the right, and more molecules exceed E_a. This change in the shape of the distribution accounts for much of the increase in the rate of chemical reactions with temperature.

the estimation of the fraction of the molecules in a population that exceed the activation energy of a reaction. When temperature increases the thermal energy of the system, the fraction of molecules with high energy also increases. This increase in energy can be observed as a change in the shape of the Maxwell–Boltzmann distribution, which shifts down and to the right. Overall, this typically results in an increase in the number of molecules that exceed the activation energy of a reaction. Thus, more collisions with sufficient energy to cause a reaction occur per unit time at a higher temperature, and this effect causes the reaction to proceed more rapidly.

The effect of temperature on the rates of reactions can be quantified using the Arrhenius equation (named after the Swedish physical chemist Svante Arrhenius, who derived it based on earlier work by Van't Hoff). The Arrhenius equation is usually written as

$$k = A\ \mathrm{e}_{\mathrm{a}}^{-E}/RT \quad \text{or} \quad \text{In}\ k = -E_{\mathrm{a}}/RT + \text{In}\ A$$

where k is the rate of a reaction, A a term called the frequency factor or the pre-exponential factor (which is generally constant across biologically relevant temperature ranges), E_a the activation energy of a reaction, R the gas constant, and T the temperature in kelvin. Using the Arrhenius equation, we can calculate the effect of temperature on reaction rate. The Arrhenius equation clearly shows that the effects of temperature on reaction rates are exponential. Assuming biologically relevant values for E_a and A, the Arrhenius equation predicts that the rate of a reaction should roughly double when the temperature is increased from 10 to 20°C (i.e., increase by ~100%). Thus, unlike the effects of increasing the rate of molecular collisions, the effects of increasing the number of molecules with energy greater than the activation energy can account for most of the observed effects of increasing temperature on reaction rates.

One important point to remember when applying the Arrhenius equation to biological reactions (which are often enzyme catalyzed or involve other types of changes in protein structure in order to occur) is that E_a (the activation energy of the reaction) is an evolved property of the protein involved in the reaction. For example, enzymes act as catalysts because they reduce the E_a of a reaction, and the degree to which they reduce E_a may differ between species, and may vary with temperature. Differences in E_a between species and with temperature could alter the way that temperature affects a biological reaction. In addition, other factors (such as substrate concentrations or other cellular conditions) may vary with temperature *in vivo*, further complicating the analysis of the effects of temperature on biochemical and physiological processes in living organisms.

Q_{10}

Biologists often quantify the effects of temperature on the rates of physiological processes using the parameter Q_{10}, which is the unitless ratio of reaction rates at temperatures that differ by 10 °C (or 10 K). Q_{10} can be calculated as

$$Q_{10} = (R_2/R_1)^{10/(T_2-T_1)}$$

where T_2 and T_1 are the temperatures in degrees Celsius or kelvin, and R_2 and R_1 are the rates of a biological process or reaction. If the rate of a reaction is independent of temperature, then Q_{10} will be equal to 1. If the rate of a reaction doubles with temperature, then Q_{10} will be equal to 2. Typically, the Q_{10}'s of enzyme-catalyzed reactions and other biological processes at biologically relevant temperatures are between 1 and 3.

Arrhenius Breakpoint Temperature

The effects of temperature on a biological reaction are often displayed using an Arrhenius plot, which relates the natural logarithm of a measured reaction rate to the inverse of temperature ($1/T$) in kelvin. This plotting method linearizes the otherwise exponential relationship between temperature and reactions rates (**Figure 4**). The y-intercept of the Arrhenius plot allows the calculation of the pre-exponential factor (A) and the slope of the line is $-E_a/R$, and is thus related to the apparent activation energy of the reaction. For biological reactions and metabolic processes, Arrhenius plots may have a breakpoint at which the slope of the

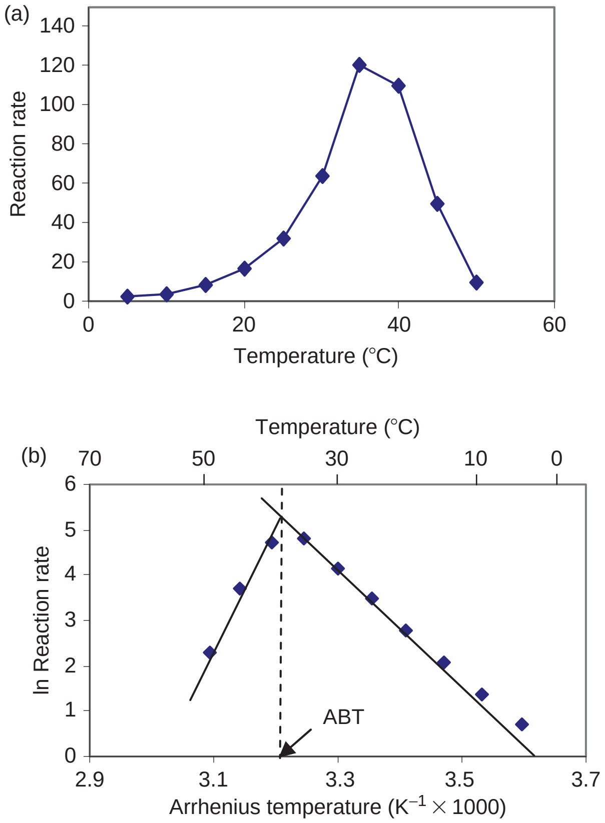

Figure 4 Effect of temperature on the rates biological reactions. Panel (a) shows how temperature affects the rate of a hypothetical reaction. Panel (b) shows the same data as an Arrhenius plot in which the natural logarithm (ln) of the reaction rate is plotted against inverse of the temperature in kelvin (K^{-1}). The slope of a line on an Arrhenius plot is an index of the activation energy of the reaction. Arrhenius plots for biological reactions often have discontinuities (or breakpoints) at which the slope of the line changes abruptly. The temperature at which these breakpoints occur is called the Arrhenius breakpoint temperature (ABT).

line changes abruptly. The temperature at which this breakpoint occurs (the Arrhenius breakpoint temperature, ABT) is often considered to be the first point at which loss of biochemical or physiological function may be occurring. At least in some species, ABTs are correlated with habitat temperature, with species from warmer habitats having higher ABTs for a given biochemical reaction or physiological function than do species from cooler habitats.

Care must be taken in applying Arrhenius plots to any multistep process such as mitochondrial respiration or whole-organism metabolic rate. The Arrhenius equation assumes that a reaction is governed by a single rate-limiting step. Processes such as mitochondrial respiration are composed of many biochemical reactions, each with its own activation energy, and thus its own slope on an Arrhenius plot. As a simplifying assumption, the rate of multistep process is often assumed to be governed by one of its steps (e.g., the rate-limiting enzyme in the pathway). However, it is possible that the step that is rate limiting within a multistep pathway could change with temperature, resulting in an Arrhenius plot with a complex shape.

Effects of Temperature on Weak Bonds

In addition to effects on rate processes, changes in temperature (and thus thermal energy) have important effects on the formation of noncovalent (weak) bonds between molecules. Weak bonds, which include bonds such as hydrogen bonds, ionic bonds, van der Waals interactions, and hydrophobic interactions, play a critical role in determining the secondary, tertiary, and quaternary structure of proteins and nucleic acids, and the behavior of biological membranes (see also **Responses and Adaptations to the Environment**: General Principles of Biochemical Adaptations). An increase in thermal energy destabilizes hydrogen bonds, ionic bonds, and van der Waals interactions, whereas an increase in thermal energy stabilizes hydrophobic interactions (see also **Temperature**: Proteins and Temperature). In general, increases in temperature will tend to destabilize proteins to the point that they eventually denature and become nonfunctional. At very low temperatures, proteins become too rigid to perform their functions effectively. Cells have a variety of mechanisms to help stabilize proteins and reduce or mitigate the damage caused by protein-denaturing stressors such as high temperatures. The best known of these mechanisms are a family of proteins known as the heat shock proteins (hsp's) which help stabilize and refold proteins (see also **Temperature**: Heat Shock Proteins and Temperature).

The effects of temperature on weak bonds are also critical for the functioning of biological membranes, which are stabilized by a combination of hydrogen bonds and hydrophobic interactions. Changes in these interactions result in alterations in the fluidity of the membrane, which can alter the function of membrane-embedded proteins (see also **Temperature**: Membranes and Temperature: Homeoviscous Adaptation). For example, changes in membrane function can affect the function of mitochondrial proteins and affect the ability of the cell to generate energy using aerobic metabolism (see also **Temperature**: Mitochondria and Temperature). Temperature effects on cell membranes may be particularly critical for excitable cells such as neurons and muscle cells that rely on electrical signals for communication (see also **Temperature**: Temperature and Excitable Membranes).

Strategies of Thermal Adaptation and Acclimation

Physiological processes and biological reactions are carried out by proteins and membrane-bound compartments whose structure and composition have been shaped by evolution. Thus, changes in macromolecular structure as a result of adaptation have the potential to compensate for the effects of temperature on biological reactions and the formation and stabilization of weak intermolecular interactions. Sir Joseph Barcroft (1934) eloquently expressed this idea saying: "…nature has learned so to exploit the biochemical situation as to escape from the tyranny of a single application of the Arrhenius equation."

The extent to which fish, and ectotherms in general, are able to escape the tyranny of thermodynamics is still a matter of vigorous debate in the literature. For example, knowledge of thermodynamics suggests that temperature effects are likely to impose trade-offs such that it is difficult to evolve to function well at both high and low temperatures. However, this and other related questions remain unresolved and are likely to occupy thermal biologists for many years to come. These questions may, in fact, become increasingly important as anthropogenic effects on the global climate result in shifts in the temperature of natural environments (see also **Temperature**: Effects of Climate Change).

Glossary

Abiotic The chemical and physical (nonbiological) variables of the environment, (e.g., temperature)

Biotic Environmental factors related to living organisms. The biological variables of the environment, e.g., predation and competition.

Ectotherm Organism whose body temperature is obtained and governed by heat exchange with its environment.

Endotherm An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Fitness Contribution of an individual to the next generation relative to other individuals, i.e., the proportion of the individual's genes in all the genes of the next generation. Traits affecting an organism's survival and reproductive success are tightly connected to fitness, i.e., fitness = survivorship' fecundity.

Heat Form of energy resulting from random molecular movements that flows between objects at different temperatures.

Lethal dose Concentration which kills 50% of the population (LD-50) in a specified time.

Loss of righting response Inability for an organism to right itself due to loss of sensory and motor control.

Poikilotherm An organism that cannot regulate body temperature except through behavioral means. An animal whose body temperature fluctuates with that of the environment.

Spasm Onset of muscular contractions caused by a physiological reaction to high temperature.

Temperature Measurement of the average kinetic energy or heat content within a substance or system.

Temperature quotient or Q_{10} A measure of the rate of change of a biological or chemical system as a consequence of increasing the temperature by 10 °C. The Q_{10} is calculated as: $Q_{10} = (R1/R2)^{10\ (T2-T1)}$, where R is the rate at a particular temperature and T the temperature in degrees celsius.

Temperature tolerance polygon Derived from a plot of temperature tolerance on acclimation temperature in $^{\circ}C^2$.

Thermoregulation Ability of an organism to behaviorally or physiologically regulate its body temperature.

Van't Hoff rule A rule of thumb that the Q_{10} for a biological or biochemical rate process equals or approaches 2.0, that is, approximately doubles for a 10 °C increase.

Temperature-Dependent Physiology: The Basis of Thermal Tolerance

Temperature is by far the most pervasive abiotic factor governing an organism's biology. Some fishes have more physiological control over temperature than others, for example, tunas and billfishes (**see also Pelagic Fishes**: Physiology of Tuna and **Fish Migrations**: Tracking Oceanic Fish). However, most fishes have low metabolic rates that cannot produce significant metabolic heat, which in combination with little or no insulation makes it difficult to maintain a temperature much different than that of the surrounding water. Thus, physiological and metabolic rate processes in fishes are governed mainly by environmental temperature (T_e).

How significantly T_e influences a fish's physiological rate processes may directly indicate its sensitivity or tolerance to temperature. Not only is exposure to low or high temperatures important, but also the magnitude and speed of T_e change (ΔT_e). We are all familiar with thermal shocking observed when fish are too quickly transferred from one thermal environment to another.

The basis of an organism's tolerance for temperature is governed by its temperature-dependent rate processes, which can be quantified using indices such as the Q_{10} (**see also Temperature**: Effects of Temperature: An Introduction). Measures of upper and lower thermal tolerance describe the functional range of temperatures for an organism, while measures such as Q_{10} and the critical thermal increment (E_a) indicate how physiological rate processes change with increasing or decreasing temperature.

Environmental Temperatures (T_e's) and Fishes

Both the presence and the success of a fish within a habitat depend upon a complex combination of environmental factors. Of these factors, T_e has been defended as the single most important and pervasive factor. Thus, a fish's fitness (survivorship × fecundity) depends on its species-specific physiological tolerance for changes in environmental factors. Following F.E.J. Fry's classification of environmental factors by their influences on animals, a classic abiotic factor such as temperature can control the rates of physiological processes, limit locomotion and hence distribution, mask the influence of other environmental factors, direct an orientation when present as a gradient, and be lethal.

These multiple effects may be surprising since temperature, that is, heat *stricto sensu*, has only two main effects on living systems. In addition to influencing the rates of chemical reactions and physiological processes, heat influences the three-dimensional shapes of biomolecules, including enzymes and DNA (**see also Responses and Adaptations to the Environment**: General Principles of Biochemical Adaptations and **Temperature**: Proteins and Temperature). Although the vast majority of fishes are obligate poilikothermic ectotherms, they are not at the mercy of T_e. The cells, tissues, and organs of fishes have evolved the capacity to acclimate, which allows them to function over a wider range of body temperatures. Fishes have also evolved behavioral measures to avoid lethal levels of heat by seeking out and occupying thermally favorable habitats. The bottom line to this brief discussion is that T_e plays a major role in the lives of fishes.

Thermal Tolerance of Fishes: A Brief History

Simply, too much or too little heat can kill organisms. As concluded by F.E.J. Fry in the late 1940s "possibly the most dramatic effect of temperature is to act as a lethal agent." Although several hypotheses have been proposed, the mechanisms resulting in thermal death are unknown. It is likely that there are several different causes of thermal death. Lethality certainly precedes coagulation of proteins at high temperature and the formation of ice crystals at low temperatures. The unknown and specific causes of thermal death have not curtailed studies of lethal temperature. The subset of environmental temperatures that a species can tolerate is an important component of its *n*-dimensional niche and the basis for understanding thermal environments and distributional patterns of fishes.

The two major contemporary methods to quantify temperature tolerance were independently developed in the 1940s. In the early 1970s, aquatic temperature studies in the US, including thermal tolerances of aquatic organisms, were stimulated by concerns of thermal pollution from cooling systems of electric generating stations, particularly those associated with nuclear reactors. More recently, thermal tolerance research has become increasingly important for understanding the impacts of global climate change (**see also Temperature**: Effects of Climate Change). Quantifying a species thermal tolerance, in particular its upper lethal temperatures, is critical to assessing the potential biological/ecological impacts of anticipated increases in temperature predicted for specific ecosystems (e.g., the Great Lakes) and the entire biosphere.

Laboratory Measures of Thermal Tolerance

Incipient Lethal Temperatures

In 1942, F.E.J. Fry and co-workers at the University of Toronto introduced the temperature static, plunge, incipient lethal temperature (ILT), or simply the Fry method for temperature tolerance assessment of fishes. A temperature that is lethal to exactly 50% of a sample of fish in a specified time is empirically determined. Endpoints are designated as the incipient lower lethal temperature (ILLT) and the incipient upper lethal temperature (IULT). ILTs are determined in groups of fish (previously acclimated to the same temperature) that are instantaneously transferred from their acclimation temperature and plunged into one of a series of constant temperatures thought to contain the lethal temperature. ILLT and IULT are dependent, to varying degrees among fish species, on the acclimation temperature. Therefore, if ILLT and IULT are repeatedly determined over a range of acclimation temperatures, a

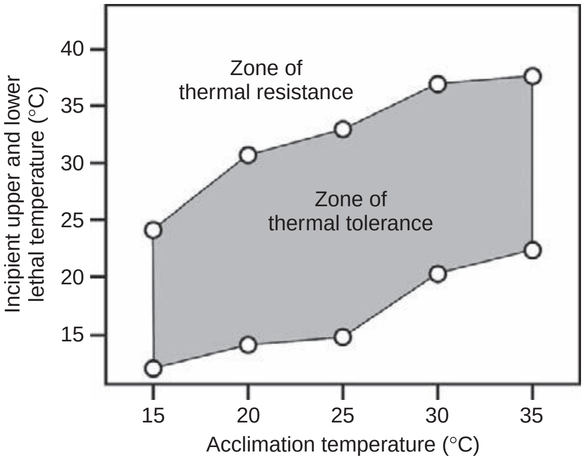

Figure 1 Thermal tolerance polygon showing the incipient lethal temperatures as the zones of thermal tolerance and thermal resistance.

temperature tolerance polygon can be constructed (**Figure 1**), separating temperature data into zones of resistance (outside the polygon) and tolerance (within the polygon). The slopes of the data lines then provide information on the role and degree of temperature acclimation.

Polygons are generated from the resistance times where 50% mortality is observed for a set of test temperatures (**Figure 2**(**a**)). These test temperatures are then regressed against resistances times for 50% mortality (**Figure 2**(**b**)) and the estimated 24 h IULT for 20 °C is determined (i.e., approximately 35 °C). Usually, this relationship is not linear with respect to resistance time; hence, data are transformed as probits and plotted against the logarithm of resistance time. The mainstays of this approach include (1) constant test temperatures, (2) mortality as the test endpoint, and (3) estimated ILLT and/or IULT at specified time intervals (e.g., 12, 24, or 96 h). If a temperature tolerance polygon is generated (**Figure 2**(**c**)), the most extreme temperature tolerances (i.e., ILLT and IULT) can be estimated. Here, **Figures 2**(**a**) and **2**(**b**) show how the single point of 35 °C is generated for the polygon shown in **Figure 2**(**c**). By finally calculating the area of the polygon in °C^2, the degree of species eurythermicity is determined. Stenothermal fish have a small area, and eurythermal fish a large area. The first ILT polygon was determined for goldfish (*Carassius auratus*), and to date, temperature tolerance polygons for <50 fish species have been published.

Temperature tolerance polygons can be further divided into intrinsic (genetic) and acquired (acclimation) temperature tolerances (**Figure 3**). In the presentation, acclimation-dependent high and low thermal tolerances equal 170 and 253 °C^2, respectively. The results ($n = 21$ species) indicated that (1) acclimation temperature was responsible for about 50% of total thermal tolerance polygon, and (2) lower acclimation-dependent areas were nearly 3 times greater than upper acclimation-dependent areas. This suggests that acclimation plays a larger role in low rather than in high thermal tolerance.

Ordinate is in probits (inverse cumulative distribution function) and abscissa logarithmic (log 10). (b) Estimation of 24-h IULT. (c) Placement of 24-h IULT of 35 °C on the temperature tolerance polygon.

Critical Thermal Methodology (CTM)

Prior to the 1940s, a few researchers reported temperature tolerances of fishes exposed to changes in temperature

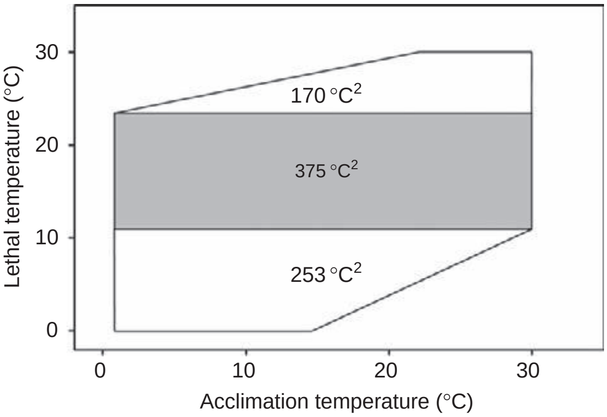

Figure 3 Generalized temperature tolerance polygon separated into acclimation temperature-independent tolerance (gray) and the lower and upper acclimation temperature-dependent areas.

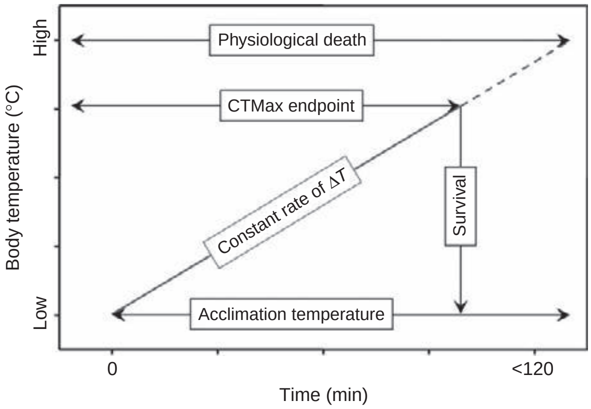

Figure 4 Generalized CTM methodology showing constant increase in T_b over time until CTMax occurs prior to physiological death.

with either lethal or sublethal endpoints. However, Cowles and Bogert's classic study published in 1944 of desert reptiles introduced and defined the critical thermal maximum (CTMax) as the thermal point at which locomotory activity becomes disorganized and the animal loses its ability to escape from conditions that will promptly lead to its death. Recovery from this incapacitation is the criterion for determining whether or not the animal has been exposed to high temperatures. From the ecological viewpoint, CTMax is the lethal temperature. Although Cowles and Bogert also defined the critical thermal minimum (CTMin), they did not quantify exposures of reptiles to decreasing temperatures. In temperature tolerance research on bluegill (*Lepomis macrochirus*), Cox further defined the CTMax as the:

> Arithmetic mean of the collective thermal points at which locomotory activity becomes disorganized and the animal loses the ability to escape from conditions that will promptly lead to its death when heated from a previous acclimation temperature at a constant rate just fast enough to follow T_e without a significant time lag.

When this experimental approach included the exposure of fishes to decreasing temperatures (i.e., CTMin), a clarification of the abbreviations became necessary. CTM now refers to the general methodology – critical thermal methodology – and CTMax and CTMin as the measured endpoints.

The keys to CTM include (1) consistent ΔT during trials, (2) ΔT should be fast enough to prevent reacclimation during a trial and slow enough to allow deep body temperature (T_b) to track T_e without a time lag, usually 0.3–1.0 °C min^{-1}, (3) choice of an obvious, repeatable near-lethal but sublethal endpoint such as the loss of righting response (LRR) or the onset of spasms (OSs), and (4) the caveat, that once its CTM endpoint is observed, the animal will survive if immediately captured and quickly returned to its pretest acclimation temperature (**Figure 4**).

Just as ILTs are used to generate a thermal tolerance polygon (**Figure 3**), both CTMax and CTMin measured over a range of acclimation temperatures can be used to construct a dynamic thermal tolerance polygon.

Comparison of ILT and CTM

These two approaches attempt to quantify thermal tolerance from different perspectives: static versus dynamic temperature exposures and lethal versus sublethal endpoints. Neither method is superior to the other. The ILT method may offer a more complete reflection of a species temperature tolerance. With additional data, it is possible to elucidate smaller polygons of growth and reproduction within the temperature tolerance polygon. In contrast, the CTM requires far less fish, is nonlethal (hence, threatened species can be tested), can be conducted over a relatively short time (usually <2 h), and is an excellent tool to bioassay biotic and abiotic factors that may influence thermal tolerance. Finally, it is also theoretically possible to predict CTM endpoints from resistance data generated by ILT trials.

CTMax Endpoints

Much discussion has been given to using the OS versus the LRR as the most appropriate CTMax endpoint. Although OS may be more biologically meaningful due its increased precision and greater physiological relevance, it has been recommended that both endpoints be collected and reported for data completeness and for comparisons with past studies. Because the OS occurs only a few degrees above the LRR, it is easy to continue heating trials until both endpoints are obtained. Second, studies invoking the production of heat shock proteins may require the neurological and possibly neuroendocrine responses of the more severe thermal stress associated with OS.

CTMin Endpoints

Most fishes experiencing decreasing temperatures during CTMin determinations exhibit neither OS nor consistent LRR. As T_e continues to decrease, swimming activity becomes sporadic, then ceases with fish often lying on the bottom of the test chamber still respiring. Since an obvious, overt endpoint is not apparent, the most often reported endpoint is the fish's inability to respond to prodding with a glass rod. This endpoint has been used extensively in one of the author's laboratories (TLB). If fishes at this endpoint are returned to their pretest acclimation temperature, they will generally survive.

Other Laboratory Methods

Another dynamic temperature method used to estimate lethal temperatures of fishes is the chronic lethal method (CLM). The CLM is similar to the CTM with two exceptions. First, the rate of ΔT during trials is 1 °C per day or slower. Second, death is employed as the CLM endpoint. The low rates of temperature change allow two competing processes to occur. A slower ΔT potentially allows fish to acclimate to the changing thermal conditions during an experimental trial, potentially extending their lower or upper temperature limits. Simultaneously, a slower ΔT allows more time for heat (or the lack of heat) to exert its lethal effects. The same fish species under the same acclimation temperature will demonstrate the following upper thermal tolerance relationship where CTMax > CLMax > IULT.

Laboratory Temperature Tolerance: Two Major Variables

Whether attempting to quantify thermal tolerance with either static or dynamic temperature methods, two variables need to be considered: temperature and exposure time or rate. When exposed to a series of static, high temperatures, fish acclimated at the same temperature will withstand 40 °C longer than either 42 or 44 °C. Tolerance time will be inversely related to test temperature. As a consequence, it is necessary to report both exposure temperature and time. Simply reporting a temperature is incomplete and analogous to reporting a lethal toxicant concentration as 4.2 mg L^{-1} without reporting the time of exposure. In temperature dynamic methods, these two variables are combined into a rate of ΔT. As opposed to the static method, both key variables are changing during a trial.

Influences on Thermal Tolerance

A fish's thermal tolerance is typically greater under a single environmental factor than its tolerance under a combination of environmental factors. Reproducing the holocoenotic environment and its variability in the laboratory is not feasible. However, experimenters must recognize that a combination of environmental, chemical, physical, and biological factors such as thermal history, photoperiod, diel and seasonal cycles, size, reproductive status, stress, concentration of respiratory gases, pH, salinity, and diet are just some factors that must be considered. Thus, measures of thermal tolerance must consider possible multifactor interactions and standardize methods as much as possible to allow for comparisons of data among studies. In this section, we introduce and illustrate how thermal tolerance may be influenced by some commonly and not so commonly considered factors.

Acclimation Temperature

Stress and ultimately death at extreme temperatures can be thought of as an effect of temperature. In contrast, altering thermal limits via acclimation is a response to temperature. In this framework, effects are considered negative, disruptive to homeostasis, and possibly lethal. Responses are adaptive attempts to restore homeostasis or at least minimize the probability of lethality. Adjustment of thermal tolerance limits via temperature acclimation is an obvious response to heterothermal environments.

Temperature tolerances of fishes are influenced by a cornucopia of physical, chemical, and biological factors. Among these, temperature acclimation is probably the most important, yet least understood. As T_e's change, most ectotherms make internal responses involving their biochemistry and physiology to maintain homeostasis. It is important to note that changes in set temperature and resulting physiological rate processes of a fish fully acclimated to 10 °C are quite different from those of fish fully acclimated to 30 °C. Further, these same physiological rates are quite different between full acclimation versus habituation (e.g., short exposure time of a few hours) to 10 °C.

Both upper and lower lethal temperatures of fishes increase as T_e increases during the transition from winter to summer. Conversely, they both decrease with transition from summer to winter. Thus, fishes subjected to heterothermal environments consistently adjust their lethal limits to bracket T_e providing a safety zone between T_e and lethal temperatures.

Many researchers erroneously assume that fishes are acclimated to a particular temperature because they have been held at a constant temperature in the laboratory. Acclimation involves much more than just holding temperature. Exposure of fishes to higher T_e invokes accruement of heat tolerance and, simultaneously, attrition of cold tolerance. Conversely, during exposure to lower T_e, heat tolerance is lost and cold tolerance is gained. Research indicates that rates of heat and cold accruement and attrition are a function of (1) direction of T_e change, (2) the amount of T_e change, and (3) species-specific thermal tolerance. For example, channel catfish (*Ictalurus punctatus*) transferred from 10 to 20 °C required 21 days to reacclimate, whereas only 3 days were required when fish were transferred from 30 to 35 °C. Similarly, loss of heat tolerance (i.e., decrease in CTMax) occurs more slowly. Readjustment of high-temperature tolerance of catfish transferred from 20 to 10 °C and 35 to 30 °C required 54 and 9 days, respectively (**Figure 5**). Thus, heat tolerance is gained 2.5- to 3-times more rapidly than heat tolerance is lost. Fishes therefore require different amounts of time to adjust temperature tolerance limits to different magnitudes and directional changes in T_e. In addition, the rates of reactions required for the acclimation processes are likely to proceed at slower rates at cold temperatures compared with warmer ones.

In addition to acclimating fish at constant temperatures, diel oscillating sine waves of temperature create thermocycles or thermoperiods which may influence measures of thermal tolerance. Some researchers hypothesize that thermocycles better simulate natural exposures to temperature. In other cases, fishes are exposed to thermocycles in an attempt to extend the upper limits of thermal tolerance. Finally, other investigators have attempted to determine if thermocycles result in temperature tolerances consistent with fishes being acclimated to the maximum, average, or minimum temperature of the thermocycle.

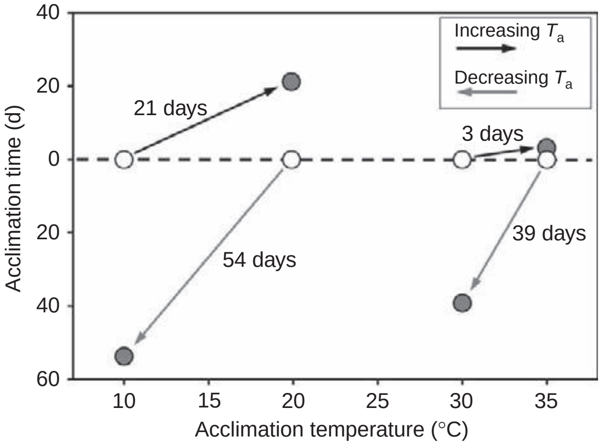

Figure 5 Relative acclimation times for increasing and decreasing acclimation temperature.

Seasonality and Photoperiod

There are numerous examples of seasonal effects on thermal tolerance. Both LRR and OS for two centrarchid species were shown to be higher during the summer than winter (**Figure 6**). Most likely, these seasonal differences in thermal tolerance are due to acclimation affects of temperature related to seasonal change. However, we must still consider the holocoenotic environment and, therefore, we cannot rule out other seasonal influences such as photoperiod. The shorter photophase (light) and longer scotophase (dark) associated with winter months influence thermal tolerance. Shorter photophase in winter causes an increase in the hormone melatonin, which functions to suppress some physiological processes. Exogenous melatonin treatments have been shown to lower thermal tolerance in an amphibian and mammal, further illustrating how even neuroendocrine responses to environmental cues add to the complexity of multifactor interactions that confound studies of thermal tolerance. The production of antifreeze proteins in some fishes off Newfoundland in response to the fall equinox is an excellent example of how a critical aspect of temperature acclimation is triggered by seasonal photoperiod.

Environmental Stressors

Although the field of stress biology is far too vast for even a modest summary, it is worth mentioning that measures of thermal tolerance are used in research as bioassays for environmental stressors. Physiological condition and the ability to tolerate extreme temperatures are compromised

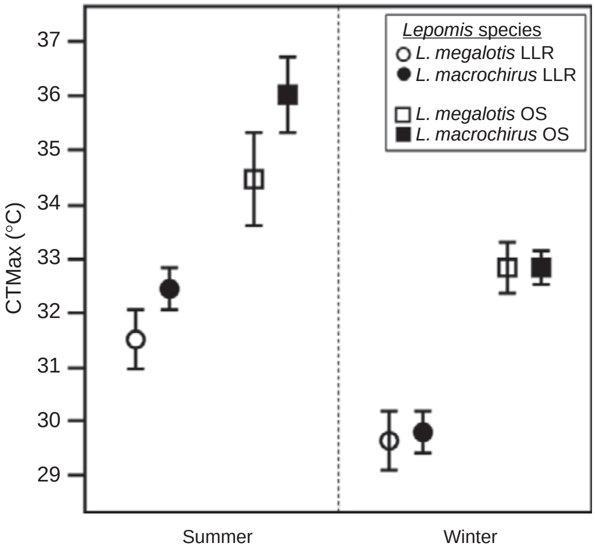

Figure 6 Seasonality of thermal tolerance. Modified from Schaefer JF, Lutterschmidt WI, and Hill LG (1999) Physiological performance and stream microhabitat use by the centrarchids Lepomis megalotis and *Lepomis macrochirus. Environmental Biology of Fishes* 54: 303–312.

under stressful conditions. Poor habitat quality and pollutants directly influence physiological health, reducing thermal tolerance (**Table 1**). A majority of chemicals tested produced significant decreases in temperature tolerance at mg L^{-1} (ppm) concentrations and lower. Poor environmental quality and reduction in physiological health also make fish more susceptible to infection, disease, and increased parasitism. Interactions between parasites and their fish hosts are often deleterious and thus lower physiological performance. In nature, parasites may have negligible effects on a host's overall physiological performance if environmental conditions are optimal. However, under suboptimal environmental conditions, parasites can lower physiological performance and fitness. Lutterschmidt and co-workers showed a clear inverse relationship between total helminth parasite load and thermal tolerance, demonstrating that thermal tolerance can be influenced by parasites and that parasite load should be a further consideration in studies of thermal tolerance (**see also Toxicology**: The Toxicology of Metals in Fishes and The Toxicology of Organics in Fishes).

Reproductive Status and Ontogeny

Reproduction can place a significant demand upon a fish's physiological condition. Reproduction in salmon is so demanding that it results in complete exhaustion and death. For many fish, reproduction is less detrimental to physiological condition but can influence thermal tolerance. In addition to reproductive condition or status, the developmental stage or ontogeny of fish may have associated limits of thermal tolerance. Although an adult may survive particular T_e regimes, earlier developmental stages may be unable to cope with such thermal conditions.

Population and Genetic Influences

Ward and Seely's landmark study in 1996 demonstrated that harsh T_e and environments select for genotypes and play an evolutionary role in conferring increased plasticity of physiological traits. Since this publication, considerable research has addressed both intra- and interspecific differences in thermal tolerance and the relationship between genetic variation and thermal tolerance. Such studies have increased our understanding of ecophysiological theory and the role that genetically based variation in thermal tolerance plays in the evolutionary ecology of fishes. In addition, many studies investigating environmental stress have assessed genetically influenced development of morphometric traits through measures of fluctuating asymmetry rather than thermal tolerance. Increased fluctuating asymmetry in morphological traits occurs under environmental and genomic stress, leading to a reduction in developmental homeostasis. Thus, measures of fluctuating asymmetry can help in determining if populations of fishes are under environmental or thermal stress.

Ecophysiological Theory of Thermal Tolerance

Studies of physiological tolerance, including thermal tolerance, are central to understanding the distributions of fishes and how they may have adapted to these geographic regions. Both biogeography and macroecology attempt to explain such distributional patterns. Liebig's law of the minimum suggests that distributions are governed by those factors for which species have the narrowest tolerance and least adaptability. Species have different abilities in coping, acclimating, and adapting to T_e and its variation. Temperature adaptation, unlike acclimation, requires genetic change over evolutionary time. Investigations of how harsh thermal environments select for genotypes and allow for plasticity in physiological traits are central to ecophysiological theory. Physiological plasticity leads to increased performance breadths, niche diversification, increased geographic distribution, changes in genetic population structure, and ultimately changes in

communities and ecosystems. These invoke theoretical discussions in biology, central to the study of physiological ecology and evolutionary biology.

Biological Applications of Thermal Tolerance

Measures of thermal tolerance may be important in the future assessment of global climate change. The importance of thermal tolerance to the biogeography of fishes is realized when estimating the potential impacts of environmental perturbations on fish populations. Global climate change is a significant environmental threat to numerous species and several studies have documented the effects that climate change will have on the ecology of fishes (**see also Temperature**: Effects of Climate Change). Despite the high specific heat of water and, hence, its resistance to rapid temperature change, global climate change will have a great effect on fishes. This is particularly true for fishes living in shallow, isolated streams, ponds, and lakes. Numerous researchers have specifically addressed how climate change will cause local extinctions, reduce species richness, and affect the distributional status of fishes, including commercial fisheries. However, little is known about the physiological mechanisms that mediate the impacts of climate change. Rates of T_e change, predicted by some models, will exceed the adaptive capacities of most fishes. There is little doubt that temperature exerts selection pressures on the microevolutionary processes of communities and community structure by selecting against individuals with narrow ranges of thermal tolerance. Future investigations of thermal tolerance will be invaluable to fish ecologists, especially in light of the potential impacts of global climate change on the normal thermal regimes of environments.

Concluding Remarks

The history and vast literature clearly demonstrate the importance of thermal tolerance to the field of fish biology. We briefly introduced and illustrated how thermal tolerance is measured and how it has played an important role in our understanding of the ecology and physiology of fishes. Our hope is that this information gives adequate direction for those students of ichthyology and physiological ecology to further explore this truly interesting area of research.

Glossary

Catalytic rate The rate at which an enzyme converts substrate into product.

Conformation The three-dimensional shape a folded protein occupies in aqueous solution. One protein molecule can occupy a number of different conformations.

Denaturation The process by which a protein unfolds from the native state to a random coil that is no longer functional. Denaturation can be caused by high or low temperature, pressure, or chemical denaturants.

Enthalpy A thermodynamic parameter measuring the total heat energy of a system. In a folded protein, enthalpy is roughly correlated with the number of bonds maintaining a particular conformation.

Entropy A thermodynamic property measuring the amount of disorder in the system. Greater disorder is energetically favorable; thus, entropy favors unfolding of proteins.

Enzyme homologs Enzymes that share the same catalytic function in different species, and that arose from the same molecular ancestor.

Ligand A molecule that binds to another molecule, such as an enzyme substrate cofactor, or signaling molecule (Latin ligare = to bind).

Native state The three-dimensional conformation or set of conformations in which an enzyme maintains catalytic activity.

Poikilotherm An organism that cannot regulate body temperature except through behavioral means. An animal whose body temperature fluctuates with that of the environment.

Substrate affinity A measure of the likelihood or strength of binding between substrate and enzyme.

Temperature compensation A change in the rate of a biological process, such as enzymatic rate, to adjust for the accelerating effect of high temperature or the decelerating effect of low temperature. Temperature compensation can occur through acclimation or adaptation.

Introduction

As poikilotherms, fish can experience a wide range of body temperatures, from ~45 °C in pupfish (*Cyprinodon* spp.; **see also Bony Fishes**: Life in Hot Water: The Desert Pupfish) in the southwestern desert of North America or intertidal fish of the tropics and subtropics, to the freezing point of seawater (–1.9 °C) for polar fish such as Antarctic notothenioids. Further, many species of fish occur in environments where temperature can fluctuate greatly on a seasonal or even daily basis. Maintaining adequate physiological performance across this broad range of temperatures requires a variety of adaptations, especially on the biochemical level, many of which involve changes in the composition of macromolecules. For example, temperature-induced changes in the physical properties of membranes in response to thermal stresses are well described, especially in the context of optimization of membrane viscosity to maintain membrane fluidity and the function of embedded membrane proteins (homeoviscous adaptation; **see also Temperature**: Temperature and Excitable Membranes and Membranes and Temperature: Homeoviscous Adaptation). In addition, there is growing evidence that nucleic acids involved in both functional and information-storage roles may be under selective pressure to alter stability in response to environmental temperature. This article focuses on the acute effects of temperature on proteins, especially catalytically functional proteins (enzymes), examines the structural modifications that allow proteins to function optimally in stressful temperature regimes, and describes the locations within enzymes where such structural modifications are most likely to occur.

Effects of Temperature on Enzyme Function

Most enzymes are remarkably specific in the reactions they catalyze, efficiently binding substrate and forming product, while excluding from the binding site molecules that often are structurally very similar to these ligands. Such enzyme specificity is based largely on the detailed interaction between the active site and substrate, dependent partly on geometry – the three-dimensional complementarity between ligand and active site structures – and partly on thermodynamic interactions, for example, between oppositely charged groups or hydrophobic regions.

In addition to substrate affinity, however, appropriate enzyme function also depends on adequate catalytic rate. A highly specific enzyme with negligible turnover of substrate to product would be useless! Thus, in addition to three-dimensional complementarity between substrate and enzyme, adequate flexibility in the enzyme molecule is also necessary. Most enzymes must undergo conformational changes to proceed through the catalytic cycle. Specifically, the enzyme must occupy one conformation appropriate for binding ligands, but be able to modify that conformation in order to produce the transition state and protect that intermediate from substances in the medium (including, for instance, water molecules) that might interfere with the catalytic chemistry. Finally, a further conformational shift is necessary to release product and return the enzyme to its original state, ready to bind another substrate molecule. An overly stable or rigid enzyme molecule, then, would inhibit catalysis by increasing the activation energy necessary to move from one conformation to another. These two attributes of enzymes, structural specificity and flexibility, are both affected by temperature, but in ways that make optimization of enzyme function to a broad range of temperatures difficult.

Substrate Affinity and the Apparent Michaelis–Menten Constant, K_m

The affinity of an enzyme for its substrate is most commonly measured using the apparent Michaelis–Menten constant, K_m, which can be defined most simply as the amount of substrate necessary to allow an enzyme to function at half its maximal velocity. (A more rigorous definition of K_m, employing on- and off-constants of substrate and product, is not necessary for this discussion of the effects of temperature on enzyme function.) Thus, K_m has units of concentration (molar) and a higher K_m value indicates an enzyme with lower substrate affinity (i.e., a higher substrate concentration is necessary to allow the enzyme to reach a certain reaction rate). If an enzyme is assayed across a range of temperatures, the most common pattern encountered is that the K_m of the enzyme rises with temperature (**Figure 1**, heavy black line). To understand this process, it is informative to imagine not one static enzyme molecule encountering substrate, but many enzyme molecules, each of which can occupy a range of conformations. At low temperatures there are relatively few such conformations, and most are able to bind substrate, leading to a relatively low K_m. As temperature increases, however, enzyme molecules are able to occupy a broader range of conformations, a greater proportion of which cannot adequately bind substrate because of modifications to the geometry of the active site. Any one enzyme molecule may shift between binding-competent and binding-incompetent conformations, but in aggregate, the population of enzymes has a lower binding affinity. In essence, the increased heat energy present in the medium (i.e., the increased kinetic energy of solute molecules and the protein itself) induces the breakage of some of the weak interactions that are responsible for holding the active site of the protein in a given conformation, allowing other conformational states to be entered (**see** the section ‘Structural modifications in proteins important for temperature adaptation’). Experimentally, we observe this as an increase in K_m.

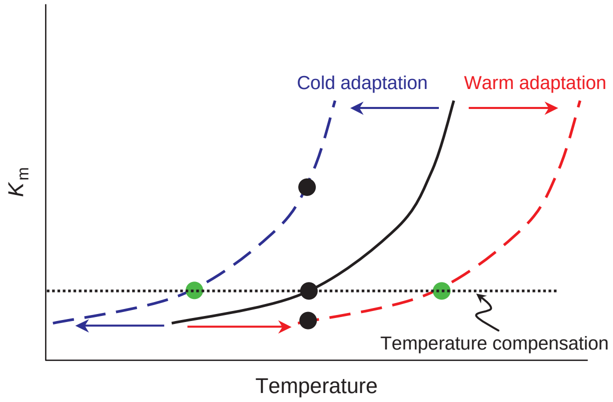

Figure 1 An idealized representation of the effect of temperature on the apparent Michaelis–Menten constant, K_m. Higher temperature increases K_m (thick black line), representing a loss of substrate affinity. Over evolutionary time, adaptation to warm (red arrows) or cold (blue arrows) temperature can lead to temperature compensation – the cold-adapted homolog has a much higher K_m than the warm-adapted homolog at a single measurement temperature (black dots), but the enzymes have similar K_m values when measured at each species’ physiological temperature (green dots).

Given the sensitivity of enzyme substrate affinity to temperature, and the importance of adequate substrate binding to enzyme activity, it is not surprising that enzymes of species adapting to new environmental temperatures demonstrate modified K_m’s. Specifically, as enzymes adapt to colder conditions, K_m values increase at a given measurement temperature, while adaptation to warmer temperature leads to decreased K_m values (**Figure 1**, black dots). The resulting temperature compensation in K_m is such that substrate affinity of the enzyme remains similar at the new environmental temperature (**Figure 1**, green dots). In fact, compensation in substrate affinity has been observed repeatedly in studies of enzyme homologs of closely related fish species living in different thermal environments. Generally, enzymes from more warm-adapted species have lower K_m values at a given measurement temperature, but have similar K_m values within the range of temperatures to which they are adapted. The pattern for cold-adapted species is reversed.

Catalytic Rate and the Turnover Number, k_{cat}

If substrate affinity were the only attribute important in enzyme adaptation to temperature, it would seem plausible that enzyme molecules would adapt to become as rigid as possible, in order to maintain active site structure and affinity regardless of the temperature experienced. However, as described above, excessive rigidity in the enzyme molecule impairs enzyme function by limiting catalytic rate. Catalytic rate in enzymes is measured by the turnover number, k_{cat}, defined as the number of substrate molecules converted to product per active site per unit time (k_{cat} is reported in units of reciprocal time, s^{-1}). As with K_m, k_{cat} for most enzymes is temperature sensitive and increases with increasing temperature. This is because increased thermal energy induces the breakage of weak bonds maintaining enzyme three-dimensional structure, allowing the enzyme to undergo necessary conformational changes more quickly. The result is that enzyme activity tends to increase exponentially with temperature until enough thermal energy is present to cause the relatively sudden denaturation of the enzyme molecule and loss of enzyme activity (**see also Temperature**: Effects of Temperature: An Introduction).

As with substrate affinity, studies of enzyme homologs from different thermal environments show that the flexibility of catalytically important regions of the molecule is increased in enzymes adapting to colder temperatures through the loss of stabilizing interactions, leading to greater mobility with less available thermal energy. Conversely, in those enzymes adapting to warmer conditions, enzyme structure is stabilized through the formation of greater numbers of weak noncovalent interactions.

Based on the above description of the effect of temperature on K_m and k_{cat}, it appears that there are competing and incompatible selective pressures on enzymes adapting to temperature change – increases in rigidity will enhance substrate affinity at the expense of catalytic rate; increased flexibility will increase catalytic rate, but negatively affect substrate affinity (**Figure 2**). The former would be expected in enzymes adapted to warmer temperatures (**Figure 2**, red circle), and the latter in enzymes adapted to cold (**Figure 2**, blue circle). Importantly, then, it appears that while an enzyme may become adapted for optimal function (balancing substrate affinity and catalytic rate) across a narrow temperature range, it may be impossible for an enzyme to maintain optimal function across a broader range of temperatures (**Figure 2**, green circle).

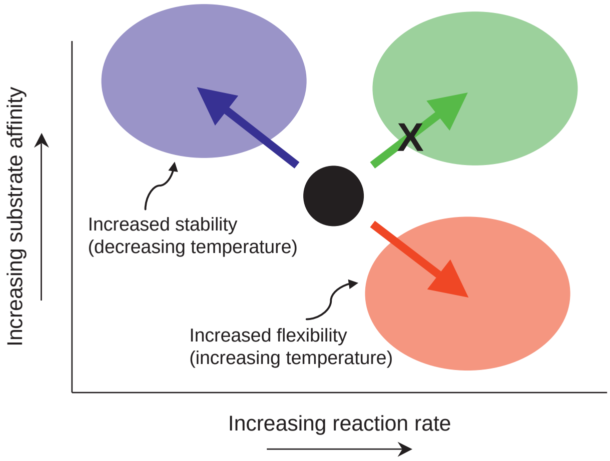

Figure 2 An idealized view of the trade-off between substrate affinity and reaction rate in enzymes. An enzyme with a given substrate affinity and catalytic rate at one measurement temperature (represented by the black circle) will be affected by changes in temperature as shown by the blue-and red-shaded areas – cold increases substrate affinity while decreasing catalytic rate, and higher temperature has the opposite effect. Optimization of enzyme function to maintain or increase both affinity and rate (green shaded area) as temperature changes may not be possible.

Structural Modifications in Proteins Important for Temperature Adaptation

Over short periods of time, that is, within the lifetime of an individual, poikilotherms can use a number of strategies to compensate for changes in enzyme activity due to temperature fluctuations. For instance, organisms can increase enzyme activity at colder temperatures by increasing the copy number of enzymes in the cell, although this may be energetically costly. In addition, for those organisms with the luxury of multiple isoforms of enzymes (and tetraploid fish taxa such as carp (Cyprinidae) and salmon (Salmonidae) are notable here), it is possible that different isoforms will become adapted to, and expressed under, different conditions.

Over evolutionary time periods, it is more likely that selection will optimize enzyme performance through structural modifications. In other words, genetic mutations (leading to amino acid substitutions) will accrue, tending to increase molecular flexibility during cold adaptation, and increase stability during warm adaptation. After considering the balance between stabilizing and destabilizing forces that occurs within proteins in solution, this section describes the types of amino acid substitutions that have been found in enzymes adapting to different temperatures.

Factors Leading to Protein Stabilization or Destabilization

Given the above description regarding the importance of both stability and conformational flexibility in enzyme function, it is not surprising that enzymes in aqueous solution are only minimally stable, with denaturation and renaturation of local regions of the molecule occurring as the enzyme moves from one conformation to another. In fact, although there may be thousands of stabilizing interactions among residues within an average enzyme molecule, the net stabilization of the molecule often is energetically equivalent to only a few hydrogen bonds. This is because there are powerful destabilizing forces acting on the enzyme as well. Unfavorable interactions between amino acids within the polypeptide play an important role in destabilizing the molecule, as do favorable interactions between buried residues and the solute (mainly water) upon unfolding. However, the dominant destabilizing factor affecting proteins is the increase in entropy that occurs during unfolding. Because a denatured protein can occupy many more conformations than the same protein in native form, unfolding leads to an increase in entropy, an energetically favorable condition that is continually pushing the folded form toward denaturation. Thus, the balance between stability and flexibility described above in the context of optimal catalytic function must also be understood as a balance between destabilizing forces (mainly entropic) and stabilizing forces (mainly enthalpic, i.e., based on the formation of weak attractive interactions among atoms) within the protein molecule. Adaptation of an enzyme molecule to function optimally at a new temperature thus involves amino acid substitutions that can affect the magnitude of entropy and enthalpy changes between the native and denatured states.

The types of interactions that stabilize an enzyme molecule, including changes in amino acid composition, hydrophobic interactions, van der Waals interactions, salt bridges between oppositely charged residues, and covalent bonds such as disulfide bridges, are relatively well understood. It is important to emphasize, however, that because of the complexity of proteins made up of many hundreds of amino acids, and the multitude of possible interactions among these residues, it still remains challenging to determine *a priori* how a particular amino acid substitution will affect the stability of a protein in aqueous solution.

Modification of Amino Acid Composition

A hallmark of temperature adaptation in enzymes is modification of the mobility of local regions of the molecule that move during catalysis. Thus, amino acid substitutions that affect structural flexibility have an important role in temperature adaptation. For example, the amino acid glycine is unusual in having no side chain, and thus the peptide backbone on either side of a glycyl residue is relatively free to rotate without physical interference (i.e., there is a minimum of steric hindrance) from neighboring residues. Therefore, mutations increasing the proportion of glycyl residues increase the flexibility of protein structures and allow shifts in conformational states with an input of less thermal energy from the medium.

Conversely, amino acids with bulky side chains, such as the aromatic amino acids tryptophan, tyrosine, and phenylalanine, tend to inhibit rotation of the peptide backbone, simply because the large side chains of these amino acids are difficult to move past neighboring residues without large-scale unfolding of the protein. As a result, these types of residues tend to make protein structures more rigid. A special example of an amino acid that stabilizes proteins through increasing the rigidity of the backbone is proline, which is the only amino acid whose side chain binds to the backbone in two places. The ring structure of proline severely limits the rotation of the backbone near a prolyl residue, and greatly increases the rigidity of the protein in that location. Indeed, researchers examining amino acid composition of organisms adapted to relatively warm or relatively cold environments have discovered a tendency to increase the proportion of glycyl residues in cold-adapted forms, while increasing prolyl residues and aromatic side chains in more warm-adapted species. Note, however, that studies describing changes in proportions of particular amino acids during temperature adaptation do not necessarily address the location of these substitutions within the protein molecule. The location of temperature-adaptive substitutions with respect to the active site, then, is as important as the type of substitution (**see** section 'Location of amino acid substitutions important in enzymic temperature adaptation').

Hydrophobic Interactions

Hydrophobic interactions arise among amino acid residues that are relatively nonpolar (e.g., valine, leucine, and alanine). Because these residues cannot form hydrogen bonds, they interact less favorably with water molecules in the surrounding medium than the water molecules do with one another. It is important to note that stabilization of proteins through hydrophobic interactions does not depend on special interactions between nonpolar residues *per se*, but instead involves the energetic favorability of water–water interactions in comparison to water–residue interactions. The presence of a nonpolar amino acid in water leads to the formation of ordered water molecules that can only hydrogen-bond to a limited subset of neighbors, that is, a cavity is formed in the water structure in which surrounding water molecules lose some rotational and translational freedom. If the nonpolar structure is buried in the interior of a polypeptide – that is, the protein remains folded – the water molecules in solution are free to hydrogen-bond with a greater number of neighbors, increasing the entropy (and energetic favorability) of the system. Thus, a core of hydrophobic residues tends to stabilize the native state of the protein.

The nature of the interactions between amino acid residues and water, and among water molecules themselves, makes the hydrophobic effect temperature dependent. Simply put, within the temperature range fish experience, the hydrophobic effect is weak at lower temperatures and becomes stronger at high temperatures. At low temperatures, close to the freezing point of water, water molecules in the surrounding medium have relatively little kinetic energy, and so will form relatively long-lived hydrogen bonds with neighbors. Under these conditions, the introduction of a nonpolar amino acid residue to the aqueous solution will not force many extra water molecules into more ordered interactions – there is a relatively small entropic penalty, and thus proteins stabilized by hydrophobic interactions will be less stabilized and more likely to unfold in the cold (this is the basis of cold denaturation of proteins). Conversely, at higher temperatures, when water molecules form and break hydrogen bonds with neighbors much more rapidly, introduction of nonpolar side chains becomes more disruptive – the ordered water structures that must form are energetically more costly. Thus, at higher temperatures hydrophobic interactions become more stabilizing. Again, empirical evidence supports these observations – generally, more warm-adapted enzymes tend to have a greater proportion of nonpolar amino acids.

Hydrogen Bonding, Ionic Interactions (Salt Bridges), and van der Waals Interactions

In addition to hydrophobic interactions, proteins can be stabilized by a number of other weak (i.e., noncovalent) interactions dependent on the types of contacts among amino acids in the three-dimensional structure of the native state. For example, in the average-sized protein there can be many hundreds or thousands of hydrogen bonds among polar amino acid residues, or between polar side chains and the amide or carbonyl groups of the peptide backbone. Not surprisingly, among proteins adapted to cold, the necessity for greater flexibility generally leads to a reduction in intramolecular hydrogen bonds. Similarly, salt bridges, which are attractive electrostatic interactions among oppositely charged ionizable side chains, can also provide stability to protein structures. Salt bridges form between the acidic (i.e., negatively charged) residues of aspartate and glutamate and the basic (positively charged) residues of lysine, arginine, and, sometimes, histidine. Comparative analyses of enzymes from species adapted to different temperatures reveal that warm-adapted homologs tend to have relatively more charged residues, presumably because salt bridges between pairs of these residues add to protein stability.

A further type of interaction significant in stabilizing the three-dimensional structure of a protein involves efficient packing of residues and concomitant van der Waals interactions. These interactions occur when uncharged atoms are brought into close proximity: fluctuations in the positions of electrons around the nucleus of one atom can produce a temporary dipole that induces a complementary dipole in the neighboring atom. The weak dipoles attract each other, drawing the two atoms together until they reach an optimal distance in which attractive and repulsive forces balance. Because stabilization via van der Waals interactions depends on close association of interacting atoms, efficient packing of residues in the interior of a folded protein may lead to greater stabilization by encouraging the formation of more, stronger van der Waals pairs. Efficient packing seems to depend in part on residue volume (i.e., the sum volume of atoms in the residue side chain – tryptophan for example – having a greater volume than alanine (227.8 vs. 88.6 Å^3)), and thus increased van der Waals stabilization correlates with a greater number of residues of relatively large-volume amino acids. Again, given our expectations of temperature adaptation in enzymes, it is not surprising that warm-adapted enzymes generally have increased average residue volumes relative to their cold-adapted homologs, thereby enhancing van der Waals interactions.

Disulfide Bonds

Disulfide bonds are highly stabilizing covalent interactions between the sulfhydryl groups of neighboring cysteinyl residues. Due to the strength of the –S—S– bond, these interactions provide extreme stabilization against denaturation. However, because of the highly reducing environment of the cytoplasm disulfide bonds do not appear to be employed in the stabilization of intracellular enzymes, regardless of the temperature the species experiences. Instead, disulfide bonds are most prevalent in proteins targeted for extracellular function.

Location of Amino Acid Substitutions Is Important in Enzymic Temperature Adaptation

The structural modifications described above have important effects on the stability of enzyme molecules, and evidence indicates that each (except for disulfide bonds) can be used to modify enzyme activity for optimal function at different temperatures. It is important to note, however, that temperature-adaptive amino acid substitutions do not appear haphazardly throughout the structure of an enzyme. Instead, such stabilizing or destabilizing substitutions tend to occur in discrete locations relative to mobile regions of the enzyme.

Remarkably, active site residues – those amino acids that bind substrate and cofactor and are directly involved in the catalytic chemistry mediated by the enzyme – rarely are modified during adaptation to different temperatures. In other words, it appears that the three-dimensional relationship of these residues with ligands is so important to catalysis that the residues cannot be substituted without severely affecting substrate affinity and catalytic rate. Thus, as a nearly universal rule, enzyme adaptation to temperature does not involve changes to the active site.

Instead, studies of homologs of a number of enzymes from species adapted to both cold and warm temperatures indicate that temperature-adaptive substitutions tend to occur in regions bordering the active site, and especially those regions that must move during catalysis. An idealized enzyme molecule can be imagined to have a relatively static core, which does not move during catalysis and is highly stable. The static core acts as a scaffold on which is built the active site and mobile structures nearer the periphery of the molecule. These mobile structures, which may comprise loops, α-helices, or larger components based on multiple secondary structures, control access to the active site and create the catalytic vacuole through their movements. While the mobile structures themselves may retain appreciable rigidity, small areas of the protein act as hinges allowing the structures to move. Analysis of differentially adapted homologs indicates that these hinge regions are the predominant locations of functionally relevant amino acid substitution during enzymic temperature adaptation.

Glossary

Acyl chain The nonpolar hydrocarbon chains composing the central core of biological membranes. Phospholipids typically contain two acyl chains, whereas triglycerides contain three. Acyl chain length ranges between 10 and 26 carbons and the number of double bonds influences their conformation. In this article, the term fatty acid is used interchangeably with acyl chain.

Apoptosis Programmed cell death that can be initiated by mitochondrial liberation of cytochrome C.

Arrhenius break temperature Temperature at which the relationship between maximal rates and assay temperature shows an abrupt transition.

Bilayer The basic phospholipid structure of biological membranes. Two layers of phospholipids are placed such that their polar head groups are at opposite sides, whereas the nonpolar acyl chains join each other in the center. The structure is like a sandwich with the head groups being the bread and the acyl chains the filling.

Cardiolipin A phospholipid only found in mitochondria that contains four acyl chains conjugated to a diglycerol backbone.

Electron transport system (ETS) A series of multisubunit protein complexes and two mobile electron carriers, embedded in or associated with the inner mitochondrial membrane. The ETS transfers electrons from reducing equivalents to oxygen to form water and in so doing forms an electrochemical gradient.

Mitochondria Organelles that synthesize most of the adenosine triphosphate (ATP) needed by the cell, using oxygen as the final electron acceptor.

Oxidative phosphorylation The production of ATP by the F_1F_0ATPase using the electrochemical gradient produced by the ETS. Oxidation by the ETS is coupled with phosphorylation by the F_1F_0ATPase.

Phospholipids Molecules composed of a polar head group and two nonpolar acyl chains.

Reducing equivalents Molecules that transfer electrons in oxidation–reduction reactions.

Saturation (unsaturation) Acyl chains that do not contain double bonds are said to be saturated, containing all the hydrogen possible. Unsaturated acyl chains contain at least one double bond and polyunsaturated acyl chains contain more than one (up to six in the case of DHA) double bond.

Introduction

Mitochondria are often referred to as the powerhouse of the cell, as they are the site of oxidative phosphorylation in eukaryotic cells. Oxidative phosphorylation is the most efficient biological means by which fuels, such as carbohydrates and proteins and lipids, are converted into the cellular energy currency, adenosine triphosphate (ATP). First, the Krebs cycle, located primarily in the mitochondrial matrix, generates reducing equivalents from these fuels. The electron transport system (ETS) uses these reducing equivalents to produce a proton gradient across the inner mitochondrial membrane. Oxygen is the final electron acceptor of the ETS. This electrochemical gradient provides the thermodynamic impetus for a multisubunit protein complex in the inner mitochondrial membrane, the F_1F_0ATPase, to add a phosphate group to adenosine diphosphate (ADP) and produce ATP. When ATP is produced by anaerobic glycolysis, the yield of ATP per glucose is approximately 10-fold lower than that as a result of oxidative phosphorylation. As acidification of the cytoplasm accompanies glycolytic ATP production, its duration is restrained by the limited tolerance of pH fluctuations typical of living systems.

Although mitochondria provide the cell with most of its ATP and, in a sense, potential energy for work for the remainder of the cell, living with mitochondria has its difficulties. To begin with, the cell needs to keep conditions comfortable for mitochondria. If the mitochondrial membrane potential drops below a critical value, apoptosis can be triggered, resulting in controlled, but nonetheless irreversible, cell death. Thus, under extreme conditions when the mitochondrial membrane potential is drastically diminished due to a lack of oxygen, glycolytically generated ATP may be used by the F_1F_0ATPase to pump protons in the reverse direction, to re-establish the mitochondrial membrane potential.

Another negative aspect of mitochondrial activity is the production of reactive oxygen species (ROS) by the ETS. ROS can damage proteins, lipids, and deoxyribose nucleic acid (DNA). Particularly when mitochondria are idling, poised for ATP synthesis, ROS production can be considerable due to side reactions in which oxygen combines with electrons and becomes more reactive. Proton leak across the inner mitochondrial membrane is activated by ROS. The ensuing decrease in the membrane potential slows down ROS formation, but reduces the overall ratio of ATP produced to the amount of oxygen consumed.

Thus, having mitochondria has benefits and costs (**Figure 1**): the efficiency of ATP production is vastly increased by oxidative phosphorylation, but if the polarization of the inner membrane is not maintained, apoptosis may result. Maintaining the inner membrane potential when ATP synthesis is slow favors the production of ROS that damage cellular components. While proton leak minimizes ROS formation, it liberates energy as heat, and not as useful ATP. Regulation of mitochondrial activity must strike a balance between these conflicting requirements.

Mitochondrial membranes have interesting structural particularities. The inner membranes have the highest protein density of all intracellular membranes. As only a small number of lipid molecules is thought to separate the proteins, localized changes in membrane phospholipids may be critical in establishing the activities of membrane proteins. In all vertebrates examined to date, mitochondrial membranes do not contain cholesterol, in contrast to the plasma membrane, which generally contains cholesterol. The mitochondrial inner membrane is the only cellular structure containing cardiolipin, a phospholipid composed of four acyl chains attached to a di-glycerol backbone. Cardiolipin molecules are tightly associated with several protein complexes of the ETS, in particular, cytochrome C oxidase (CCO) and the F_1F_0ATPase, as well as with adenine nucleotide translocase (ANT). An unusual acyl chain, vaccenate, is a central element of the oxygen-transport system in CCO from the eukaryotic cows to the prokaryotic soil bacteria, *Paracoccus denitrificans*. The conservation of vaccenate in this critical position across such a huge phylogenetic distance argues for an important functional role besides an ancient origin. These specific structural attributes and phospholipid requirements of mitochondrial membrane proteins suggest not only that these lipids play critical functional roles but also that thermal change could perturb mitochondrial performance. But what would these consequences of thermal change be?

As fish are water breathers, changes in habitat temperature translate into changes in body temperature for most species. Temperature affects the kinetic energy of molecules and modifies rates of diffusion and molecular interactions. As thermal change has differential impacts upon the weak bonds (hydrophobic and hydrophilic) responsible for tertiary protein structure, it can affect the stability and the activity of critical mitochondrial proteins (**Figure 2**) (**see also Temperature**: Effects of Temperature: An Introduction).

Thermal change can also profoundly alter membrane properties, by causing phase shifts in phospholipid bilayers. Those for whom this concept is foreign need only to think of how butter melts when heated. These transitions between gel and liquid phases occur over a range of temperatures for lipids. The more saturated a fat (e.g., butter), the lower the temperature at which the gel state is favored. Saturated lipids have linear acyl chains that become ordered more easily than the kinky acyl chains of unsaturated fats. Lipids with polyunsaturated acyl chains have extreme acyl-chain curvature and high transition temperatures. One of the most highly unsaturated acyl chains, docohexanoic acid (DHA; 2:6*n*-3),

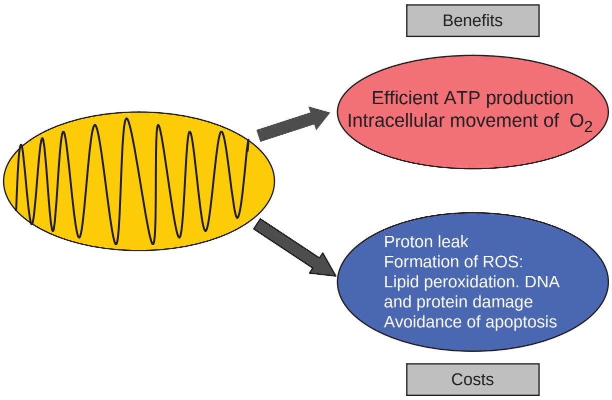

Figure 1 Costs and benefits of mitochondria.

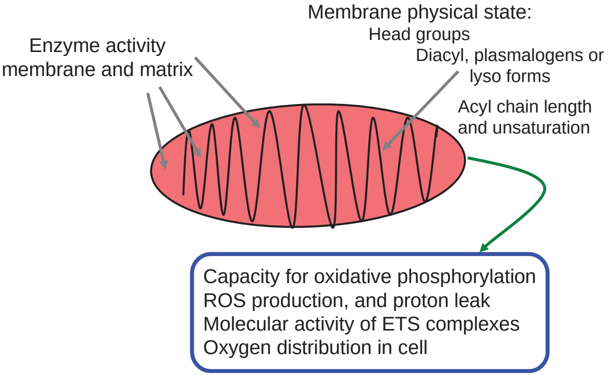

Figure 2 What mitochondrial properties are sensitive to thermal change?

assumes a pyramidal shape in phospholipid bilayers. This conformation facilitates dynamic modifications of membrane structure. Cholesterol tends to prevent phase changes; so, its absence in mitochondrial membranes suggests that they would be more likely to be perturbed by thermal change than other intracellular membranes. Phospholipid head groups also influence membrane order. Phosphatidylethanolamine (PE) destabilizes membranes whereas phosphatidylcholine (PC) increases membrane stability. Thus, both the phospholipid and acyl-chain composition of a membrane will influence its physical state and how it is affected by thermal change.

The physical state of cellular membranes has been proposed to act as a metabolic pacemaker by setting the rates at which membrane-bound proteins carry out their activities. Therefore, the impact of temperature on the physical state of mitochondrial membranes could have far-reaching functional consequences. The fact that, of cellular membranes, mitochondrial membranes show the most complete thermal compensation of fluidity and dynamic physical state may reflect the importance of maintaining the balance between the positive and negative roles of mitochondria under a range of environmental conditions.

Particularly for fish from temperate zones, both diurnal and seasonal fluctuations in environmental conditions can be pronounced. Strong seasonal cycles in temperature, photoperiod, and food availability are typical, especially for anadromous or catadromous species. Daily thermal fluctuations in shallow ponds or intertidal pools can be more pronounced than seasonal changes in marine habitats. Just as aquatic habitats differ in their seasonal and diurnal temperature fluctuations, the fish exploiting these habitats vary in the temperatures and thermal fluctuations they can tolerate. These tolerances change during development with larval and juvenile stages often having narrower limits than adults. Thermal tolerances also change with an individual's thermal history and can differ between latitudinally separated populations. Such tolerances are a major determinant of biogeography and are of increasing interest in the context of global climate change.

It is likely that fish that better tolerate thermal fluctuations will have proteins that are damaged little by typical thermal excursions, or they possess better rescue systems to resurrect damaged proteins. Fish that tolerate thermal instability should either have a mitochondrial membrane composition that minimizes the impact of thermal change upon its functional properties, or be able to rapidly adjust composition in response to thermal change. In the following an overview of how fish mitochondria respond to acute thermal change and how changes in macromolecular design have allowed adaptation of mitochondria to vastly different thermal regimes over evolutionary time is given. This is followed by an examination of how fish can modify their mitochondria in response to thermal acclimation. While knowledge in this area is grounded in decades of study, it is rapidly expanding, with the application of genomic and proteomic techniques that allow concomitant examination of the expression of thousands of genes. Such molecular studies are confirming previous findings and are extending our understanding of the plethora of changes occurring during transitions between thermal regimes in eurythermal fish.

Fish Mitochondria and Thermal Change

Most experimental studies of thermal effects vastly simplify thermal dynamics in comparison with the patterns observed in nature. Acute thermal effects are evaluated using isolated preparations, thereby minimizing *in vivo* adjustments that could mitigate the impact of thermal change. These acute thermal shifts are vastly larger and often exceed the range of temperatures encountered by the species. Studies of thermal acclimation expose fish to constant temperatures, often at constant, and therefore unrealistic, photoperiods. Sampling fish at different seasons in their habitat is more realistic, but interpretation of results is complicated by concomitant changes in biotic and abiotic factors. Few studies have examined the time course of the response to temperature. Thus, our knowledge of the effects on temperature upon fish mitochondria can be compared to an impressionist painting, with broad strokes providing a reasonable overview, but details lacking for most species. The impressive diversity of fish, not only in their phylogeny and evolutionary history, but also in their habitats and lifestyles, should prevent biologists from assuming that there is just a single response of fish mitochondria to temperature.

Responses to Acute Thermal Change

For enzymes, covariation of pH and temperature minimizes the impact of thermal change on substrate affinities, but maximal rates remain subject to the tyranny of Arrhenius (**see also Temperature**: Effects of Temperature: An Introduction). Insofar as maximal rates of substrate oxidation are concerned, a similar picture applies to fish mitochondria: maximal rates rise with temperature, even though maximal capacities vary seasonally and rates at habitat temperature fall during winter months (**Figure 3**). The thermal sensitivity of mitochondrial affinities for carbon and adenylate substrates is less well documented, but affinities for carbon substrates tend to be maintained, when pH covaries with temperature. The ADP affinity of rainbow trout (*Oncorhynchus mykiss*) muscle mitochondria and its thermal sensitivity vary seasonally, with ADP Km_{app} increasing with assay temperature only during warm periods (**Figure 4**). Acute thermal change does not perturb the pH gradient across the inner membrane of mitochondria from carp

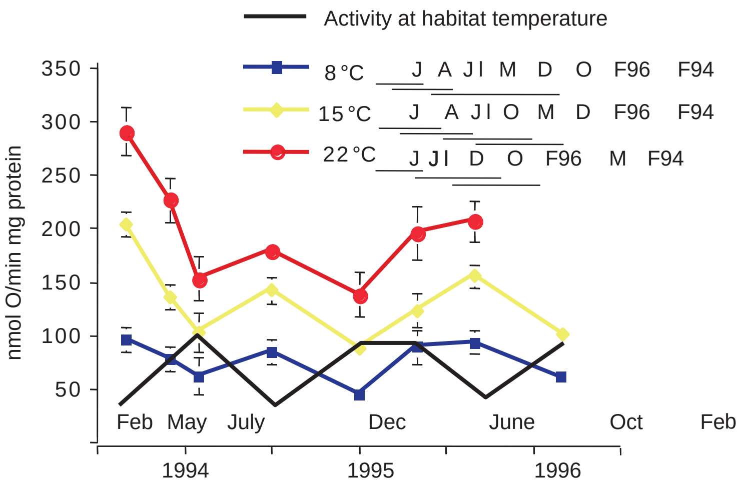

Figure 3 Seasonal cycles of maximal oxidative capacity of muscle mitochondria (at 8, 15, and 22 °C) from naturally acclimatized trout.

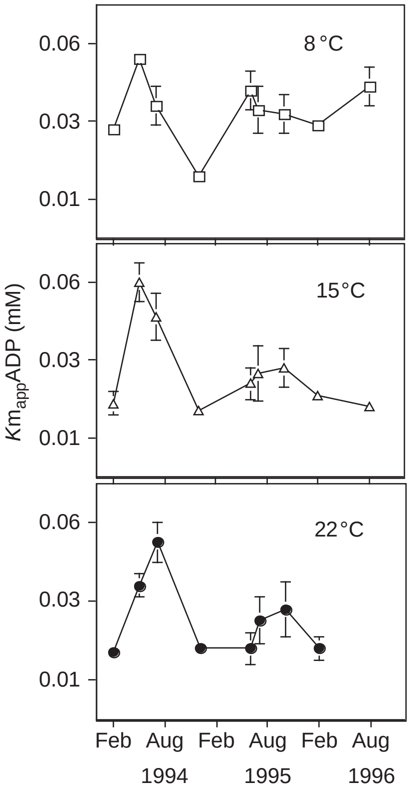

Figure 4 Seasonal cycles of ADP affinity in trout muscle mitochondria.

muscle. Q_{10} values for maximal rates of mitochondrial substrate oxidation vary seasonally, but maximal rates always fall as temperature drops (**Figure 3**). This consistent, acute thermal sensitivity of mitochondrial oxidative capacities may underlie the frequently observed compensation of oxidative capacity during thermal acclimation of cold-active species (see below).

During acute thermal change, mitochondrial membranes undergo changes in physical state that could be mitigated *in vivo*. Thus, when desert cyprinids (*Agosia chrysogaster* and *Notropis lutrensis*) are sampled at different times of the day at a wide range of temperatures, the membrane phospholipid head-group composition differs. Indeed, head-group composition can change quite rapidly, with marked shifts completed within 2 days of thermal transfer. Such mechanisms may alleviate the functional impact of acute thermal change *in vivo*. Protective effects of heat-shock proteins could also minimize acute thermal effects during exposure to extreme temperatures *in vivo*.

Evolutionary Thermal Adaptation

The specialization of fish mitochondria for different habitat temperatures is shown by interspecific comparisons of mitochondrial respiration rates. On the one hand, one relationship describes the thermal sensitivity of oxidation rates of mitochondria isolated from muscle of a variety of percid fish from Antarctic to subtropical habitats. For each species, assay temperatures closely bracketed habitat temperatures. On the other hand, the Arrhenius break temperatures (ABTs), obtained from curves relating respiration rates to assay temperature, vary markedly between tropical and Antarctic fish. In these assays, mitochondrial respiration rates are measured at temperatures up to 25 °C above habitat values. Mitochondria from tropical fish show considerably higher ABTs for the different respiratory states than mitochondria from Antarctic fishes. When measured at a common temperature, membrane fluidity is lower in the species from warm waters than in those living at cooler temperatures. Thus, membrane properties of mitochondria have adjusted to typical habitat temperatures over evolutionary time, but protein-specific mitochondrial respiration rates for fish from polar waters have not increased to compensate for the cold temperatures. Over short-term evolutionary timescales, mitochondrial function seems quite conserved. Thus, despite specialization of Arctic and Brook chars (*Salvelinus alpinus* and *Salvelinus fontinalis*) for different thermal habitats and divergence of their protein structures, ETS complex activities and thermal sensitivities were maintained in naturally occurring hybrids.

When fish species with similar lifestyles are compared, fish inhabiting permanent cold have higher mitochondrial volume densities in their muscles than those living in warmer or more variable climes. These high mitochondrial contents by far surpass those in mammalian heart and presumably curtail the space that can be devoted to other organelles, including the myofibrils that are responsible for contractile activity. Various interpretations have been given for these high volume densities, including thermal compensation of capacity and facilitation of oxygen distribution. This mitochondrial abundance may enhance rates of ROS production, explaining the high levels of superoxide dismutase, the major enzymatic protector against ROS, in Antarctic species. Abundant mitochondria also require maintenance of the membrane potential despite proton leak. The associated metabolic cost would increase standard metabolic rate and become problematic when ventilatory costs reduce the availability of oxygen.

Membrane phospholipid composition differs markedly with thermal habitat, such that the membrane physical state is similar at different body temperatures. To this end, modifications in the unsaturation and in the proportion of long-chain polyunsaturated fatty acids are accompanied by shifts in the relative levels of the major phospholipids (choline, serine, ethanolamine, etc.) (**Figure 2**). Membrane phospholipid composition follows tissue temperature more than central temperature. These compositional modifications conserve the dynamic nature of the membrane, such that organismal temperature is approximately centered between the temperatures of the phase transitions (fluid–gel transition and formation of inverted vesicles). The concept of homeoviscous adaptation (**see also Temperature**: Membranes and Temperature: Homeoviscous Adaptation), which refers to the maintenance of membrane fluidity or viscosity, is often used to justify the compositional changes. The greater polyunsaturation of membrane phospholipids at low body temperatures also facilitates the movement of oxygen within the more fluid hydrophobic core of the membrane. However, greater polyunsaturation of phospholipids at low temperatures may increase proton leak and enhance susceptibility to lipid peroxidation. Presumably to mitigate these difficulties, polar fish maintain exceptionally high levels of lipid antioxidants, such as vitamin E.

Response of Fish Mitochondria to Thermal Acclimation

The metabolic strategy used by a fish species to respond to thermal acclimation should depend upon whether it remains active at all seasons. Thermal acclimation is typically studied by holding fish at different temperatures for several weeks while leaving other parameters as constant as possible. When thermal acclimation modifies rate functions so that the rate at the new temperature is not simply dictated by their Q_{10}, thermal compensation is said to have occurred.

Herbert Precht separated responses to thermal acclimation (or acclimatization) into overcompensation, perfect compensation, partial compensation, no compensation, and inverse compensation. These categories illustrate the strategies available for coping with thermal change. For example, when fish are faced with an upcoming winter, they can:

1. slow their processes by following Q_{10} effects (no compensation),
2. depress metabolism by enhancing thermal effects (torpor and negative compensation), or
3. use partial or perfect compensation to offset Q_{10} effects.

Isolated mitochondria from cyprinids, salmonids, and sculpins fall in the last category. Mitochondrial enzyme levels in muscle increase with cold acclimation of numerous cold-active species, suggesting that oxidative phosphorylation is particularly sensitive to cold. Intriguingly, mitochondrial proliferation in the anoxia-tolerant crucian carp (*Carassius carassius*; **see also Bony Fishes**: Crucian Carp) is similar to that in cold-active species. Crucian carp release ethanol to maintain their energy status during prolonged winter anoxia, and markedly depress metabolic demands during these periods. Tissue-specific responses may occur; for example, cold acclimation of carp decreases uncoupling protein-1 (UCP-1) levels in the liver but increases them in the brain.

Many studies have shown that cold acclimation can increase muscle oxidative capacities in temperate-zone fish (**Figure 5**). Muscle oxidative capacities rise (as demonstrated by rises in the activity of mitochondrial enzymes), through increases either in mitochondrial content or in the oxidative capacities of mitochondria. An increased proportion of oxidative fibers in the musculature may contribute. Mitochondrial proliferation can occur within glycolytic or oxidative fibers. The response of striped bass, *Morone saxatilis*, has been particularly well characterized: cold acclimation increases muscle oxidative capacity, mitochondrial volume density, lipid concentration, and lipid oxidation capacity. The increase in muscle lipid contents (both triglycerides and mitochondrial membranes) partially offsets the impact of cold on the intracellular diffusion of oxygen. Increases in the capacity for lipid oxidation and storage are also seen during cold acclimation and seasonal cold acclimatization of rainbow trout. Antioxidant systems respond to thermal acclimation, but as ROS production rises with temperature, while susceptibility to ROS damage increases with cold-induced lipid polyunsaturation, the patterns are difficult to interpret. In rainbow trout, optimal swimming performance occurs after acclimatization (in outdoor ponds) to 11 °C and despite increases in mitochondrial capacities, rates at habitat temperature fall in winter (**Figure 3**). While mitochondria are a primary target of thermal compensation in oxidative and glycolytic muscle, compensation is rarely perfect and performance may be optimal at intermediate temperatures.

Figure 5 Cold acclimation of winter active fish.

Mitochondrial proliferation requires coordinated expression of nuclear and mitochondrial encoded genes, and relies on the integrated activity of DNA-binding proteins and their coactivators. In contrast to mammals, the nuclear respiratory factor-1 is the primary activator of mitochondrial proliferation in fish, while the peroxisome proliferator-activated receptor is linked with fatty-acid metabolism. All the ETS complexes contain many subunits, with most encoded by the nucleus but some in mitochondria. Understanding of the regulation of their synthesis is far from complete. Sufficient quantities of membrane must be produced to lodge the mitochondrial proteins. Oxidative capacities of existing mitochondria may be enhanced by either increasing the number of ETS complexes per inner membrane area or changing the phospholipid composition.

Thermal acclimation causes extensive remodeling of the phospholipid and fatty-acid composition of mitochondrial membranes, leading to changes in the activity of mitochondrial enzymes per milligram mitochondrial protein. This may be the basic response to thermal change. Within hours after transfer to cold temperatures, changes in phospholipid structure are initiated. Changes in phospholipid head groups occur after 8 h, the ratio of saturated to monenoic acyl chains shifts within 2–4 days of thermal transfer, whereas changes in the proportions of long-chain polyunsaturated fatty acids require weeks of thermal acclimation. Cold acclimation of cyprinids (**Figure 6**) markedly changes mitochondrial phospholipids, increasing the proportion of PE to the detriment of PC and raising the proportion of unsaturated and polyunsaturated fatty acids in PC, but not in CL. The changed lipids account for the increased activity of succinate dehydrogenase, CCO and the F_1F_0ATPase with cold acclimation. Activation of the Δ9-desaturase by changes in membrane order with falling temperature increases the unsaturation of the central core of the phospholipid bilayer. Production of Δ9-desaturase mRNA during cold acclimation further increases enzyme number and activity. Shortly (2–4 days) after transfer to their new temperature, the oxidative capacities of rainbow trout muscle mitochondria change actually accentuating the impact of thermal change, but longer acclimation leads to thermal compensation (**Figure 7**). During warm acclimation of rainbow trout, the phospholipid composition of isolated mitochondria changes more than contents of cytochromes or ANT. Marked changes of acyl-chain composition in minor phospholipids, such as the plasmalogen forms of PE and PC as well as cardiolipin, suggest that specific compositional changes in these

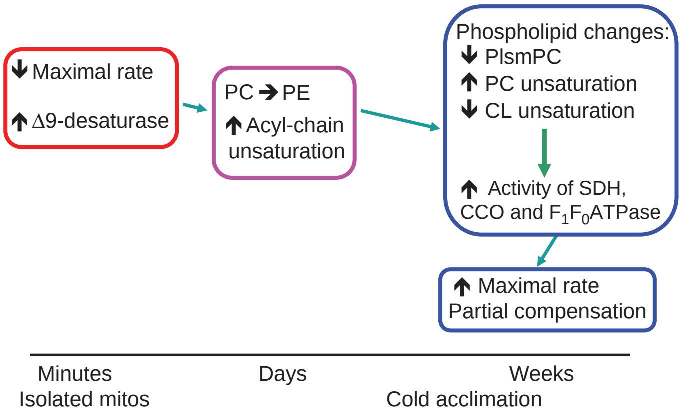

Figure 6 Responses of isolated mitochondria to cold acclimation in cyprinids.

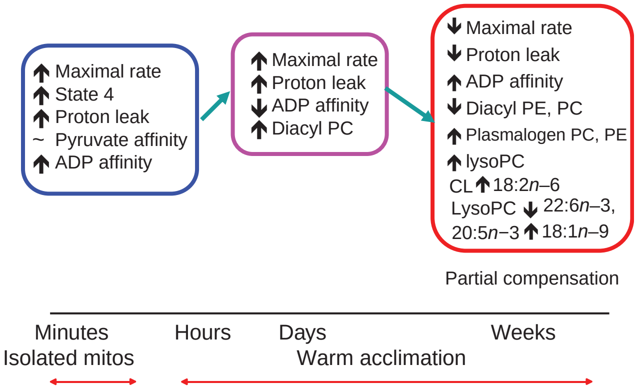

Figure 7 Time course of responses of muscle mitochondria during warm exposure: rainbow trout.

phospholipid classes modulate the activity of the ETS complexes. Cold-acclimated rainbow trout have more PE in the inner half of the inner mitochondrial membrane than warm-acclimated rainbow trout. The enrichment of membranes from cold-acclimated rainbow trout (5 °C) with these membrane-destabilizing lipids helps maintain the dynamic behavior of the membrane at low temperatures. The response to thermal acclimation can vary among latitudinally separated populations, with northern populations of killifish (*Fundulus heteroclitus*) compensating more for low temperatures than the southern populations.

Responses to laboratory acclimation may differ from those occurring when fish are acclimatized to natural changes in photoperiod and temperature, or are sampled in their habitat at these temperatures. These changes were noticed when comparing the oxidative capacities of mitochondria from rainbow trout sampled at various periods during their annual cycle. The compensatory increase in maximal rate was particularly marked during the autumnal decrease in temperature. In other words, although habitat temperatures had only begun to fall, the increase in mitochondrial oxidative capacity was greater than needed to compensate for the actual thermal change, suggesting that the fish were anticipating the expected seasonal change. Effectively, rainbow trout acclimated to short day lengths at warm temperatures increase the oxidative capacity of isolated muscle mitochondria, but to a lesser extent than trout acclimated to short day lengths and cold temperatures. Thus, photoperiod control allows fish to prepare their mitochondria for the upcoming season. Furthermore, if thermal acclimation is carried out at seasonally inappropriate photoperiods, fish performance differs radically from that obtained under appropriate photoperiods. The signals involved are yet to be identified.

Temperature and Fish Mitochondria in the Genomic Era

Whereas most of the foregoing article is based on experimental tests of hypotheses concerning specific parameters, such as mitochondrial oxidative capacities, activities of mitochondrial enzymes, or phospholipid composition, the study of thermal acclimation has plunged into the genomic age with the development of DNA chips allowing the examination of changes in expression of thousands of genes. Together with

Transcriptomics:
Cold acclimation of carp enhances expression of approximately 3400 genes involved in:

- RNA processing
- Translation initiation
- Modification of higher membrane (Δ9 desaturase)
- Mitochondrial metabolism
- Muscle atrophy
- Proteasome components
- Unknown functions….

Figure 8 Transcriptomics: cold acclimation of carp enhances expression of approximately 3400 genes involved in various processes.

proteomic and metabolomic analyses, these powerful approaches show when and how functional groups of genes respond to environmental change and reveal responses of gene sequences of unknown function. This exploratory approach has the potential to move understanding to an entirely new level. A pioneering study followed the tissue-specific responses of carp during cold acclimation using a gene chip with approximately 13 000 sequences. While induction of the Δ9-desaturase in all tissues and increases in expression of mitochondrial proteins confirmed previous findings, other increases in expression were more surprising (**Figure 8**). For example, the ubiquitin-linked proteasomic pathway and genes stimulating muscle atrophy were markedly activated during cold exposure. When links between the changes in expression and the levels of the product are examined, the correlations between changes in message and in the protein products are positive, but vary in time as well as in strength. As the message and the protein are at different stages of a highly regulated sequence, such confirmation is needed for sound interpretation of expression patterns.

These discovery-based investigations will identify new processes involved in thermal change in fish as well as clarify the integration between previously identified processes. With the increasing availability of sequence data and complementary DNA (cDNA) micro-arrays for many fish species, our understanding of the responses to temperature should increase by leaps and bounds in the coming years. Given the impressive phylogenetic diversity of fish and the variety of habitats they exploit, study of mitochondrial responses to temperature among these species will reveal central processes in the coevolution between mitochondria and the organisms they serve.

Glossary

Action potential A small and transient change in voltage across the cell membrane. The action potential is possible because of the activity of ion channels embedded in the cell membrane, selectively allowing certain inorganic ions to pass through their pore.

Activation Transformation of the ion channel from the resting closed state (i.e., inactivation gate open and activation gate closed) to the open state by the opening of the activation gate.

Conduction velocity The rate at which an action potential proceeds along the cell membrane.

Deactivation Transformation of the activation gate of an ion channel from its open position to the closed position.

Depolarization The reduction in electrical potential difference (voltage) measured across a cell membrane. This means the inside of the cell becomes less negative with respect to the outside of the cell. Depolarization occurs during the upsweep of the action potential (opposite of repolarization).

Excitable membrane A cell membrane of neurons and muscle cells (and some glandular cells) which generates self-propagating action potentials. Nonexcitable cells can produce local voltage changes that dampen quickly.

Homeoviscous adaptation Adaptation of the lipid membrane to changing temperature via alterations in its chemical composition, which counteracts temperature-dependent changes in membrane fluidity (viscosity) mainly by changes in saturation level of fatty acids.

Inactivation Transformation of the ion channel from an open state to a closed state (i.e., activation gate open, inactivation gate closed) by the closure of the inactivation gate.

Inward current A flow of positively charged ions across the membrane into the cell.

Ion channel A protein or a group of proteins that form water-filled pores in the cell membrane. It allows a rapid flow of ions through the cell membrane. Each channel type is specific for one inorganic ion (sodium, calcium, potassium, or chloride).

Ion channel gating Conformational changes of ion channel proteins responsible for open and closed states of the ion channel.

Ligand-gated channel A transmembrane ion channel whose opening is activated by the binding of a specific physiologically active compound (ligand) to channel protein.

Lipid rafts The microdomains of cell membrane mainly consisting of cholesterol, sphingolipids, and proteins. These are centers of cellular signaling that float freely within the lipid bilayer.

Outward current A flow of positively charged ions across the membrane out of the cell.

Refractory period A finite period of time after the action potential during which a new action potential cannot be generated, due to time- and voltage-dependent recovery of ion channel from inactivation.

Repolarization A change of membrane voltage back to the polarized state that prevailed before the action potential was generated, that is, increase in the negativity of membrane potential.

Resting membrane potential The stable negative membrane potential (–70 to –90 mV) of the resting cell.

Threshold potential The value of membrane voltage needed to excite a full-blown action potential. It is the membrane voltage (about –60 mV) at which sodium influx exceeds potassium efflux across the cell membrane and results in depolarization of the cell membrane.

Voltage-gated channel An ion channel whose opening and closing are governed by changes in membrane voltage. Opening and closing of the channel take certain time, that is, the operation is voltage and time dependent.

Voltage sensor A special domain of the ion channel protein that senses the voltage across the cell membrane. Movement of the voltage sensor causes opening and closing of channel gates.

What Is an Excitable Membrane or Cell?

All animal cells maintain a voltage difference across the cell membrane, which is termed the 'resting membrane potential' (RMP). The RMP is used to power transport of substances across the membrane against their concentration gradients. In addition, changes in the RMP can act as signals within the cell. Most changes in the RMP dampen within a short distance of their origin, and cannot be used as long-distance signals. However, some cells (including neurons, skeletal, cardiac, and smooth muscle cells and some endocrine glands) can produce transient changes in their RMP that are called action potentials (APs). (In fish skeletal muscles, only the fast focally innervated fibers produce APs, while multiply innervated slow fibers are activated by local potentials. Thus, in a strict sense, all slow fibers in fish are not excitable.) APs can propagate along the cell membrane without change in amplitude, and are thus a means of fast transmission of information across long cellular distances, which can be the order of meters for nerve axons. Cells that are able to produce these self-propagating APs are referred to as electrically excitable.

In the resting state, electrically excitable cells have a negative RMP of −60 to −100 mV relative to the extracellular medium. A change in membrane potential from the RMP in the positive direction is termed as 'depolarization', while a change from the RMP in the negative direction is termed as 'hyperpolarization'. The AP begins with a small (50–100 mV) and transient change of voltage across the cell membrane from the RMP in the positive direction (**Figure 1**). This depolarization is then followed by a repolarization of the membrane potential toward the RMP, which then may (or may not) be followed by a brief hyperpolarization, depending upon the cell type. The ability to produce APs is critical for the functioning of the nervous and muscular systems. Thus, ectothermic organisms such as fish must maintain electrical excitability as environmental temperature changes in order to maintain physiological functions.

Ion Channels Are Necessary for Excitability

APs are produced by the opening and closing of ion channels. Ion channels are pore-forming membrane proteins that allow passage of certain inorganic ions through otherwise impermeable lipid membrane. These channels are triggered to open and close by changes in membrane potential (voltage-gated channels) or binding of a physiologically active compound, for example, a neurotransmitter, to the channel (ligand-gated channels). The presence of voltage-gated channels is required for the generation of APs.

Opening and closing of voltage-gated ion channels are produced by complex changes in three-dimensional conformation of the channel protein, which can be described as changes in the position of molecular gates of the channel pore (**Figure 2**). Voltage-gated ion channels often have two gates: an activation gate and an inactivation gate. In the resting, nonconducting channel, the inactivation gate is open and the activation

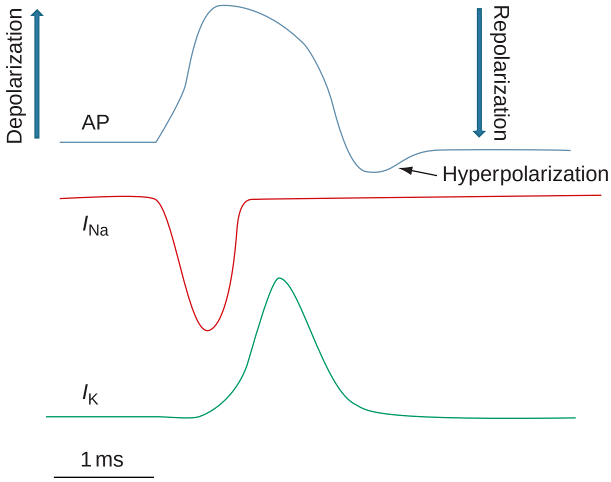

Figure 1 Schematic presentation of the neuronal action potential. An action potential is produced by the sequential opening of sodium and potassium channels. Opening of sodium channels causes inward flow of sodium ions, which results in rapid depolarization of the membrane potential slightly above the zero membrane potential. Closure of sodium channels and the delayed opening of potassium channels cause repolarization of membrane potential by the net outward potassium current. Differences in the rate of opening, that is, in the rate of the voltage sensor displacement, between sodium and potassium channels produce the balance of sodium and potassium currents needed for action potential generation.

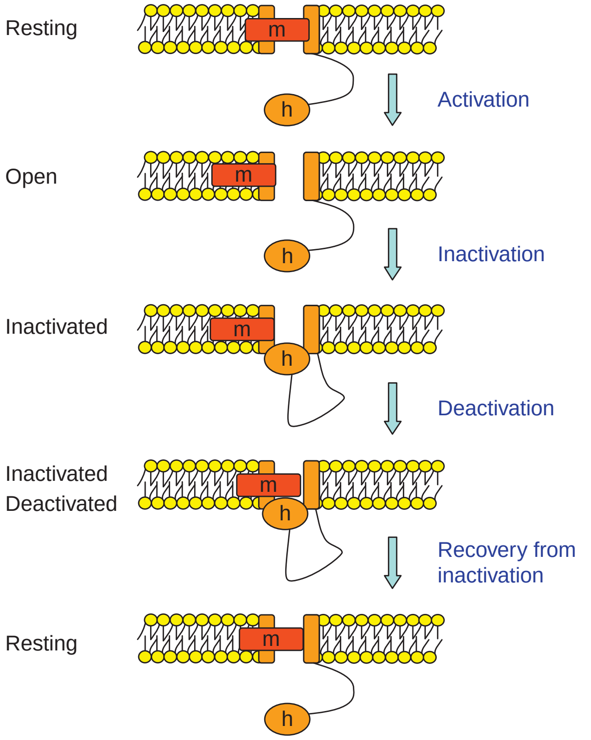

Figure 2 Opening and closing of the ion channel by the movements of the voltage-dependent gates. An ion channel cannot reopen unless it has resumed the resting state. This is a time- and voltage-dependent process and makes the cell membrane refractory to stimulation immediately after the action potential. The order of deactivation and recovery from inactivation varies between voltage-gated channels.

gate is closed. When the activation gate opens, the channel changes to open state (activation), that is, it allows passive flow of ions through its open pore. Next, the inactivation gate closes (inactivation) and makes the channel nonconducting again (inactivated state). The channel cannot reopen, unless it achieves the resting state again, that is, the inactivation gate must open (recovery from inactivation) and the activation gate must close (deactivation). This gating process is determined by changes in membrane voltage, which the channel senses with a positively charged domain of the channel protein called the 'voltage sensor'. In the resting cell, the voltage sensor is close to the inner surface of the membrane (attracted by the negative RMP) and moves in the outward direction when cell membrane starts to depolarize. Movements of the voltage sensor cause opening and closing of the gates.

The depolarization phase of an AP is triggered by an initial graded depolarization of the excitable membrane. This is normally caused by a spread of AP from the neighboring cell, as in cardiac and smooth muscles, or by an opening of a ligand-gated ion channel by a neurotransmitter in the postsynaptic membrane of neuron or skeletal muscle cell. When the depolarization reaches a level known as the threshold potential, sufficient voltage-gated channels are opened that a self-reinforcing positive-feedback loop occurs, resulting in an AP.

How Does Temperature Affect Excitability?

Excitability of cell membrane can be altered by temperature as a result of temperature-dependent changes in (1) RMP, (2) the generation of APs, (3) the velocity of AP propagation, and (4) the duration of the AP. These alterations in membrane excitability are reflected in alterations in neuromotor functions such as sensory transduction, motor reflexes, locomotion, heart function, learning, and memory of fish.

Temperature dependence of excitability stems from the function of ion channels. Passive flow of ions through an open ion channel has a low-temperature dependence ($Q_{10} = 1.0–1.4$; **see also Temperature**: Effects of Temperature: An Introduction), similar to that of diffusion. Therefore, ion permeation through the open channel has only relatively a small effect on temperature dependence of ion currents. In contrast, the opening and closing of ion channels have activation energies similar to enzymatic reactions and therefore function of the channel is temperature dependent. Usually, the Q_{10} of ion channel gating is around 3, but can be as high as 8. At the single-channel level, the frequency of ion channel openings and closings and the duration of open and closed times are affected by temperature. At a macroscopic level, these appear in temperature sensitivity of channel activation, inactivation, deactivation, and recovery from inactivation (**Figure 3**).

Effects of Temperature on RMP

The value of the membrane potential is determined by those ion channels that are open, and reflects a balance of the equilibrium potentials for each ion and the relative permeabilities of the membrane for each ion. In most excitable cells, the RMP is maintained by a small potassium efflux across cell membrane via the inward rectifier potassium (Kir2) channels that mediate an inwardly rectifying potassium current, the I_{K1}. Other ion conductances of the resting cell are only a fraction of the potassium conductance and therefore RMP is close to the equilibrium potential of potassium ions (–80 mV). Acute decreases in temperature have been observed to cause a depolarization of the membrane. For example, in the extraocular muscle of the Antarctic teleost, *Pagothenia borchgrevinki*, RMP changes 22 mV/10 °C. Depolarization is often due to the reduced density of the I_{K1}, as in trout cardiac myocytes (**Figure 4**). The decreased potassium conductance appears as increased membrane resistance.

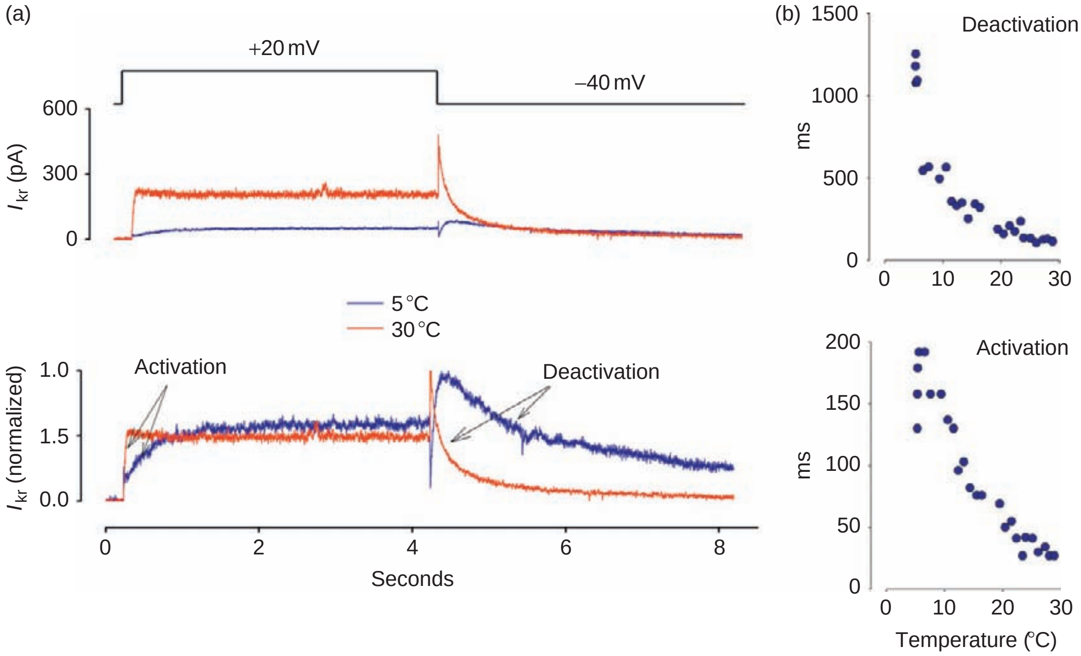

Figure 3 Temperature changes density and kinetics of ion currents. (a) The rapid component of the delayed rectifier potassium current (I_{Kr}) at 5 and 30 °C generated by the voltage-gated potassium channel Kv11.1. The upper panel shows temperature-dependent difference in current density. Effect of temperature on activation (depolarizing pulse to +20 mV) and deactivation (repolarizing pulse to –40 mV) kinetics is clearly evident from the normalized tracings of the lower panel. (b) Temperature dependence of activation and deactivation kinetics of the I_{Kr} between 5 and 30 °C. Deactivation kinetics is composed of two kinetically different components, but for clarity only the time constant of the rapid component is indicated. Activation kinetics is given as a time to half-maximal activation. All recordings and data are from the same atrial myocyte from a rainbow trout heart.

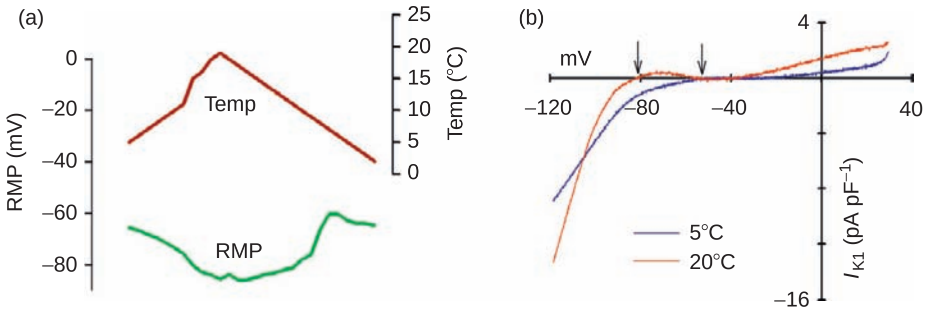

Figure 4 Effect of temperature on resting membrane potential. (a) Reversible changes of resting membrane potential (green line) of trout ventricular myocyte. (b) Inward rectifier current, I_{K1}, through Kir2 channels of the same myocyte. Resting membrane potential (arrows) is set by the reversal potential of the I_{K1}.

This depolarization of the membrane at the RMP improves excitability of the membrane, because less depolarizing current is needed to bring membrane potential to the threshold of AP generation. If everything else remains constant, decreased potassium conductance would be expected to increase the excitability of neurons and muscle cells in the cold.

On the other hand, acclimation of animals to the cold often results in compensatory increase in the density of the I_{K1}, which counteracts the direct effect of temperature on I_{K1} and tends to stabilize RMP. In the majority of the fish species examined, cardiac I_{K1} is upregulated in the cold. However, in rainbow trout (*Oncorhynchus mykiss*), I_{K1} is depressed in cold acclimation, which enforces the effects of acute temperature change, that is, increases excitability of myocytes.

Species-specific responses to temperature in the density of I_{K1} are associated with altered expression of Kir2 channels. The Kir2 subfamily has five members (Kir2.1–Kir2.5), and three of them (Kir2.1, Kir2.2, and Kir2.5) are expressed in the fish heart. In the rainbow trout heart, enhancement of the I_{K1} with warm acclimation is associated with increased expression of the Kir2.2 subunits, although Kir2.1 is the main Kir2 transcript in both warm-acclimated and cold-acclimated hearts. In contrast, in the crucian carp (*Carassius carassius*), the cold-induced increase in the density of I_{K1} is based on strong upregulation of the Kir2.5 transcripts at the expense of Kir2.2. Arguably, the Kir2.5 is the cold-adapted isoform and the Kir2.2 is the warm-adapted isoform of the fish heart. Rainbow trout heart does not express Kir2.5, which may explain the absence of thermal compensation of the I_{K1} with cold acclimation. Transcripts of the Kir2 channels are also abundantly present in brain and skeletal muscle of the fish, but effects of temperature on skeletal muscle and brain Kir2 channels have not been examined.

Effects of Temperature on the Velocity of AP Conduction

Increases and decreases in temperature accelerate and decelerate, respectively, conduction velocity of APs. For example, in Mauthner cells of the goldfish (*Carassius auratus*) brainstem, conduction velocity of AP is reduced by the cold, affecting the fast escape behavior (startle response) of the fish. Similarly in the vagus nerve of the carp (*Cyprinus carpio*), conduction velocity is strongly dependent on temperature in both unmyelinated and myelinated nerve fibers.

The rate of impulse conduction is dependent on the upstroke rate of AP, which is determined by the sodium current (I_{Na}), the largest inward current in most excitable cells. When the threshold potential is exceeded, a large number of sodium channels open almost simultaneously causing a rapid change of membrane voltage. Changes in conduction velocity of AP in an excitable cell will therefore largely result from changes in the magnitude and kinetics of I_{Na} and their temperature dependence.

An acute decrease in temperature decreases the density of the I_{Na}, which is expected to decrease upstroke velocity and amplitude of AP with a subsequent decrease in the speed of impulse conduction. Thus, direct effects of cold temperature on I_{Na} tend to decrease excitability by reductions in impulse conduction velocity.

The acute effects of low temperature on I_{Na} could be alleviated by compensatory increases in the density and/or kinetics of I_{Na} with cold acclimation. Indeed, the density of I_{Na} in rainbow trout cardiac myocytes increases with cold acclimation and, as well, activation of sodium channels occurs at more negative voltages. While increased current density and reduced threshold of I_{Na} activation will increase excitability of fish cardiac myocytes, the thermal compensation is only partial (density of I_{Na} at 4 °C is 59% of the density at 18 °C). There is also partial thermal compensation in the rate of I_{Na} inactivation.

I_{Na} is produced by the activity of voltage-gated sodium channels, which consist of a pore-forming α-subunit and one or two ancillary β-subunits. The family of vertebrate sodium channels has nine members ($Na_v1.1$–$Na_v1.9$) which differ with regard to electrophysiological properties and expression profiles. The compensatory changes of the rainbow trout cardiac I_{Na} are associated with a small change in the expression of sodium channel α-subunits (ventricular muscle expresses three sodium channel α-subunits: $Na_v1.4$, $Na_v1.5$, and $Na_v1.6$). Relative transcript (messenger RNA (mRNA)) levels of these channels in the warm-acclimated ventricle are 61.5%, 38.4%, and 0.1% for $Na_v1.4$, $Na_v1.5$, and $Na_v1.6$, respectively. With cold acclimation, the portion of $Na_v1.4$ increases to 81.8% at the expense of $Na_v1.5$ (18.2%).

In contrast to rainbow trout, crucian carp shows inverse thermal compensation: I_{Na} density is strongly depressed in the winter-acclimatized fish so that the density of I_{Na} at 4 °C is only 21% of that at 18 °C in summer-acclimatized fish. There is also no thermal compensation of I_{Na} kinetics. Thus, in crucian carp, thermal acclimation of I_{Na} decreases excitability of cardiac myocytes. It should be noted that this occurs simultaneously with increase in I_{K1}, which also decreases excitability. Thus, I_{Na} and I_{K1} act synergistically to reduce excitability of the crucian carp heart. This inverse thermal compensation of I_{Na} probably reflects the inactive lifestyle of the crucian carp in its habitat, which becomes severely hypoxic and even anoxic during winter.

Effects of Temperature on AP Duration

AP duration affects the frequency response of excitable cells. When an AP has swept along a nerve or muscle cell, a second AP cannot be initiated immediately after the previous AP. A finite time, known as the refractory period, must elapse before another AP can be elicited. This stems from the time and voltage dependence of ion channel gating. The return of activation and inactivation gates to their initial positions in the resting channel requires certain time at the RMP and only after which the channel can open again. The refractory period sets a limit to the frequency at which APs can be conducted along a nerve or muscle fiber.

In view of this, AP duration is important for all neuromuscular and cardiac function (**see also Design and Physiology of the Heart**: Action Potential of the Fish Heart), since information transmission is often dependent on the frequency of impulses, a factor that is limited by temporal width of an AP. Sensory information is frequency-modulated in that the strength of response is directly related to the frequency of APs elicited in the sensory nerve. The rate of locomotion is dependent on contraction frequency of skeletal muscle fibers. In addition, cardiac pumping is partially frequency-modulated because cardiac output is dependent on the heart rate (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping).

Acute decreases in temperature broaden APs. For example, the AP of the goldfish brainstem Mauthner cell is 31.3% broader at 5 °C and 26.9% narrower at 25 °C compared with fish acclimated at 15 °C. AP broadening in the Mauthner cell is due to prolongation of both depolarization and repolarization phases of the AP, suggesting that density/kinetics of both sodium and potassium currents are depressed in the cold. Unlike neuronal and skeletal APs, cardiac myocytes have a long AP duration (0.3–3 s) with a distinct plateau phase near the zero membrane potential. In six species of fish, temperature between 4 and 18 °C affected cardiac AP duration with a mean Q_{10} of 2.4 and 1.9, for the atrial and ventricular muscle, respectively.

Temperature compensation is evident in AP duration of both nerve and muscle cells of fish: acclimation to cold counteracts the acute effects of low temperature and prevents excessive lengthening of AP by the cold. Ion channels responsible for nervous and skeletal APs in fish are poorly understood, and at present molecular data on ion channels exist only for cardiac muscle. Duration of cardiac AP is regulated by a delicate balance between inward calcium current (I_{Ca}) and outward potassium currents (I_{Kr}, I_{Ks}, and I_{K1}). All these currents are sensitive to temperature and contribute to temperature-dependent changes in AP duration. In rainbow trout heart, density and kinetics of I_{Ca} do not change much under thermal acclimation. In contrast, the repolarizing potassium currents I_{Kr} and I_{K1} are strongly upregulated by cold acclimation in several fish species. Increased density of the I_{Kr} seems to be a ubiquitous response in teleost myocardium and this current is probably of prime importance in the regulation of AP duration. Increase in I_{Kr} is mainly due to cold-induced increase in the number of channels. I_{K1} is also upregulated in majority of species in the cold.

Significance of Membrane Lipids in Thermal Responses of Excitable Cells

Membrane lipids provide the physical environment where ion channel proteins go through complex conformational changes necessary for opening and closing of channels. Not surprisingly, ion channel function is dependent on chemical composition and physical properties of the lipid membrane. These requirements may involve interactions of the channel with special lipid components of the membrane, for example, cholesterol, or certain physical qualifications, such as fluidity of the lipid bilayer.

As discussed in articles **Temperature**: Proteins and Temperature and Mitochondria and Temperature, acute cooling decreases the fluidity (increases the viscosity) of the membrane which could impede conformational changes of the channel. On the other hand, temperature acclimation induces changes in the composition of lipid membrane that tend to maintain physical properties of the membrane independent of temperature changes. Although membrane lipids are known to modulate ion channel gating, there is currently no direct evidence indicating that membrane fluidity or homeoviscous adaptation affects ion channel function in excitable membranes of fish or any other ectotherm.

Lipid membranes are heterogeneous structures consisting of areas that differ in physical properties and molecular composition. Specific areas enriched in cholesterol and sphingolipids form microdomains called 'lipid rafts' that float in the more fluid lipid phase, like icebergs on the ocean. A number of vertebrate ion channels, including members of sodium, calcium, and potassium channels, reside in lipid rafts. Cholesterol of the lipid rafts exerts inhibitory action on several ion channels and therefore cholesterol removal (e.g., using β-methylcyclodextrin) from the membrane increases current densities in mammalian systems. For example, Kir2.1 channels are partially silenced, that is, stabilized in the closed state, by cholesterol.

In fish, temperature acclimation affects the cholesterol content of cell membranes, including the cells of the central nervous system. Cholesterol's inhibitory effect on Kir2.1 channels is largely dependent on leucine in the position 222 of the channel that mediates the interaction to cholesterol. Similar to mammals, the corresponding residue in the fish Kir2.1 is leucine, while Kir2.2 and Kir2.5 channels have isoleucine (which cannot mediate the interaction) in this position. In rainbow trout heart, Kir2.1 is abundantly expressed and, therefore, in this species and tissue cholesterol content of the membrane could affect I_{K1}. In contrast, in crucian carp heart, I_{K1} is produced mainly by Kir2.2 and Kir2.5 subunits and, therefore, the effect of cholesterol content on cardiac I_{K1} is expected to be minor.

Evolutionary Thermal Adaptation of Excitability

A fish's body temperature is variable and usually lower than in endotherms. An interesting question is: Are ion channels of the ectothermic fish somehow adapted to low temperatures in comparison to those of the endotherms, or is the ion channel performance simply scaled down with temperature in fish?

Comparison of Fish and Mammals

Most of the data regarding the effects of temperature on the functions of excitable cells in fish and mammals are available for cardiac muscle. The peak density of I_{Ca} in rat cardiac myocytes is about 16 $\mathrm{pA\,pF^{-1}}$ at 36 °C and

7 pA pF^{-1} at 23 °C. In rainbow trout cardiac myocytes, the peak I_{Ca} is 5.5 pA pF^{-1} and 2 pA pF^{-1} at 21 and 7 °C, respectively. Therefore, at the equivalent temperature, the density of I_{Ca} is similar in mammalian and fish hearts, that is, there seems to be no evolutionary temperature compensation in the density of I_{Ca}, a very important current for cardiac contraction (**see also Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux and Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element).

The I_{Ca} in rainbow trout atrial myocytes has a Q_{10} of 1.8–2.0 between 4 and 21 °C, while in mammals the Q_{10} varies from 2.3 to 5.8 at >22 °C. The lower Q_{10} for fish I_{Ca} may relate to their natural temperature variability. The rate of I_{Ca} inactivation shows no evolutionary temperature compensation: at 25 °C, the fast and slow time constants of I_{Ca} inactivation in rabbit ventricular myocytes are 12.6 and 51 ms, respectively, while the values are 27 and 73 ms in rainbow trout ventricular myocytes at 20 °C. Although less data are available for I_{Na} than I_{Ca}, similar conclusions as for I_{Ca} seem to apply to sodium channel function. There is little evolutionary thermal compensation in the function of inward currents, neither in current density nor in gating kinetics. As a consequence, the size of I_{Ca} and I_{Na} is scaled down in a temperature-dependent manner.

The situation for repolarizing potassium currents seems to differ from the inward currents. The peak density of the rapid component of the delayed rectifier, I_{Kr}, is generally substantially larger in fish cardiac myocytes than in mammalian cardiac myocytes. Among six teleost species, the ventricular I_{Kr} varies between 0.6 and 5 pA pF^{-1} at 11 °C, while in mammalian ventricle the I_{Kr} density is about 1 pA pF^{-1} or less at >22 °C. There seems to be also thermal compensation in activation, inactivation, and deactivation kinetics of the fish I_{Kr} because the rate of channel gating in fish at 11 °C is similar to that of the mammalian channels at room temperature (22–24 °C).

In addition, the density of the I_{K1} is larger in fish than in mammalian cardiac myocytes. In mammals, ventricular I_{K1} is generally between –4 and –12 pA pF^{-1} at temperatures above 22 °C, while the density of the I_{K1} varies between –7 and –25 pA pF^{-1} at 18 °C in fish ventricular myocytes. On the other hand, the density of the adenosine triphosphate (ATP)-sensitive potassium current (produced by Kir6 channels) is much higher in mammals than in fish.

Current data suggest that there is some evolutionary thermal adaptation in repolarizing potassium currents in fish. However, practically all data are from the cardiac muscle, a tissue in which large species-related differences exist in the composition of repolarizing currents. Therefore, the true adaptive value of those compensations remains an open question.

Comparison of Antarctic and Temperate Fishes

The nerves and muscles of Antarctic fish operate in extreme and stable cold. Therefore, appropriate thermal adaptations in excitability of nerve and muscle cells might be expected when compared with temperate or tropical fish.

Findings from neuromuscular systems suggest that there is relatively little evolutionary temperature compensation in muscle function, while the nervous system shows more extensive adaptation. Indeed, partial temperature compensation has been documented for conduction of peripheral sensory nerves and in the burst frequency of motoneuronal firing associated with the saccade eye movement. These findings suggest that the excitability, and therefore ion channel function, of central and peripheral neurons is thermally adapted. Compensation in conduction velocity and firing frequency suggests that adaptation involves changes in the function of depolarizing sodium current (conduction) and repolarizing potassium currents (AP duration). However, the molecular arrangements behind these adaptations are unknown, but could involve changes in channel isoforms analogous to those of thermal acclimation. Changes in the lipid membrane and/or altered interaction of channel proteins with membrane lipids could also be involved.

Glossary

Acyl group A fatty acid esterified to another moiety, glycerol in the case of phosphoglycerides.

Amphipathic A molecule with one hydrophilic and one hydrophobic end.

Ceramide Sphingosine esterified to a fatty acid.

Cholesterol A steroid that exerts complex effects on membrane fluidity.

Diacylglycerol A molecule with two fatty acids esterified to a glycerol backbone, typical in the first and second position.

Glycolipid Distinct from phosphoglycerides, glycolipids are diacylglyceride plus a carbohydrate.

Homeoviscous adaptation Modification of the lipid composition of cellular membranes that achieves stability in the static order (fluidity) of the bilayer. Counteracts temperature-dependent changes in membrane fluidity (viscosity) mainly by changes in saturation level of fatty acids.

Hydrophobic This term, which literally means water-hating, describes chemical tendency of molecules to interact through mutual avoidance of water.

Lysophospholipid A phospholipid with the organic component of its polar headgroup removed, or diacylglycerol plus phosphate.

Membrane order The degree to which membrane constituents are able to undergo free rotation and lateral movement.

Phosphoglyceride A molecule composed of a glycerol backbone with fatty acids esterified to positions 1 and 2, and a phosphate group linking glycerol to a polar headgroup.

Phospholipids Molecules composed of a polar head group and two nonpolar acyl chains.

Phosphotide Diacyl glycerol esterified to an inorganic phosphate.

Polar headgroup A hydrophilic molecule that is attached to a lipid backbone, to create an amphipathic lipid.

Sphingolipid A lipid consisting of a sphingosine backbone, esterified to a fatty acid and a polar headgroup.

Introduction

Biological membranes permit cells to organize their inner workings in useful ways. Cell membranes allow animal cells to create differences in internal and external ions, enabling them to generate membrane potentials (**see also Temperature**: Temperature and Excitable Membranes). Organelle membranes allow cells to isolate metabolic pathways and other cellular functions in discrete regions. Membranes play vital roles in structural organization, acting as anchor points for the cytoskeleton. Although membranes confer benefits to organization of cellular functions, they also represent barriers to free movement of ions and molecules.

Membrane proteins mediate electrical and chemical communication and catalyze transfers of molecules from one side to the other. The ability to carry out these vital functions depends upon the membrane proteins forming appropriate interactions with membrane lipids. The role of membrane lipids in both structure and function depends upon maintaining the appropriate degree of intermolecular movement. Membrane constituents must be able to move within the membrane. If a membrane is too fluid, then its ability to act as a barrier is compromised. If a membrane is too rigid, then it compromises the function of membrane proteins that require room to move.

Physicochemical challenges, such as temperature, can change the fluidity of membranes. Cells and organisms can remodel their membrane lipids to compensate for deleterious changes in fluidity, a response known as homeoviscous adaptation (HVA). In doing so, cell membrane fluidity at the new temperature is returned to a desired state. HVA has been shown in virtually all taxa as a response to temperature changes. The same patterns of membrane differences are also seen when comparing species of fish that have evolved in different thermal environments, from the Antarctic to the Amazon. The term is now applied to any adaptive response to conditions that perturb membrane fluidity, including pressure, pH, ionic strength, specific ions, and organic solutes.

Structure of Cellular Membranes

As outlined in the fluid mosaic model of membrane structure, phospholipids (PLs) are arranged laterally into a sheet, with polar headgroups displayed on one surface and hydrophobic tails aligned along the other surface, forming a monolayer. The membrane consists of two of these monolayers arranged tail to tail, with polar headgroups forming the inner and outer surface. Central to the fluid mosaic model is the ability of the molecular constituents to move. Proteins and lipids rotate within the membrane and each component moves laterally along the monolayer (PL, proteins) or bilayer (proteins).

The physical properties of the membrane are due to the cumulative influences of the membrane constituents and the way they are brought together to form the membrane. Each polar headgroup occupies a volume of space on the surface of the membrane. The hydrophobic core of the bilayer is essential to maintain a barrier to hydrophilic molecules, such as ions and most metabolites. Small hydrophobic molecules such as oxygen can pass between the polar head groups, enter the bilayer and exit on the other side of the membrane.

Lipid-Dependent Proteins

Integral proteins are firmly attached to or embedded in membranes, so much so that they cannot be released by the action of mild detergents. They may be embedded in one monolayer, penetrate across the bilayer, or be anchored covalently to another membrane constituent. Integral proteins include membrane transporters and plasma membrane receptors. In contrast, peripheral proteins are loosely associated with membrane components (PL, integral proteins, and carbohydrates) and can be released with a mild detergent. Examples of peripheral proteins include cytochrome *c*, the cytoskeletal protein spectrin, and many soluble protein kinases. The degree of interaction between membrane protein and lipid is important because integral proteins experience the effects of changes in membrane fluidity, whereas peripheral proteins may not.

Proteins are influenced in complex ways by the surrounding lipids. Some proteins have lipid moieties incorporated directly into their structures. For example, the mitochondrial enzyme cytochrome oxidase has an unusual requirement for a specialized lipid molecule, cardiolipin. When cardiolipin is removed from the enzyme, its catalytic properties suffer dramatically. Other membrane proteins, such as the transporter Na^+/K^+ adenosine triphosphatase (ATPase), have more complex membrane requirements. In the absence of lipid, activity is lost.

Many other proteins are influenced in nonspecific ways by fluidity. When membrane proteins undergo a catalytic cycle, they change the volume of space they occupy. In an environment where such volume changes are restricted, the catalytic properties of the protein suffer. Thus, maintenance of fluidity allows catalytic proteins (enzymes and transporters) to change shape within the lipid environment.

Lipid Components

The lipid component of membranes includes an astonishing array of molecules, including phosphoglycerides (PGs), sphingolipids (SLs), glycolipids, cholesterol, and membrane antioxidants. The complexity in structures makes it difficult to come up with a terminology that avoids ambiguity. With a focus on physical properties of membranes, we discuss the two main lipid elements of membranes: amphipathic and hydrophobic molecules.

Cellular membranes are often said to be composed primarily of PLs, which, in the strictest sense, refer to lipid molecules with phosphate attached (see **Figure 1**). This includes all PGs but excludes other amphipathic membrane lipids, such as glycolipids and many SLs. Collectively, these amphipathic lipids share an overall shape and specific chemical features. The hydrophobic component typically has a two-tailed structure that extends deep into the bilayer, whereas the hydrophilic component – the polar headgroup – is more globular and sits on the surface of the bilayer. In all of these molecules, a fatty acid contributes one (SL) or two (PG) of the tails. The fatty acids can vary in the length (typically 16–22 carbon atoms long) and the degree of saturation (0–6 double bonds). The polar headgroup can be one of many organic compounds (amino acids, amino sugars, polyols, monosaccharides, oligosaccharides, and modified sugars).

In an effort to make this article as accessible as possible, we continue with the convention of referring to the various amphipathic molecules as PL, acknowledging that this is not, in the strictest sense, accurate. However, it is worthwhile to consider the chemical distinctions between the various amphipathic membrane lipids:

1. PGs are composed of diacylglycerol + phosphate + polar headgroup. The most common PGs are phosphotidylcholine (PC), phosphotidylethanolamine (PE), phosphotidylserine (PS), and phosphotidylinositol (PI).

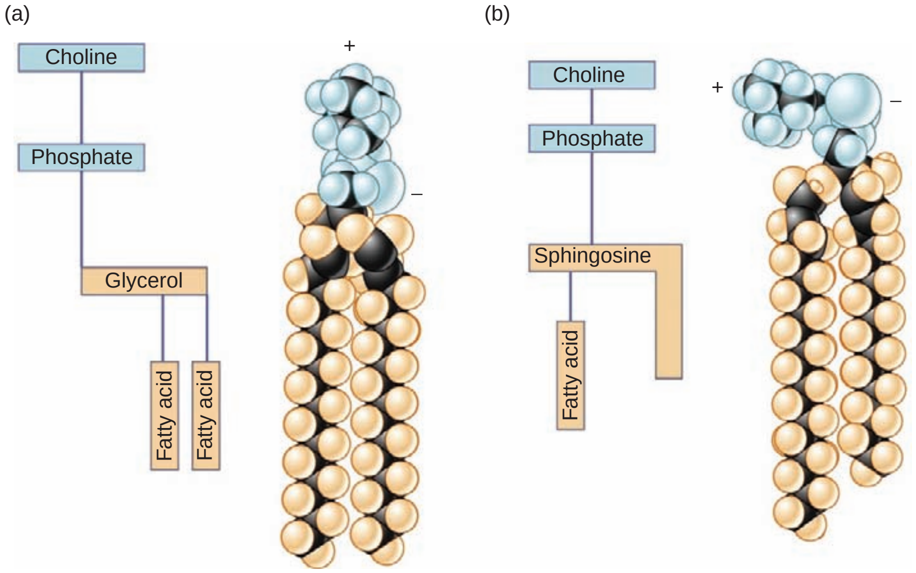

Figure 1 Structures of the amphipathic components of cellular membranes. (a) Phopshoglycerides; (b) sphingolipids. From Moyes CD and Schulte PM (2006) *Principles of Animal Physiology*, 2e, figure 2.36 (p.56).

2. SLs are composed of sphingosine + fatty acid (collectively ceramide) + a polar headgroup. Some are true PLs (e.g., ceramide + phosphocholine is sphingomyelin) but others lack phosphate. Sphingoglycolipids (ceramide + carbohydrate) include cerebrosides (ceramide + monosaccharide), sulfatides (ceramide + a sulfated sugar), globosides (ceramide + glycosaminoglycan), or gangliosides (ceramide + oligosaccharide decorated with sialic acid, a seven-carbon sugar).
3. Glycolipids are in the strictest sense carbohydrate plus lipid (without phosphate). They include diacylglycerol + a monosaccharide, as well as many of the SLs.

In addition to the amphipathic molecules, there is a collection of hydrophobic molecules within membranes, the most important of which is cholesterol (**Figure 2**). This steroid has a four-ring structure that creates a wedge-like shape. This allows it to insert within the hydrophobic tail zone, fitting best alongside of SL molecules. However, it can intersperse among other amphipathic membrane lipids as well. Cellular membranes also contain other hydrophobic compounds, including vitamin A (retinoic acid) and vitamin E (α-tocopherol). These vitamins are important antioxidants, conferring protection from oxidative damage, which influences membrane properties.

Regional Membrane Specializations

Cells are able to control which types of lipids are where within the plasma membrane. Many cells exhibit polarity in cell membranes, where the lipids in one region are distinct from those elsewhere in the cell. Perhaps the best example of this is distinction between the plasma membranes in the apical versus basolateral regions of transport epithelial cells (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes). For an epithelial cell, such as a gill epithelium, the tip of the cell exposed to the external world is called the apical membrane. The sides of epithelial cells interact with each other through tight junctions, which are belts of protein–protein connections that allow cells to adhere to each other to limit paracellular exchange and also prevent membrane constituents from moving from one end to the other. Below the tight junction zone, on the sides and the bottom of the cell, is the

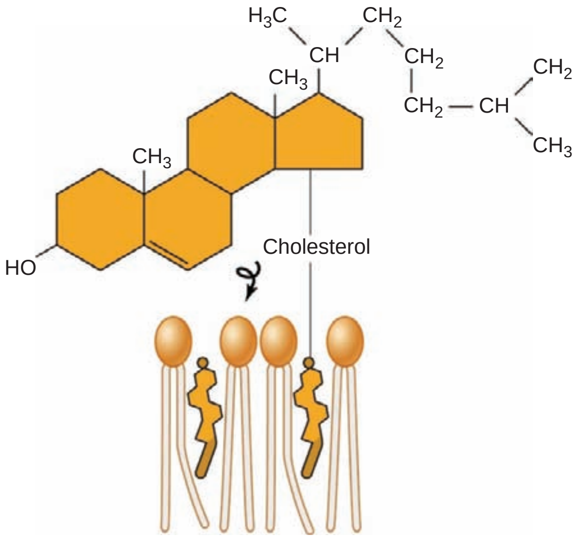

Figure 2 Structures of hydrophobic components of cellular membranes. From Moyes CD and Schulte PM (2006) *Principles of Animal Physiology*, 2e, figure 2.44 (p.65).

basolateral membrane. Many cells show distinct differences between the lipid composition of the apical and basolateral membranes.

Within any particular region of the membrane, lipids can coalesce into physically and chemically distinct islands. There are regions where SL and cholesterol accumulate, leading to a general thickening of the membrane, which in turn allows the accumulation proteins with longer transmembrane domains. These regions, called lipid rafts, are important sites for signal transduction. They have a distinct lipid profile and, thus, when changes in membrane composition occur, they can follow different trajectories in the main region of the membrane and the isolated lipid rafts. In some cases, regions of lipid rafts form invaginations into the cell, structures called caveolae. Like other lipid rafts, they play important roles in signal transduction, increasing the surface area of the membrane and providing deeper access into the cell interior.

There are also differences in the nature of the lipids in the inner and outer monolayers of the bilayer. Some amphipathic lipids are distributed roughly equally in the two layers. Within most plasma membranes, much of the PE and PS are in the inner monolayer, whereas much of the PC and sphingomyelin are in the outer leaflet. When cells initiate programmed cell death, the enzyme flippase takes internal PS and flips it into the external monolayer, sending a signal (extracellular access to PS) to the immune system to encourage removal of the apoptotic cell.

Mechanisms for Controlling Membrane Composition

All cells exert control over the composition of their membranes via diverse pathways, modifying them as needed. The main mechanism by which membrane lipid composition is altered is through the intracellular sorting pathways. Much of the synthesis and modification of membrane lipids occurs in the endoplasmic reticulum (ER) and Golgi apparatus. Endocytosis removes regions of membranes and carries the resulting vesicle into the cell for modification. Vesicle membranes fuse to the ER and Golgi, where the constituents can be modified and returned to the cell membrane by exocytosis. This cycle of intracellular traffic allows cells to remodel the plasma membrane, as well as membranes of the lysosome, ER, and Golgi.

Cells also have a capacity to remodel some membrane lipids *in situ*. One mechanism is deacylation and reacylation. Phospholipase A_2 removes a fatty acid from a membrane PL, then lysophospholipid acyltransferase attaches a replacement fatty acid that is more suitable. Cells possess ATP-dependent enzymes that transfer PL between monolayers. Flippases bring PL inward, from outer to inner monolayers, and floppases send PL from the inner to the outer monolayer. These enzymes are central to establishing the membrane asymmetries that are critical for cellular function. As noted above, translocation of PS from the inner to the outer monolayer is an early step in programmed cell death. However, it is also likely that flippases can be used in membrane remodeling in response to changing environmental conditions.

Membrane Fluidity

PLs play important roles in membranes because of their overall shape, their amphipathic nature, and the ability to form weak bonds laterally within the monolayer. The physical nature of the membrane is governed by the magnitude of the weak bonds between membrane constituents. Throughout most of the membrane, the PLs are not so well connected as to prevent rotation and lateral movements. This condition has been called a fluid, liquid, or disordered state. At any point in time, there will be small regions within the membrane that are much more rigid, where rotation and lateral movements are very restricted. These regions are considered viscous (less fluid), gel like (less liquid), or ordered.

It is now clear that there is a third state within membranes: the liquid-ordered state. Lipid rafts are small, isolated patches of the cell membrane where fluidity remains but much more order exists. The molecule that is central to the maintenance of this liquid-ordered state is cholesterol, which we discuss in the next section. Cells build membranes to ensure that much of the membrane remains in the dynamic liquid state, and, as discussed later, when environmental conditions impose a solid-ordered state, cells compensate to regain fluidity.

The Unusual Role of Cholesterol

Cholesterol plays a complex role within membranes and many questions remain about its function. It is a critical component in the lateral organization of monolayer. Working in conjunction with SL, cholesterol acts as a focal point for the formation of lipid rafts, helping to maintain the liquid-ordered phase. Apart from cholesterol, lipid rafts are dominated by SL and PG that have long, saturated fatty acids. Regions rich in these lipids would tend to become more solid and ordered. Cholesterol is able to disrupt these interactions, ensuring that the lipids in these islands remain sufficiently fluid. Thus, cholesterol ensures that fluidity is maintained in membrane regions that would otherwise become ordered.

Cholesterol is also important in limiting the permeability of membranes. The membrane core is hydrophobic, so membranes generally have a low permeability to small hydrophilic solutes. Even in the simplest of membranes, the lipid tails are not sufficiently linear to eliminate spaces between PL molecules. Low-molecular-weight solutes can penetrate the membrane, jumping from gap to gap within the membrane core. Cholesterol reduces this minor permeability essentially by filling in the gaps between PL molecules, driving surrounding fatty acids closer together. Thus, cholesterol induces order in fluid regions, thereby reducing permeability. The complex effects of cholesterol on membrane fluidity mean that changes in cholesterol content and distribution are central to HVA.

Environmental Effects on Fluidity

Although HVA is known to occur in response to many environmental factors, temperature is the best studied. Whether changing rapidly, as fish swim through a thermocline, or daily, or seasonally, changes in temperature exert effects on membranes. Under normal conditions, membrane lipids ensure that the membrane maintains an appropriate fluidity, a balance between order and disorder. When membranes become too ordered, restricting lateral movement of membrane constituents, they also experience a detrimental thickening. When membranes become too disordered, the membrane lipids move too much and the membrane loses its integrity as a barrier. In many situations, changes in temperature result in relatively minor effects on fluidity until a critical temperature is reached, triggering a dramatic structural transition that is catastrophic for membrane function. This change in membrane structure at the transition temperature can be abrupt or gradual depending on its lipid composition. Cholesterol plays a major role in determining how abrupt the transition is. Cellular responses, including adaptational changes, to the effects of temperature change need to include responses that modify the transition temperature (e.g., lower it in cold environments), maintain appropriate fluidity, and maintain membrane thickness.

The time course of responses varies with the most rapid responses involving thermal modulation of existing desaturases and demethylases to alter saturation and headgroup (PE vs. PC) content. Processes requiring induction of protein synthesis take longer (e.g., Δ5 and Δ9 desaturases). Responses such as would be required for diurnal adaptation in intertidal areas or desert ponds may be limited to the more rapid modifications. The time course is also influenced by the direction of temperature change with changes from cold to warm temperatures occurring more rapidly than those from warm to cold.

Though HVA is a very common response to temperature in fish, and, in fact in all organisms, there are many examples where HVA is not seen. Some fish species do not remain active at cold temperatures (e.g., overwintering) and may not undergo HVA to the same extent as fish that remain active. Although the membrane lipids have been examined in some dormant overwintering crustacean species, it has not yet been examined in fish. Membrane fluid properties may be altered as part of metabolic depression to reduce membrane leakiness and downregulate membrane ion pumps. This could be viewed as a reverse HVA. This has been observed in estivating African lungfish (*Protopterus dolloi*).

Although temperature is the best studied, other physiochemical factors can alter fluidity, including hydrostatic pressure and diverse chemical effectors such as solute profile, ionic strength, pH, and toxicants. While these factors can certainly influence fluidity experimentally, whether they do so under natural conditions and whether they trigger HVA are not always clear. Some may interact with temperature effects.

Adaptive Remodeling of Membranes in HVA

One of the outcomes of HVA is to help maintain function of membrane-bound proteins such as enzymes and transporters. A plot of the log of enzyme activity versus inverse temperature in kelvin (Arrhenius plot) demonstrates how changing temperature affects a membrane-bound enzyme (**Figure 3**; **see also Temperature**: Effects of Temperature: An Introduction). There is a characteristic temperature at which the change in activity abruptly changes. Below this temperature, the activity rapidly decreases. Modification of membrane lipids (HVA) changes the temperature at which the enzyme activity abruptly declines with the result that the activity at the new colder acclimation temperature is restored to values similar to that at the warmer acclimation temperature.

The fluidity of a membrane depends on many qualitative and quantitative features of the lipid components, and, not surprisingly, adaptive changes in fluidity can target different molecules. Each of the following strategies has been shown to occur in some example of HVA, although not every strategy occurs in each cellular membrane. Mitochondria, for example, lack cholesterol and thus it

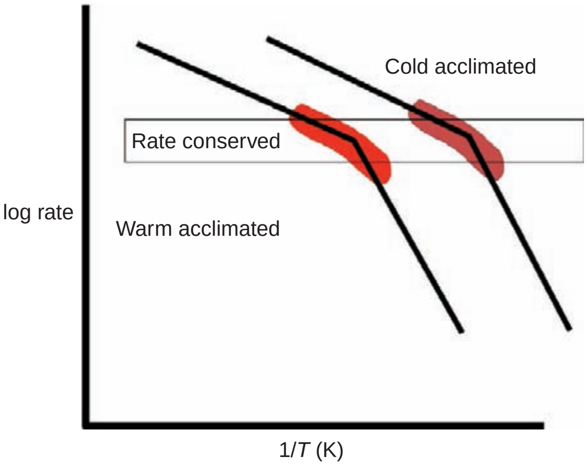

Figure 3 Effects of temperature acclimation on membrane-bound enzyme activity.

Table 1 Mechanisms of homeoviscous adaptation of membranes due to cold acclimation

Lipid component	*Change observed*	*Type of membrane or tissue involved*
Head group	PE more PC less PE:PC higher	Plasma membranes, mitochondrial membrane
	Sphingomyelin higher	Plasma membranes
	PI increase	Mitochondria (inner membrane)
	PS decrease	Mitochondria (inner membrane)
	Cardiolipin no change or decrease	Mitochondria
Phospholipid acyl chain saturation	Less saturated fatty acids More Monoenoic fatty acids More Polyunsaturated fatty acids	Plasma membranes, mitochondria
Phospholipid acyl chain double bond position	Increased n-3, n-6, n-9	Plasma membrane
Phospholipid acyl chain position	Position 1 – more unsaturated fatty acids	Plasma membrane
Phospholipid acyl chain length	Increased when unsaturation increases	Plasma membrane
Gangliosides	Increased sialic acid content	Brain membranes
Phospholipid acyl linkages	Reduced PE plasmalogen content	Brain
Cholesterol	Reduced	Plasma membranes, smooth and rough endoplasmic reticulum
Raft domains	Cholesterol content decreased Phospholipid content increased	Plasma membranes

does not contribute to HVA in this organelle. **Table 1** summarizes the known responses during cold adaptation.

Headgroup modification

The conical shape of PE tends to disorder membranes and thus can be used to offset the ordering effect of low temperature. PC, on the other hand, assumes a more cylindrical shape in the membrane conferring a more ordered state. Thus, the PE/PC ratio increases in situations where there is a need to fluidize the membrane. This can be accomplished *in situ* by converting the PE into PC by adding three methyl groups via N-methylation. This is one of the most rapid responses of HVA and is involved in diurnal changes in membranes such as those seen in desert pupfish (**see also Bony Fishes**: Life in Hot Water: The Desert Pupfish).

Deacylation–reacylation

Deacylation–reacylation in cold acclimation replaces a less unsaturated acyl chain (e.g., 18:1) with an unsaturated fatty acid (e.g., 22:6n-3). The reassigning of acyl chain positions within a PL may be an important role for this process, for example, changing a membrane with PCs 18:0 18:0 and 18:1 18:1 to PCs 18:0 18:1 18:0 18:1 may alter membrane properties with no net change in membrane composition. This mechanism may be important in rapid responses and during cold acclimation since existing acyl chains can be used.

Fatty acid saturation

The acyl chains attached to various PL headgroup have an important effect on membrane fluidity and are modified to maintain membrane fluidity. These can be modified in several ways. Changing the fatty acids available for the normal turnover of membrane acyl chains can be accomplished by modifying the relative rates of production of saturated and unsaturated fatty acids. The higher Q_{10} of fatty acid synthetase than that of desaturases results in a greater proportional production of saturated fatty acids at higher temperatures simply due to the effects of temperature on enzyme activities.

Desaturation and elongation

Animals are able to add a double bond in the $\Delta 9$ position and thus can synthesize 16:1 and 18:1. They cannot add double bonds beyond the $\Delta 9$ position and thus n-6 and n-3 series fatty acids are essential in animals. The n-6 fatty acids such as linoleic acid (18:2n-6) can be further desaturated and elongated by animals to produce 20:3n-6 and 20:4n-6. Similarly, n-3 fatty acids such as linolenic acid (18:3n-3) can be elongated and desaturated to produce 20:5n-3 (eicosapentaenoic acid) and 22:6n-3 (docosahexaenoic acid). Adding double bonds has the effect of introducing kinks into the acyl chain, which effectively shortens the chain length. Elongation by adding two carbons is an important part of HVA since it helps maintain membrane thickness. Thus, although lengthening acyl chains would have the effect of increasing the transition temperature, it is necessary to maintain membrane thickness and this is offset by the decrease in transition temperature due to the addition of double bonds.

Sialization

As important components of nervous tissue, ganglioside properties must be regulated to maintain nerve conduction. Gangliosides can be modified by sialization. At low temperatures, the increased sialization that is observed increases the polarity of the molecules and helps fluidize membranes. Antarctic fish have the highest levels of sialization of gangliosides of any vertebrate and represents a clear adaptation to frigid water temperatures.

Plasmalogen content

Ether-linked lipids occupy a smaller profile in the membrane and hence confer order and reduce permeability. Plasmalogen content especially in PE tends to be higher at high temperatures.

Cholesterol content

Cholesterol disrupts the packing of gel-phase lipids and has an ordering effect on fluid-phase lipids. The membrane content of cholesterol, as expressed by the cholesterol:PL ratio, can be altered to change the fluid properties. In general, the effects on fluid-phase lipids seem to be more important in HVA. Raft domain cholesterol content declines with cold acclimation. Cholesterol also has the effect of broadening the transition temperature as its proportion in the membrane increases. The mechanisms whereby cholesterol dynamics are mediated have not been established for HVA.

Sensing and Responding to Changes in Fluidity

Anticipation of seasonal changes can be cued by photoperiod for whole organism anticipatory responses, while more rapid temperature changes may be signaled by temperature change itself with individual cells being responsible for their own adaptation. A variety of hormones have been implicated in temperature adaptation of fishes, including prolactin, glucagon, insulin, thyroxine, and cortisol, but the extent to which these mediate HVA is not clear. There are temperature-sensitive cells in the preoptic region of the central nervous system of fish that determine preferred body temperature. Because of the thermosensitivity of electrical sensors such as the ampullae of Lorenzini of elasmobranchs and similar ampullae of teleost fish, they may function as thermoreceptors in fish. As membranes undergo conformational changes in response to temperature, they can be used as sensors to initiate cellular changes needed in response to temperature stress. Since isolated cells from fish are capable of adapting to temperature change, much of the adaptive response may not require elaborate central sensing or processing. Several aspects of the biochemical machinery responsible for membrane remodeling are sensitive to temperature. The higher Q_{10} (**see also Temperature**: Effects of Temperature: An Introduction) of fatty acid synthetase than that of desaturases results in a greater proportional production of saturated fatty acids at higher temperatures simply due to the effects of temperature on enzyme activities. Membrane-bound desaturases are sensitive to temperature in such a way that they are activated at low temperatures as membranes stiffen, and the resultant increase in unsaturated fatty acids when incorporated into membrane lipids fluidizes the membrane, thereby inactivating the desaturase in a feedback regulatory phenomenon. The Q_{10} for cholesterol synthesis is high ($\sim$3), enhancing the availability of cholesterol for membranes at higher temperatures. Similarly, Q_{10} effects result in preferential synthesis of PC compared to PE at higher temperatures.

Conclusions

Biological membranes are complex and dynamic, making it challenging to study their structure and function. The HVA response is a common phenomenon, exhibited by fish, as well as other animals, and other eukaryotes. Despite the rich history in this field, and the ubiquity of the response in eukaryotes, many questions remain about how the changes in membrane constituents seen in HVA alter the biophysics of membranes. The mechanisms by which cells sense and respond to changes in membrane fluidity also remain an active area of research.

Glossary

Critical thermal maximum (CTM) The maximum temperature that can be tolerated by an organism. In fish, this variable is most often measured by acutely increasing the temperature (e.g., by 2 °C h^{-1}) until the fish loses equilibrium.

Ectotherm (adj. ectothermic) An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Endotherm (adj. endothermic) An animal that uses its own metabolism as the major source of heat to maintain its body temperature greater than that of the surrounding environment.

Eurytherm An ectotherm able to survive over a broad range of environmental temperature.

Heat shock protein A protein that interacts with other proteins, promoting productive folding pathways to ultimately stabilize cellular proteins and membranes.

Heat shock response The induction of heat shock proteins in response to a thermal stress.

Molecular chaperones Proteins that interact or chaperone other proteins to guide folding into the correct three-dimensional structure; heat shock proteins are molecular chaperones.

***Pejus* temperature** Latin for turning worse; it represents the upper thermal limit of regular animal function.

Protein denaturation A change in the three-dimensional structure of a protein that renders the protein nonfunctional.

Stenotherm An ectotherm able to survive only within a narrow range of environmental temperatures.

Introduction

The capacity of fish to cope with temperature change has fascinated physiologists for decades. Issues of climate change and the warming trends observed in our oceans and freshwater systems have certainly accelerated interest in this area. Because the body temperatures of most fish species are within 0.1–1.0 °C of water temperatures, understanding the biological effects of temperature change is particularly compelling. Fish, like all organisms, live within a limited range of body temperatures where growth, reproduction, foraging, and behavior are optimum. During cooling and warming, performance may be compromised and at temperatures outside thermal limits, mortality is likely (**see also Temperature**: Measures of Thermal Tolerance.

At or beyond these thermal limits or critical temperatures, a fish's aerobic capacity is diminished, proteins begin to aggregate or misfold, and cellular membranes are impaired. In order to cope with temperatures near the thermal limit, fish rapidly turn on the inducible heat shock proteins (HSPs; the number (e.g., HSP70 and HSP90) indicates the apparent molecular weight, in kilodaltons, of the HSP family) in their cells to protect proteins and membranes from temperature damage. This phenotypic response is generally considered adaptive, where the induction of HSPs may extend the life of the cellular constituents and thus the organism. It is important to note that the induction of HSPs is but one of several molecular responses used by fish to cope with temperature stress (e.g., changes in enzymes, cell signaling intermediates, and membrane dynamics).

Heat Shock Proteins

The HSPs are one of the most highly conserved groups of proteins in nature, found in nearly every species examined to date – from bacteria to humans. These proteins are molecular chaperones in that they interact with other proteins, promoting productive folding pathways and ultimately stabilizing cellular proteins and membranes. HSPs are not only important during cellular stress; they are present in cells constitutively, such that under normal growth conditions they help to guide protein folding and movement throughout the life of the cell, performing important housekeeping functions associated with protein synthesis and maturation. When the cell is subjected to stress, HSPs facilitate recovery of protein structure by helping to prevent protein aggregation, encouraging appropriate refolding and/or targeting proteins damaged beyond repair for destruction. Temperature stress is certainly the most well-known and consistent inducer of the HSPs but because their induction is not limited to heat stress (see below), these proteins are also known as stress proteins. It is now well established that HSPs are critical for proper cell functioning in all organisms including fish – both under normal conditions and following stress.

The heat shock response was discovered by Ritossa in 1962 when he observed puffing of the polytene chromosomes in fruit flies that had been accidentally exposed to heat shock after one of his lab mates accidentally turned up the temperature on his incubator! This puffing Ritossa observed represented rapid (i.e., in minutes) synthesis of new genes. These same genes, which we now know were hsp genes, were also synthesized with uncouplers of ATPases (ATP, adenosine phosphate) and with recovery from anoxia. It took several years before the impact of this important and serendipitous finding was felt within the scientific community.

HSPs are traditionally grouped into families according to their molecular weight, each with several members: high-molecular-weight HSPs (~100–110 kDa), HSP90 (85–90 kDa), HSP70 (68–73 kDa), and low-molecular-weight HSPs (16–47 kDa). All family members are expressed in fish cells (**Table 1**), although the most well-known family is the HSP70 family, with both constitutive (heat shock cognate (HSC)70; the constitutive isoform of the HSP) and inducible (HSP70) forms. Fish possess high levels of HSC70 within their cells and have at least two isoforms of the inducible HSP70. There is a high level of genetic similarity or conservation between HSP70 and HSC70 in fish.

Because body temperatures of ectotherms fluctuate with the environment, their cells and proteins have a greater likelihood of experiencing thermal injury. Thus, fish may have an enhanced need for HSPs compared to organisms with a more stable body temperature such as mammals. So, despite their ubiquity, one could argue that HSPs are more important in the survival of ectotherms, like fish, than in endotherms.

HSPs and Fish

With one exception (see below), the heat shock response is present in all freshwater and marine fish species in which it has been studied (**Table 1**). Much of the research on the heat shock response with high temperature in fish has been performed in teleosts, although there is now evidence that this response is also present in elasmobranchs and agnathans. Two members of the

Table 1 HSPs and examples of fish (whole animal, tissues, and/or cells) exhibiting induction with thermal stress

HSP (gene and/or protein)	*Example fish species*

HSP40	*Gillichthys mirabilis*
HSP47	*Danio rerio*
HSP100 (100-108 kDa)	*Gillichthys mirabilis, Pimephales promelas, Poeciliopsis lucida, Salmo salar*
HSP10	*Cyprinus carpio*

cold-adapted, Antarctic Nototheniidae family of icefishes (*Trematomus bernacchii* and *Harpagifer antarcticus*) are examples of only a very few organisms that appear to lack the heat shock response. These stenothermal fish never encounter temperatures above 0 °C and die of heat death above 4 °C. These notothenioids have the ability to synthesize HSPs, but do not induce HSPs upon temperature stress. Their strategy is to maintain high basal levels of the constitutive and inducible HSP70 to aid with increased protein damage and problematic protein folding at low temperatures. This lack of a heat shock response may mean that their range of thermal tolerance is attenuated. In light of current and predicted increases in seawater temperature, these cold-water fish could be in serious jeopardy from thermal stress.

HSPs in the Cold

Many of the physiological effects of heat stress, such as increased protein denaturation, are also apparent in exposure to the cold. There is some evidence in bacteria, plants, insects, and mammalian cells, indicating that HSPs are induced with cold stress. In fish, although there is limited information on the induction of HSP genes or proteins with cold, members of the small HSP family (e.g., HSP10) are turned on with cold stress in fish as are HSP70 and HSP90. Notably, HSP90 and HSP70 may have an important role in stabilizing other transcription factors that are turned on in the cold, such as the hypoxia inducible factor (HIF)-1α).

Plasticity of the Heat Shock Response

As noted above, HSPs are turned on with stressors other than temperature. In some fish, HSPs are induced with low oxygen or hypoxic stress exposure to contaminants such as heavy metals and during disease. However, in many cases these stressors result in species- and HSP-specific responses. To illustrate, hypoxia-sensitive fish such as rainbow trout (*Oncorhynchus mykiss*) exhibit a robust induction of HSP70 with chronic and acute heat stress, but hypoxia does not induce HSP70, although there is some indication that lower-molecular-weight HSPs are turned on. On the other hand, hypoxia-tolerant fish (e.g., sculpins, *Oligocottus maculosis* and mudminnow, *Umbra limi*) appear to induce HSP70 with exposure to low oxygen. The heat shock response to high temperature in fish also exhibits considerable tissue specificity for reasons that are not completely clear, but may be related to differences in the degree of protein damage incurred by each tissue. The suite of specific HSPs induced during a temperature stress is also highly variable. In thinking about temperature stress in fish specifically, the heat shock response is further affected by thermal history, the intensity and magnitude of the temperature stress, the geographic population, and the developmental stage of the fish.

Thermal History

Although the fish heat shock response occurs at temperatures within the physiological limits for the species, the stress needed to induce HSPs is strongly related to the thermal niche of the animal. In general, cold-water species will induce HSPs at a lower temperature than warm-water species. However, both the minimal temperature at which HSPs are induced (the threshold induction-temperature) and the temperature of maximal synthesis are quite variable and this variation is due to several factors.

First, the recent thermal history of the fish is an important consideration in the nature of the heat shock response. Depending on the species' thermal niche, fish will often experience fluctuations in temperature on a daily and seasonal basis and this variation will influence the induction and magnitude of the heat shock response. Second, there is evidence in both eurythermal and stenothermal fish that exposures to chronically high temperatures lead to higher levels of HSPs, possibly because these conditions are more stressful and result in more protein damage. On the other hand, daily, cyclical fluctuations in environmental temperatures (i.e., >10 °C) such that would be experienced by eurythermal fish such as killifish (*Fundulus heteroclitus*) or sculpins are not necessarily coordinated with increases in HSPs. The rapid induction of HSPs observed during daily temperature fluctuations in intertidal invertebrates such as snails does not necessarily occur in fish and this may reflect different fish life-history strategies and species variations in cellular stress tolerance for fish.

Intensity of Thermal Stress

Keeping the thermal history of the fish in mind, another factor influencing the nature of the heat shock response is the intensity of the heat stress. In fish, the earliest temperature where aerobic function begins to decline is known as the *pejus* (Latin for turning worse) temperature, the upper thermal limit for regular animal function. Interestingly, HSPs are not induced at these temperatures in fish, even though physiological function is compromised. HSPs appear to be induced when fish go beyond this *pejus* temperature to a critical thermal temperature, likely when circulatory and ventilatory activity begins to fail, protein structure is threatened, and protein damage has accrued. For example, the induction of HSP70 in rainbow trout acclimated to 13 °C occurs precisely at 24 °C, a temperature where salmonid fish typically have little aerobic scope for physiological activity. Although it is tempting to approximate an overall temperature change at which

HSPs will be induced in fish (e.g., 10–12 °C above acclimation temperature), considering the influences of thermal history, such an estimate would be imprudent.

The intensity of the heat stress is more than just the temperature of induction; it is also determined by the amount of time the fish or cell is experiencing the stress as well as the rate of temperature change. These factors exacerbate the extent of protein damage and result in a more robust heat shock response (i.e., higher levels of HSPs), but it is unclear if a higher heat shock response is adaptive or deleterious. Indeed, overexpression of HSPs is thought to have negative consequences for growth and development. On the other hand, lack of HSP induction may have deleterious effects on thermal/stress tolerance (see below). Thus, in evaluating the nature of the heat shock response, one could speculate that the HSP induction temperature is a more appropriate indicator of an adaptive response than the actual magnitude of the response. Regardless, this point underscores the importance of understanding the overall fitness implications of the induction of HSPs with temperature stress.

Temporal Variation

There is a temporal component to the heat shock response that is also dependent upon the intensity of the heat stress. In fish, the heat shock response reaches its highest levels only after the stress has been removed and the animal or cell is returned to optimal physiological temperatures. It has been suggested that because the synthesis and function of HSPs demand considerable energy, the recovery process offers a higher potential for the aerobic generation of ATP. The heat shock response in fish is transcriptionally regulated. The kinetics of gene regulation and transcription are such that maximal HSP gene expression usually occurs within an hour after the stress with protein expression peaking from 8 to 24 h during recovery from the stress. Again, it is difficult to generalize the time course of the heat shock response to all fish and fish tissues as it is species and tissue specific, as well as dependent on the particular HSP being studied.

Geographical Population Variation

The magnitude of the heat shock response and its threshold induction temperature also varies with different populations of the same fish species. This has been effectively illustrated by Schulte and colleagues in the estuarine killifish (*Fundulus heteroclitus*) who have shown that although the coding sequences of HSP70 genes do not differ between northern and southern populations, there are distinct population differences in HSP induction temperatures and in the magnitude of response. These differences may be indicative of one population experiencing more protein-damaging stress than the other and/or one population being better equipped to cope with temperature stress.

Development and Aging

Fish, like most other organisms, exhibit characteristic patterns of HSP expression during embryonic development, and enhanced heat resistance is correlated with the induction of several HSPs. As a fish ages, the magnitude of the heat-induced expression of HSPs declines and the subcellular localization of specific HSPs changes. Furthermore, younger cells (e.g., nucleated red blood cells) have a greater capacity to mount a heat shock response compared to older cells. This more robust heat shock response in younger fish/cells may partly explain the general phenomenon of why juvenile fish are more tolerant to high temperature than their older counterparts.

Thermal/Cross Tolerance

There is considerable evidence correlating HSP induction patterns and resistance to damaging effects of temperature stress (i.e., thermotolerance) in several species of fish. This suggests that the heat shock response, at least in part, allows fish to survive temperatures that would otherwise be lethal. However, without mechanistic information linking the expression of specific HSPs to the thermotolerant state, we still do not understand how HSPs may confer temperature tolerance in fish. Experiments on genetically tractable fish such as zebrafish (*Danio rerio*) will soon fill this knowledge gap. Regardless, the heat shock response in fish is important for thermal flexibility and has a protective role in a fish's natural tolerance to environmental change.

HSPs are also thought to have a role in cross-protection or cross-tolerance, whereby the exposure to one stressor affords protection against another distinct stressor. This phenomenon has been observed several times in fish and fish cells. For example, a prior heat shock, sufficient to induce HSP70, is associated with increased tolerance to a subsequent osmotic shock. As was the case with thermotolerance, there is strong correlative evidence linking HSP induction to the mechanism of cross-tolerance in fish, but we have yet to directly establish HSPs as mediators of this phenomenon.

Triggers of the Heat Shock Response

Although the signal triggering the heat shock response has not been thoroughly elucidated, there is considerable evidence, including in fish, that the presence of damaged or denatured proteins is the proximate trigger for the induction of HSPs. Wherever protein synthesis occurs, there is the danger of improper folding or aggregation. During stresses such as high temperature, the probability of protein misfolding, damage, and/or aggregation increases and if this damage becomes too high, cell death is likely. HSPs prevent inappropriate protein interactions and effectively reduce the degree of protein damage in the cell (**Figure 1**). In fish, the heat shock response is triggered at temperatures that lie within the upper reaches of their normal body temperatures, providing indirect evidence that thermal damage to proteins occurs under natural environmental conditions.

If, however, proteins are denatured or damaged beyond repair, they must be removed from the cell. Molecular chaperones are an important part of this process. A small chaperone called ubiquitin covalently and irreversibly binds to damaged proteins so that they will be directed to the proteasome for destruction. This protein is ubiquitous among organisms and we know that fish cells make use of this ubiquitin–proteolytic system to ensure protein quality control so that malfunctioning proteins do not accumulate in the cell.

Molecular Regulation of the Heat Shock Response

Given the variation that exists in the heat shock response, one model will not explain the regulation of all families of HSPs in all species. However, a few generalizations on the mechanisms of HSP regulation can be made. The genes encoding HSPs can be grouped into three regulatory classes: (1) constitutively expressed during growth and development, (2) constitutive and inducible, and (3) strictly inducible. The primary form of regulation of HSPs in fish and other organisms is through transcription, but there is also a degree of posttranscriptional regulation (e.g., messenger RNA (mRNA) stability, translational regulation, and subcellular localization) in the stress-induced increase of HSPs. Most HSP genes do not contain introns, so the mRNA is rapidly translated into new proteins within minutes to hours of exposure to a stressor.

In all organisms, the heat shock response is mediated by a family of heat shock transcription factors (HSFs). There are at least four known HSF genes (HSF1, HSF2, HSF3, and HSF4) where HSF1 is the master regulator of the heat shock response in eukaryotes. To date, HSF1 and

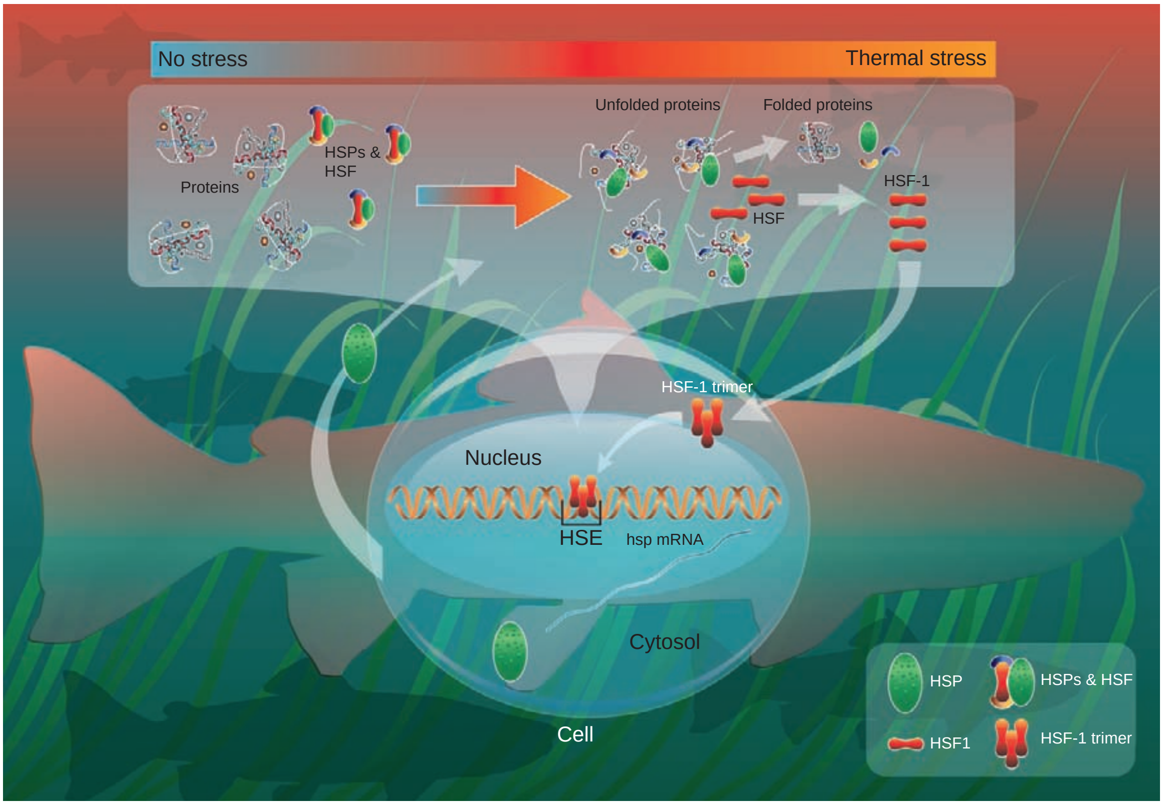

Figure 1 A model depicting the molecular regulation of HSP induction in fish cells. Under optimum temperature conditions, HSPs are transiently associated with HSF-1 monomers in the cell. During thermal stress, proteins may unfold and/or aggregate and this process triggers the release of HSPs from the HSF. The free HSF monomer moves into the cell nucleus where it trimerizes and binds to specific HSE regions of the DNA, resulting in transcription of HSP genes. These genes are translated to HSPs within the cytosol that can chaperone accumulating denatured proteins.

HSF2 have been identified in fish and two HSF1 genes (HSF1a and HSF1b) have been identified in rainbow trout. Furthermore, the regulation of both HSF1 and 2 in fish is very similar to that of other vertebrates. Under nonstress conditions, these transcription factors are maintained in a non-DNA-binding form as a monomer through transient interactions with HSPs (e.g., HSP70, HSP90, and HSP40; **Figure 1**). Induction of the heat shock response, likely through an accumulation of damaged, unfolded proteins, recruits HSPs from the HSF, removing the repressive effect and allowing the unbound HSF to move into the nucleus. Once inside the nucleus, HSF monomers trimerize and bind to specialized sequences on the DNA where they are activated through phosphorylation, resulting in transcription and subsequent translation of heat shock genes and proteins, respectively. The main DNA targets for HSF binding are heat shock elements (HSEs) within promoter regions of heat shock genes (**Figure 1**). High rates of transcription are maintained only when HSF1 trimers remain bound to HSEs. When either the stress signal is removed or damaged, proteins are no longer generated, the heat shock response is rapidly diminished. This quick downregulation of the heat shock response in the absence of stress is important to reduce energetic costs of HSP synthesis and to prevent any possible deleterious effects of overexpression. The variation we observe in the heat shock response in fish may be explained by differences in the regulatory regions of the different fish HSFs (post-translational modification), the HSF DNA-binding kinetics as a function of thermal history, and/or the interaction of HSFs with HSPs and other chaperones.

Physiological Regulation of the Heat Shock Response

It is now clear that aspects of the physiological responses to temperature stress in fish, such as changes in stress hormones and fatty acids, play a role in the regulation of the heat shock response. Acute heat stress in fish results in transient increases in the catecholamines, adrenaline and noradrenaline, and in the glucocorticoid stress hormone, cortisol, as well as changes in cell membrane dynamics leading to the release of polyunsaturated fatty acids (PUFAs). In fish, these humoral factors all directly but differentially impact the heat-induced expression of HSPs. Overall, catecholamines and PUFAs enhance, whereas cortisol attenuates the heat shock response. Clearly, the physiological regulation of the heat shock response in fish is complex but is likely optimally coordinated to ultimately delay or prevent thermal injury during heat stress (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids, **Hormonal Responses to Stress**: Catecholamines, Hormone Response to Stress, and Stress Effect on Growth and Metabolism).

Conclusion

Climate change is emerging as a significant threat to the world's dwindling fish stocks. It is therefore critical that we have a solid understanding of the physiological and molecular mechanisms underlying the capacity of fish to maintain key biological functions to help us predict the consequences of thermal stress on populations and ecosystems. The induction of HSPs is an integral component of a fish's response to temperature change. To appreciate the impact of HSP expression on animal fitness, future research must establish a direct role for HSPs in stress tolerance and integrate HSP induction with whole animal physiological function.

Glossary

Aerobic scope The capacity of an animal to increase its level of aerobic metabolism beyond that which is required for maintenance alone and thereby support activities such as muscular exercise, growth or reproduction; it sets the capacity for oxygen-consuming physiological processes that an animal may perform at a given time. Aerobic scope is the difference between minimal and maximal oxygen consumption rate.

Climate change The global and local trends of changes in atmospheric climate conditions, which are, on average, associated with trends of warming and acidification, as well as expanding hypoxic zones in the world's oceans.

Life-history stages Successive stages of shape, morphology, functioning, and lifestyle during development from the egg into adulthood.

Ocean acidification A trend of reduction in the pH of ocean waters which is elicited by the dissolution of accumulating atmospheric CO_2.

Oxygen- and capacity-limited thermal tolerance (OCLT) A physiological concept explaining the specialization of animals on limited ranges of ambient temperatures (thermal windows) and their intolerance to temperature extremes. It builds on the finding that the functional capacity of tissues, including those involved in oxygen supply, is restricted to a limited range of temperatures and supports aerobic scope within that range.

Introduction

Ongoing climate change is projected to affect individual organisms during all life stages, thereby impacting populations, communities, and the functioning of ecosystems. These impacts of climate change on organisms can be direct, for example, through changing water temperatures, hypoxia events, ocean acidification, or climate-induced shifts in hydrodynamics and sea level, or indirect and mediated through changes in the composition of the food chain.

All effects occur via impacts on individual specimens in a population, involving phenomena at four interlinked levels of biological organization:

1. Whole-organism physiological responses to changes in environmental parameters such as temperature, dissolved oxygen, and ocean pH. This includes the physiological processes providing energy from food and those using that energy to support performance of the whole organism.
2. Behavioral responses at the level of the individual. This includes the avoidance of unfavorable conditions and, if possible, movement into suitable areas.
3. Changes in population dynamics as a result of alterations in the balance between rates of mortality, growth, and reproduction. This includes the dispersion of early life stages by ocean currents, which lead to the establishment of new populations in new areas or abandonment of traditional habitats.
4. Ecosystem-level changes in productivity and/or food-web interactions due to different responses by organisms at different levels of the food web. These observed impacts of global warming on fish at organismal, population, and community/ecosystem levels will be species specific and build on physiological changes at molecular, cellular, and whole-organism levels.

Ecosystem Level Phenomena: Populations and Communities

In the oceans, temperature defines the large-scale geographical distribution of marine water-breathing animals, within conditions set by geomorphology, ocean currents, water depth, and stratification or salinity. As a result of thermal specialization, warming or cooling would then drive marine fish to higher and lower latitudes, respectively. In fact, ocean warming is currently one of the main driving forces causing species-specific changes in distribution and abundance and, thus, in species composition in marine ecosystems. Shifts in geographical distribution are generally most evident near the northern or southern boundaries of the geographic range of a species. A number of studies have documented such changes within particularly well-studied ecosystems of the world's oceans including the North Sea and other parts of Europe. Furthermore, the seasonal timing of crucial events (phenology) also changes in relation to one another. For example, the timing of spawning and development of the fish larvae may shift out of phase with that of phyto- and zooplankton production such that food availability to the fish is reduced.

Meta-analysis of available data shows that there are differences in the tolerance to extreme temperatures both within species and/or between species (**see also Temperature**: Measures of Thermal Tolerance). The difference between upper and lower lethal temperatures, or the thermal window, of marine fish species varies with latitude, and is narrowest in fishes inhabiting high and low latitudes and widest for fish inhabiting intermediate latitudes where seasonal differences in temperatures are, on average, largest (**Figure 1**). Thermal window widths also vary depending on life stage. The relationship allows one to use geographical distributions of species (Arctic, Boreal, Lusitanian, Tropical, and Atlantic) as a classification scheme to evaluate expected responses.

Ecosystem effects are not only related to shifts in seasonal or annual mean temperatures. Temperature maxima or minima, as opposed to mean temperatures, also represent strong driving forces on both the cold and the warm side of the temperature spectrum. For example, extremely low winter-water temperatures cause losses in abundance of species and ecosystem changes, as seen in the German Wadden Sea. Conversely, cold-tolerant species will suffer from increasing exposure to summer heat. Observed shifts in geographical distribution of species such as Atlantic cod (*Gadus morhua*), snake blenny (*Lumpenus lampretaeformis*), and anglerfish (*Lophius piscatorius*) in the North Sea may involve the shifting frequencies of such weather conditions. In Atlantic cod, winter warming in the Southern North Sea is closely correlated with northward shifts in the population. Recruitment of cod in the North Sea falls during warming, but rises during cooling. In contrast, recruitment of the Barents Sea (North East Arctic) cod population decreases during cooling periods and increases upon warming. These trends emphasize that cod in the Southern North Sea and those in the Barents Sea live close to the upper and lower thermal limits of the species, respectively. In line with these observations, correlations between climate-associated temperature changes and Atlantic cod recruitment are stronger at the southern and northern borders of the geographical distribution area of the species in the northeast Atlantic. As a corollary, temperature defines the southern and northern distribution limits of the species.

These principles behind species specialization and sensitivity also extend to the population and community level and ecosystem functioning. Different thermal windows of species likely influence the quality and intensity as well as the seasonal timing of their interactions in an ecosystem. In general, species coexist where their thermal windows overlap, but these thermal windows are not necessarily identical. This would explain why climate sensitivity differs among species and may be one principal reason for climate-induced changes in community composition and food-web interactions. Regime shifts may result where one species replaces another one. For example, smaller copepods replaced the larger ones in the North Sea and anchovies (*Engraulis japonicus*) replaced sardines (*Sardinops melanostictus*) in the Sea of Japan. These examples emphasize that the limited thermal window of whole-organism performance capacity is key to understanding and projecting climate-induced changes in species interactions and, furthermore, in community composition.

Most commercial species produce millions of eggs, and mortality rates of early life-history (egg and larval) stages are very high. Relatively small changes in rates of mortality can have large impacts on the recruitment success and the number of fish destined to enter the adult population. As early life-history stages are likely to be more sensitive to altered environmental conditions (see **Figure 1**), global warming is expected to have a major effect on the distribution and abundance of fish through its influence on recruitment. Productivity will also be influenced by the effect of temperature on growth rate. In a comparative study of 15 Atlantic cod stocks, sevenfold differences in the productivity among stocks corresponded to the differences in the temperature of the environment. A part of this effect is related to different (growth) performance rates of cod populations at the same temperature due to specialization in local or regional climate regimes.

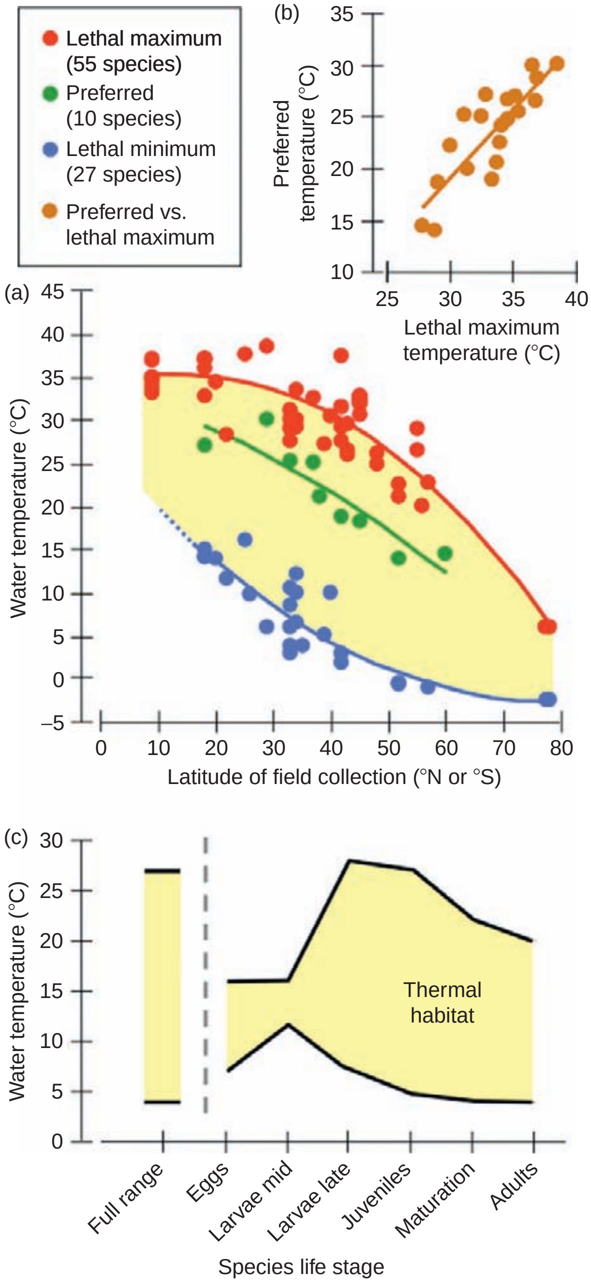

Figure 1 Thermal tolerance in marine fish species including upper lethal (blue), lower lethal (red), and preferred (green) temperatures versus latitude (°N or °S) of the fish population (a) and relationship between preferred and upper lethal temperature (b). Preferred temperatures by fish (in the laboratory) often coincide with optimal growth temperatures observed in the wild. Thermal tolerance changes with life stages (c), in this example for sole (*Solea solea*), the earliest life stages were more sensitive (had a more narrow range in thermal tolerance) than later larvae and early juveniles that can exploit the largest range in thermal habitats compared to earlier or later (adult) life stages. The tolerance range in (c) is a compilation of information from experimental work on early, pelagic life stages (eggs, larvae, and juveniles by Irvin DN (1974) Temperature tolerance of early development stages of Dover Sole, Solea Solea (L.) *Proceedings of an International Symposium on the Early Life History of Fish*, pp. 449–463. Dunstaffnage Marine Research Laboratory, Oban, Scotland, 17–23 May 1973 and Fonds M (1979) Laboratory observations on the influence of temperature and salinity on the development of the eggs and growth of the larvae of Solea solea (Pisces). *Marine Ecology Progress Series* 1: 91–99) and the range of temperatures where demersal stages of those flatfish are observed. Maturation refers to the body size at which fish become sexually mature (i.e., they first enter the adult stage) and does not refer to adult fish that are in spawning condition. Note that the lower temperature for adults is based on the lethal temperature observed during cold winters by Woodhead PJM (1964) The death of North Sea fish during the winter of 1962/63 particularly with reference to the sole, *Solea vulgaris*. *Helgolander Wissenschaftliche Meeresuntersuchungen* 10: 283–300.

As a consequence of thermal specialization, low productivity and high mortality occur when temperature conditions reach extreme values. However, additional factors interfere and interact with temperature. Mortality is elicited or enhanced during hypoxic or anoxic conditions. In some ecosystems, mass mortalities during summer have been reported in relation to harmful algal blooms. Climate change may have dramatic (negative) impacts on the productivity of fish populations by increasing the frequency of these episodic extreme events that have acute physiological consequences.

Physiological Background of Climate-Change Impacts on Ecosystems

Oxygen- and Capacity-Limited Thermal Tolerance

Specialization of marine fauna on climate-related thermal windows emerges as one overarching reason for the sensitivity of marine fauna to temperature extremes. Thermal windows differ between life stages of one species as well as between species and thereby co-define changes in higher-level processes at ecosystem level in response to climate change.

For animals, the concept of oxygen- and capacity-limited thermal tolerance (OCLT) (**Figure 2**) provides a mechanistic explanation of why, how, and at which temperature limitation occurs. It also distinguishes the thermal range of permanent, active survival from the range of time-limited passive tolerance to temperature extremes. This concept also explains the transition between those ranges. It is a suitable candidate to define the borders of the niche of functional capacity of a species with respect to temperature and species interactions.

The concept implies that oxygen supply to tissues is optimal between limits called lower and upper 'pejus' temperatures (pejus means 'getting worse'). Between pejus limits, oxygen supply can be increased to levels much in excess of maintenance demand and thereby fuel optimal performance by aerobic metabolism. The aerobic scope (the difference between the lowest and highest rates of aerobic respiration) represents the energy available for

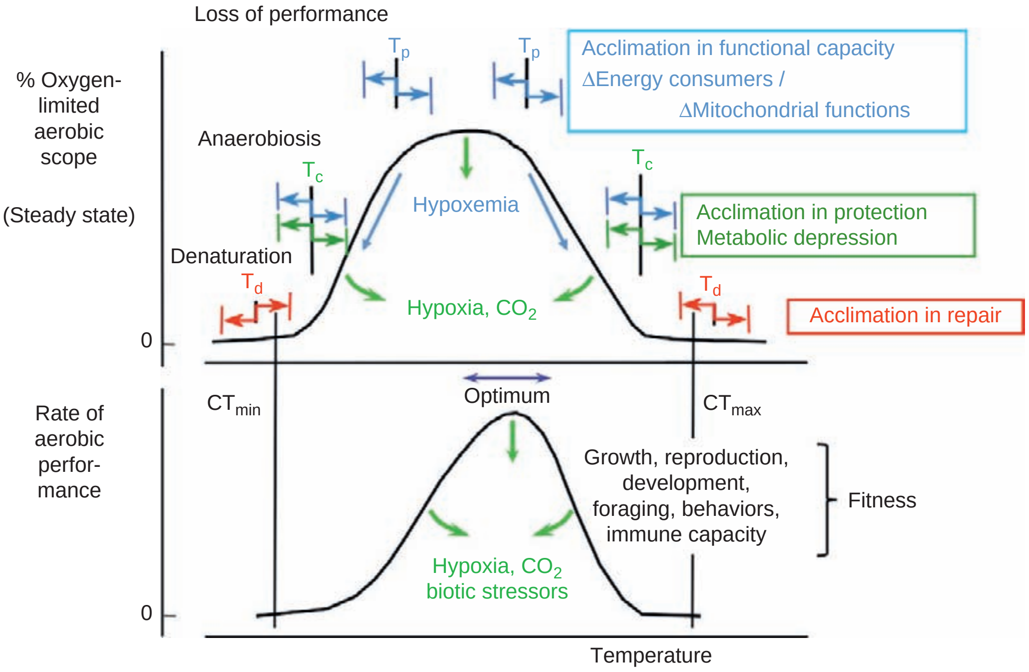

Figure 2 Conceptual model of how ocean warming, hypoxia, and acidification, as interacting stressors, shape the thermal window of performance of a species at a specific life stage, based on the concept of oxygen- and capacity-limited thermal tolerance. Oxygen supply to tissues is optimal between low and high pejus temperatures (top) and supports temperature-dependent performance capacity (bottom). Critical temperatures (T_c) characterize the onset of anaerobic metabolism and denaturation temperatures (T_d), the loss in integrity of molecular structures. Critical thermal maxima and minima (CT_{max} and CT_{min}) delineate the outermost limits where whole-organism function ceases. The kinetic stimulation of performance by warming leads to a tilted curve with a functional optimum close to the upper pejus temperature. This performance curve reflects the role or functional capacity and associated aerobic scope in ecosystem-level processes such as competition, foraging, immune response, growth, and behaviors. Ambient hypoxia and elevated CO_2 levels both cause a narrowing of thermal windows, and, possibly, lower performance optima through lower functional capacities and reduced systemic-oxygen tensions (green arrows). The graph depicts acute performance levels and limitations in response to short-term temperature fluctuations. Seasonal acclimatization causes a shift and changing widths of acute performance windows within the limits of the thermal niche of a species (horizontal arrows).

all life-sustaining processes, such as those supporting fitness and the capacity to forage, migrate, grow, or reproduce.

The kinetic slowing of performance by cooling below the optimum leads to a lower pejus limit, which is characterized by performance significantly below optimum levels. Conversely, the kinetic stimulation of performance and maintenance costs by warming causes the performance curve to be tilted to the right. Beyond the upper pejus limits, the capacity for oxygen supply becomes limiting, maintenance demand rises, and aerobic scope starts to decrease. Hypoxemia develops and whole-organism functional capacity (e.g., exercise or growth performance) declines. Once critical temperatures are reached, extreme hypoxemia sets in causing transition to anaerobic metabolism. Finally, thermal damage to the integrity of molecular structures (denaturation) may occur.

Figure 2 distinguishes between the temperature range associated with long-term survival, growth, and reproduction due to maintained performance (the active range) and the subsequent time-limited endurance of temperature extremes (passive range). The transition between the two and the loss in performance is progressive, leading to a progressively severe time limitation of thermal tolerance. The point where this transition starts is defined as the pejus temperature (T_p, the temperature at which aerobic scope begins to decline). Organisms would not survive long term at temperatures higher than T_p; time constraints become more and more severe as temperatures approach and reach beyond their critical temperature (T_c) where aerobic scope approaches zero. The product of time and heat load beyond T_p would then set the lethal temperature, which indicates the ultimate limits of passive tolerance. The lethal temperature is thus time dependent, short-term heating protocols leading to higher lethal temperatures than long-term heating protocols.

In laboratory studies, lethal tolerance limits of fishes have traditionally been determined as the onset of spasms at critical thermal maxima ($\mathrm{CT}_{\mathrm{max}}$) and minima ($\mathrm{CT}_{\mathrm{min}}$). $\mathrm{CT}_{\mathrm{max}}$ and $\mathrm{CT}_{\mathrm{min}}$ are the temperatures at which fish are definitely unable to escape conditions that will ultimately lead to thermal death (**see also Temperature**: Measures of Thermal Tolerance). These limits occur at temperatures beyond the T_c values, as defined by the OCLT concept. During exposures to extreme temperatures beyond T_p, animals progressively enhance exploitation of protective mechanisms such as the capacity of anaerobic metabolism (beyond T_c), anti-oxidative defense, and the heat-shock response. All of these contribute to extend the period of passive tolerance. The relevance of these processes varies between species and would be under strong selection in some environments where organisms are regularly exposed to thermal extremes. For example, passive extension of the range of tolerance appears crucial in thermally variable environments such as the intertidal zone.

Pejus limits reached acutely on short timescales may shift over time when the organism has the capacity to acclimate to temperature change. However, acclimation capacity is limited, such that during exposure to temperature on long timescales (as in growth studies), performance decrements occur at the limits of thermal acclimation capacity. Beyond these long-term thermal limits, the loss in fitness remains uncompensated and leads to various phenomena at ecosystem level, that is, a loss of growth performance and reduced population abundance. These were observed in eelpout (*Zoarces viviparus*) in the German Wadden Sea, where abundance falls upon exposure to extreme summer temperatures, in the same temperature range when growth performance decreases and oxygen-supply capacity by the circulatory system becomes limiting. Large individuals disappear first from the population since they are affected most by the heat stress, in line with the exacerbation of oxygen limitation at larger body sizes.

Performance Patterns and Energy Budget

Thermal specialization according to local climate conditions contributes to shape the energy budget of marine organisms. Balanced bioenergetics budgets (**see also Energy Utilization in Growth**: Energetics of Growth, **Energetic Models**: Bioenergetics in Aquaculture Settings, and Bioenergetics in Ecosystems) that include specific pathways for energy gain and loss may be a useful tool to assess the potential impacts of climate change on fish. These equations are generally written as follows:

$$C = G + R + E + F \tag{1}$$

where C is the energy gained from food consumption, G the energy gained in growth, R the energy lost via respiration, E the energy lost via nitrogenous excretion, and F the energy lost in egested fecal material. All parameters have common energetic units (e.g., joules per day). Rates of R (and E) can be subdivided to include different levels of energy loss due to basal (standard, R_S), feeding (specific dynamic action, R_{SDA}), and active (R_A) metabolism. Growth can also be subdivided to partition between gonadal (G_G) and somatic (G_S) growth. Rates of these various parameters are affected by a number of factors including water temperature, fish body size, and feeding level. Thus, balanced budgets provide a route for exploring possible impacts of environmental changes at the level of the individual. This balanced equation is most commonly used to estimate either growth or food consumption after the

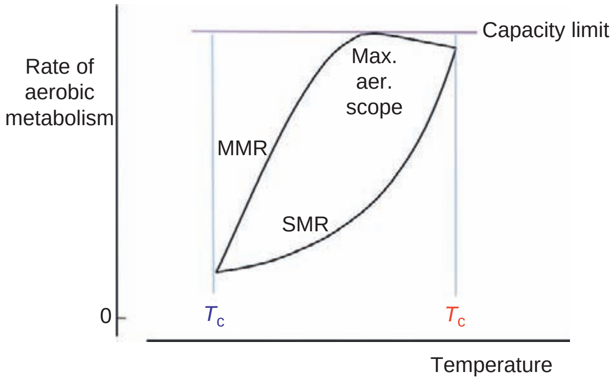

Figure 3 Conceptual model of how standard and maximal metabolic rates fit the thermal window of oxygen- and capacity-limited thermal tolerance (projected from mechanistic knowledge as in **Figure 2**). The exponential phase of standard metabolism is bordered by critical temperatures. The performance curve as in **Figure 2** results from the difference between maximum and standard metabolic rates.

other parameters are determined. For a true cause-and-effect understanding, however, the question requires consideration of which variables are dependent variables.

The effect of temperature on growth rate (*G*) follows the aerobic performance curve with net growth performance only possible above the low and below the high critical thresholds (cf. **Figures 2** and **3**). A reduced upper temperature threshold occurs when *C* is much less than *R*, *E*, and *F* (i.e., when metabolic costs cannot be met by feeding). Above the lower threshold, growth rates increase with increasing temperature until an optimal temperature is reached, when food availability is not limiting. With further increases in temperature, *G* often rapidly declines until mortality occurs even when food is available. At these suboptimal high temperatures, fish cannot consume enough food to meet increasing metabolic costs; available evidence suggests that there is not enough aerobic scope available to cover the postprandial increase in oxygen demand (cf. **Figure 2**; **see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation). Losses in appetite occur at the highest temperatures, rapidly leading to mortality.

The relationships between the levels of energy turnover, the capacities for activity, and the widths of thermal windows support an integrative understanding of specialization on climate and of sensitivity to climate change. The balance between oxygen demand for maintenance and the level of aerobic scope available for crucial performances between critical temperatures therefore appear critical for sensitivity to abiotic and biotic environmental factors (**Figure 4**). Pejus limits encompass the optimal range in temperatures (i.e., the temperatures where metabolic scope and thus performance is highest) and therefore delineate the window of highest competitiveness. In line with the predictions resulting from **Figures 1** and **2**, aerobic scope closely describes the range of performance sensitivity to environmental changes.

The range of tolerable temperatures is both species and often life-stage specific, and is a key attribute defining the observed distribution (niches and habitats utilized) by marine fish species. Global warming is not

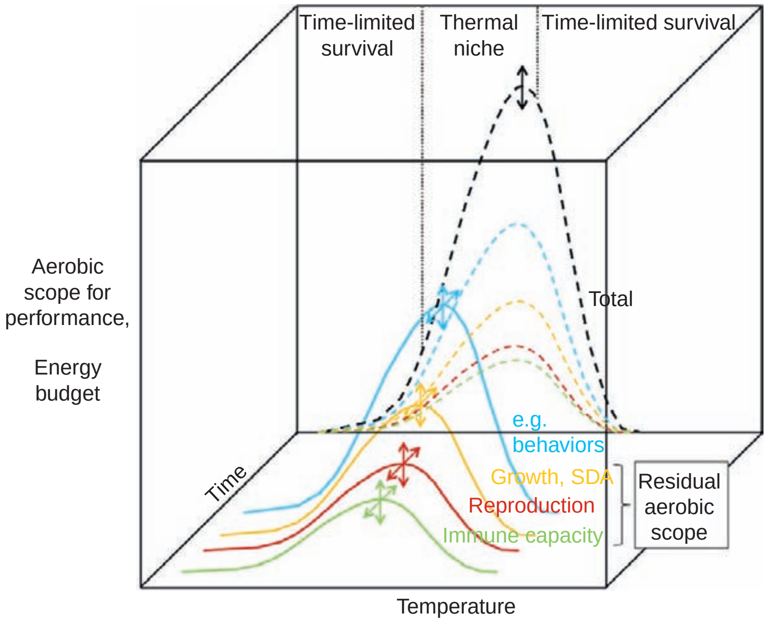

Figure 4 Energy budget for processes beyond maintenance comprising fractions of overall performance fueled by the temperature-dependent window of aerobic scope (cf. **Figure 2**). Arrows illustrate shifting fractions of various processes in the energy budget over time (order and timing arbitrary).

expected to impact all life stages of marine fishes in the same manner. For example, evidence for the common sole (*Solea solea*) and the Atlantic cod suggests that the optimum temperatures for growth decrease with increasing body size of juveniles and adults. Decreases in oxygen-limited tolerance to warm temperatures with increasing body size can be used to explain the ontogenetic shift in habitats observed in several fish species where young stages occur in shallower (warmer) waters rather than larger stages. In some species, egg and larval stages have a narrower range in tolerable temperatures than other life-history stages (particularly juveniles), making these early life stages more vulnerable to the impacts of global warming (see **Figures 1** and **5**). The sensitivity of larval stages to global warming likely relates to the ontogenetic development of convective oxygen transport during a period when diffusive oxygen supply becomes limiting. Another sensitive life stage is the mature spawner, where the egg mass may be the largest tissue to be supplied with oxygen, which narrows the tolerance range to temperature fluctuations due to the allometry of oxygen limitation. **Figure 5** outlines these patterns expected from OCLT principles.

Changes in species interactions and competitiveness at ecosystem level may also reflect these principles and may result from relative changes in performance due to different thermal sensitivities (**Figure 5**). The regime shifts described, then, not only relate to the principal effects of temperature according to thermal windows. These shifts may be accelerated by the relative changes in performance and the associated shift in competitiveness once species compete for the same resource or ecological niche.

Physiology-Based Projections of Impacts

Projections have been made of the impacts of global warming on marine fishes using a variety of methods that range from simple to complex, each of which has its own caveats and only some of which incorporate physiological mechanisms. Most projections of the impacts of global warming on fish populations, aside from simple what-if scenario tests, rely on the outputs of global climate models (GCMs).

In the most simple example, outputs from GCMs are used to adjust environmentally sensitive stock–recruitment relationships which are essentially functions estimating year-class survival (recruitment) from key population and environmental factors (e.g., spawning stock biomass and temperature, which are described by the dome-shaped relationships above). Such predictions do not reveal mechanisms, but, nonetheless, provide short-term estimates of population strength in the face of climate impacts, all other elements of the ecosystem being equal.

Bioclimatic-envelope modeling represents a second approach which is more physiology based in that it makes broad brush projections of changes in distribution based upon changes in environmental conditions correlated with the survival (or current distribution) and productivity of species. Recent modeling results for >800 commercially important marine fish species suggested that climate change could lead to numerous local extinction events by the year 2050, particularly in subpolar regions, the tropics, and semi-enclosed seas (e.g., the Mediterranean Sea), with the distribution of pelagic fish species (sardines, herring, and anchovies) and demersal

species (such as Atlantic cod, haddock (*Melanogrammus aeglefinnus*), and flatfishes) moving poleward by an average of 600 and 223 km, respectively. However, similar to simple stock–recruitment relationships described above, other climate-driven changes that may occur in marine habitats, which place constraints on the survival and persistence of populations of marine fish, are not considered.

A third example of climate model-based projections combines direct and indirect impacts of global warming (e.g., on prey fields and temperature-dependent growth performance) to examine survival of single species using coupled biophysical modeling. Such models can contain different subcomponents describing the marine ecosystem (e.g., three-dimensional (3-D) hydrodynamics and productivity at lower trophic levels) and the growth physiology of individual species. Such complex models have revealed how environmental variability potentially affected historical productivity of species. However, the reliability of this modeling approach to project future impacts depends upon obtaining robust estimates of hydrographic and lower trophic-level changes resulting from global warming. The latter is a rapidly advancing field of climate-impact research. In the future, the mechanism-based knowledge as outlined above, which has shown to be closely involved in ecosystem-level processes, would need to be extended and involved in such modeled projections, both for another level of integrative and in-depth understanding and for improved reliability of those projections.

Glossary

Anoxia Complete absence of dissolved oxygen in water.

Eutrophication A condition of aquatic systems caused by excessive primary production, fueled by excess nutrients that enter a system either as point discharges, such as sewage, or as nonpoint runoff from land, primarily from agriculture.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Importance of Oxygen and Hypoxia

Oxygen is necessary to sustain the life of fishes and most invertebrates. When the supply of oxygen is cut off or the consumption rate exceeds replacement, dissolved oxygen (DO) concentrations can decline below levels required to sustain most animal life. This condition of low DO is known as hypoxia and in the case of no DO it is known as anoxia. While many investigators and government regulatory guidelines define hypoxia as a concentration of DO below 2–3 mg-O_2 l^{-1} (milligrams of oxygen per liter of water) for marine and estuarine environments, and 5–6 mg-O_2 l^{-1} in freshwater, such an arbitrary limit may be unsuitable when examining potential impacts of hypoxia on any one given species. Species and life stages differ in their basic oxygen requirements, and oxygen requirements increase as energy-demanding metabolic processes are mobilized. The large number of hypoxia-tolerant aquatic species, and a wide variety of anatomical, physiological, and behavioral adaptations to hypoxia, suggest that low DO environments played an important role in the evolution of many adaptive strategies for hypoxia or even anoxia survival in fish (**see also Hypoxia**: Metabolic Rate Suppression as a Mechanism for Surviving Hypoxia, Respiratory Responses to Hypoxia in Fishes, and **Bony Fishes**: Crucian Carp). In contrast to terrestrial systems, adaptations to hypoxia in aquatic habitats are the rule rather than the exception.

The relatively low solubility of oxygen in water combined with two principal factors leads to the development of hypoxia and at times anoxia. These factors are water column stratification that isolates the bottom water from exchange with oxygen-rich surface water and decomposition of organic matter in the isolated bottom water that reduces oxygen levels. Both factors must be at work for hypoxia to develop and persist in deeper waters. However, in some smaller shallow systems hypoxia can form in the absence of stratification particularly at night when submerged aquatic vegetation and phytoplankton are not photosynthesizing and producing oxygen, and respiration by microbes and other organisms depletes the oxygen supply. When the primary producers start again the next day, the hypoxia dissipates. This particular form of hypoxia is known as diel-cycling hypoxia.

For temperate zone lakes, factors affecting vertical water mixing such as wind, temperature, and surface ice affect seasonal changes in the DO depth profile and can lower DO in bottom waters leading to winterkills. These physical factors alter the rate at which oxygen moves into water and how rapidly well-aerated surface waters mix with deeper ones. For example, ice and snow cover on lakes and streams can also block photosynthesis and reaeration, and may lead to hypoxia. In both of these cases, respiration needs to exceed oxygen production or resupply rates. In addition, water often becomes hypoxic on floodplains. For example, in tropical freshwaters, oxygenation is greater in rainy seasons with more water flow versus dry stagnant water seasons. In tidal areas, organisms also experience physiological hypoxia along with hypercapnia during intertidal exposure.

Much of the sensitivity of organisms to variations in the level of DO stems from the fact that oxygen is not very soluble in water and that small changes in oxygen concentration lead to large differences in percent air saturation. Depending on temperature and salinity, water contains 20–40 times less oxygen by volume and diffuses about 10 000 times more slowly through water than air. In addition, oxygen solubility strongly depends on the temperature and the amount of dissolved solids in water, with air saturation declining about 1 mg-O_2 l^{-1} per 5 °C increase in temperature and about 2 mg-O_2 l^{-1} from freshwater to seawater (35 psu) at similar temperatures (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange). Thus, what appear to be small changes in DO can have major consequences to animals living in an oxygen-limited milieu. Physiologically, higher temperatures also increase metabolic requirements for oxygen and increase rates of microbial respirations and, therefore, oxygen consumption (**see also Temperature**: Effects of Climate Change).

Where Does Hypoxia Occur?

Hypoxia is a natural component of many freshwater habitats such as swamps and backwaters that circulate poorly, stratify, and have large loads of decaying terrestrial organic matter. Lakes are also prone to thermal stratification that makes them susceptible to the development of hypoxia. However, there is mounting evidence that human activities have worsened the DO conditions in many lake and freshwater systems.

Areas of naturally low DO in coastal marine systems are limited to fjord-like systems prone to water column stratification and deep depositional basins, such as Oslofjord, Norway, or the central basin of the Black Sea, currently the largest pool of naturally occurring anoxic water on the Earth. In shallow marine and freshwater systems, depending on the balance between oxygen production and respiration, a natural diel cycling of DO from supersaturation during the day to hypoxic or near anoxic during the night can occur. In highly productive systems, calm weather conditions and extended periods of cloud cover often exacerbated the problem.

The largest natural low-DO areas on the Earth are oceanic oxygen minimum zones (OMZs) that form under areas of high surface productivity, which sinks and in the process of microbial metabolism oxygen is consumed. OMZs are unusual oxygen-depleted areas in that they are widespread and stable oceanic features occurring at intermediate depths (typically 400–1000 m), particularly severe in regions of sluggish circulation, persisting for long periods of time (at greater than decadal scales), and are controlled by natural processes and cycles (**Figure 1**). Where OMZs contact the bottom, globally about 1 000 000 km^2 along the continental margins, specialized communities have evolved to survive at DO concentrations as low as 0.1 mg-O_2 l^{-1}. Upwelling areas can also develop extensive hypoxia as additional deep-water nutrients are added to surface waters increasing production that eventually sinks and decomposes. Hypoxia associated with upwelling is not as long lived and stable as that associated with OMZs. (**see also Pelagic Fishes**: An Introduction to the Biology of Pelagic Fishes).

Rise of Anthropogenic Influence on Oxygen Budgets

In contrast to freshwater, much of the hypoxia and anoxia in shallow coastal marine and estuarine areas is recent in origin, probably beginning within the last 100 years, and closely associated with human activities (**Figure 1**). Even the natural diel cycling of DO can be exaggerated by human activities. These recent hypoxic areas, commonly called dead zones, are closely correlated with anthropogenic activities and appear to develop as a result of the cumulative effects of eutrophication in seasonally stratified or stagnant systems.

Eutrophication can be defined simply as the production of organic matter in excess of what an ecosystem is normally adapted to processing. However, it is only part of a complex web of stressors that interacts to shape and direct

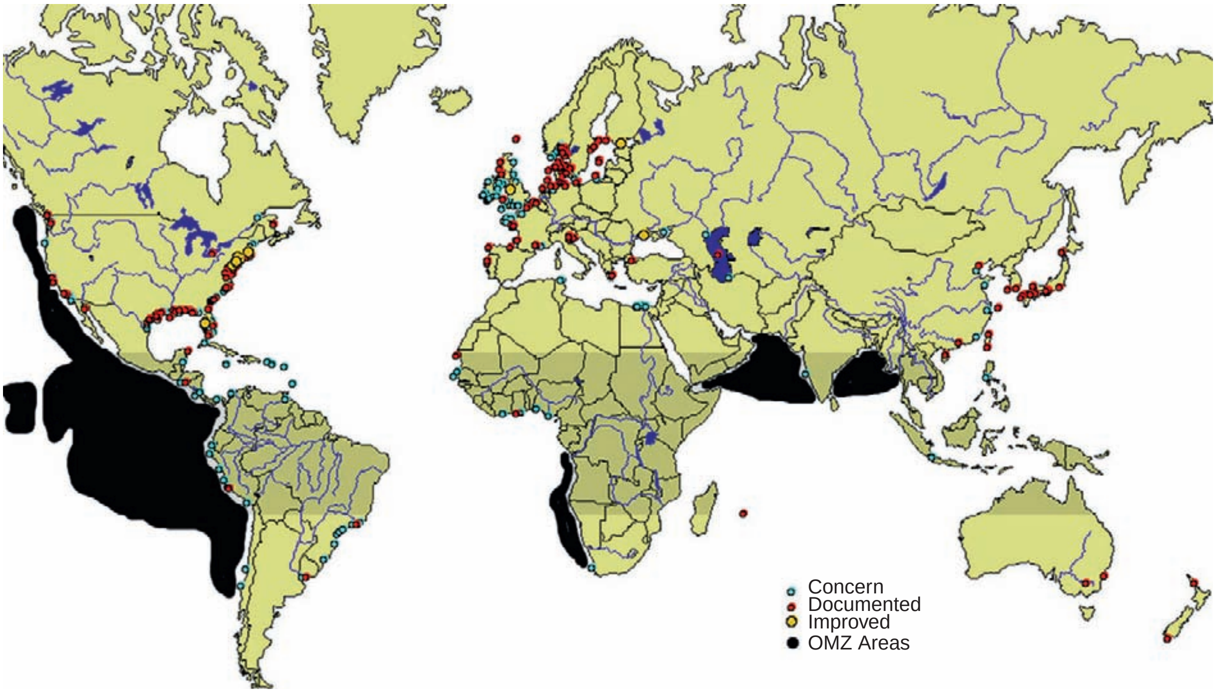

Figure 1 Global distribution of major OMZ areas and coastal hypoxic systems. Systems with documented hypoxia are red circles, areas of concern for being hypoxic are blue circles, and areas that have recovered from hypoxic conditions are yellow circles. Shading indicates the tropical regions (20 north and south of the equator) most likely to experience naturally low dissolved oxygen conditions.

ecosystem level processes. The primary driver of eutrophication in both freshwater and marine systems is excess nutrient enrichment, but physical conditions that limit reaeration are also necessary for the development of hypoxia. For freshwater systems, phosphorus tends to be the more important nutrient and for marine systems it tends to be the nitrate. This basic difference is related to the physical properties of phosphorus and nitrogen compounds, and their biogeochemical cycling through the environment.

Within the last 50 years, DO conditions of many major coastal ecosystems around the world have been adversely affected primarily by eutrophication driven by excess nutrient loading. The source of these excess nutrients is primarily agricultural runoff but also sewage and industrial discharges. As more organic matter was produced from these nutrients, more oxygen was needed to remineralize the organics, primarily through the microbial loop, and as ecosystems became overloaded DO declined. For European systems that have historical data from the early 1900s, declines in DO started in the 1950s and 1960s. However, for the Baltic Sea declining DO levels were noted as early as the 1930s in the deep central basin.

Among marine systems with long-term DO data, benthic hypoxia became a problem in the 1950s in the Baltic Sea proper, the 1960s in the northern Adriatic Sea, the 1970s in the Kattegat, and the 1980s on the Northwest continental shelf of the Black Sea. Hypoxia does not appear to be a natural condition for marine waters except for those systems previously described. Even in Chesapeake Bay where hypoxia existed even when the first DO measurements were made in 1920s in the Potomac River and 1930s in the mainstem channel, the geological record does not support the hypothesis that seasonal hypoxia is a natural condition predating European colonization. Geochronologies from the hypoxic area on the continental shelf of the northern Gulf of Mexico also indicate that the current seasonal hypoxia, which can cover over 20 000 km^2, was not present prior to the 1950s. Hypoxia was recorded with the first DO measurement made on the central Louisiana continental shelf in the summer of 1973. By 1978, hypoxia caused the first recorded mass mortality event on the Louisiana shelf. In subsequent years, hypoxia has led to extensive mortalities and low trawl catches.

Once a system arrived at the point of having hypoxia, it quickly became an annual event and a prominent feature affecting energy flow processes in many affected ecosystems. From the 1980s to the present, the distribution of hypoxia around the world has not changed appreciably in a positive way with the number of reported cases currently about 500. Only in systems that have experienced intensive regulation of nutrient or carbon inputs have oxygen conditions improved, primarily from initiation of sewage treatment or upgrades in treatment level, for example, the Hudson River in New York, the Delaware River in Pennsylvania-New Jersey, and the Mersey Estuary and Thames River in England. For example, the hypoxic zone downstream of the London's sewage input into the Thames

River was greatly reduced after upgrades to the sewage treatment plant to reduce the biological oxygen demand of the sewage being released. As a result, even hypoxia-sensitive salmonids returned to the river.

Temporary improvements have been seen in systems with changes in hydrology or nutrient inputs. In the northern Gulf of Mexico, the size of the hypoxic area responds annually to Mississippi River discharge with low flow years having less hypoxia and high flow years more. Large-scale meteorological events that disrupted stratification are also capable of reducing the area of hypoxia, as in the Gulf of Mexico and the Gulf of Finland. The northwest shelf of the Black Sea once experienced annual hypoxic events, but is now in a state of recovery largely due to the economic collapse of Eastern Europe in the early 1990s, which greatly reduced the use of fertilizer and subsequent nutrient loading in runoff. Within three years, the hypoxic area in the northwest shelf of the Black Sea went from a maximum area of about 40 000 km^2 to none. While no hypoxic events were recorded on the shelf between 1993 and 2001, a full recovery of the shallow continental shelf waters of the northwest Black Sea is far from certain. Climatic conditions caused a large hypoxic area to form during a warmer than average 2001 and the expected recovery of farming in Eastern Europe will likely lead to increased nutrient loadings.

Oxygen Budgets and Global Climate Change

The future status of hypoxia will depend upon how water column stratification is affected mainly by climate change and also by factors that affect organic matter production such as nutrient supplies that are mainly controlled by runoff and land management practices. Expanding agriculture for production of crops to be used for food and biofuels will result in increased nutrient loading and expand eutrophication effects, which in turn will expand hypoxic areas.

For climate change, general circulation models predict a decrease in the oceanic oxygen inventory through increased stratification and warming. However, the effect is several times larger than expected from warming alone and points to the importance of biology in mediating oxygen exchange. General circulation models also predict large changes in rainfall patterns. If these changes in rainfall lead to increased discharges of freshwater to coastal ecosystems, stratification and nutrient loads are likely to increase and worsen the oxygen depletion in those systems already affected and hypoxia may develop in other systems. Conversely, if stratification decreases due to increased mixing in a stormier climate, the chances for oxygen depletion will decrease. For the Mississippi River basin associated with the northern Gulf of Mexico seasonal dead zone, climate predictions suggest a 20% increase in river discharge that would lead to elevated nutrient loading, a 50% increase in primary production, a 30–60% decrease in bottom water DO, and expansion of the oxygen-depleted area.

Global warming will lead to increased water temperatures, decreased oxygen solubility, increased organism metabolism and remineralization rates, and enhance stratification. If in the next 50 years humans continue to modify and degrade coastal systems as in previous years, human population pressure will be the main driving factor in spreading of coastal dead zones, and climate change factors will be secondary (**Figure 2**). Climate forcing, however, will tend to make systems more

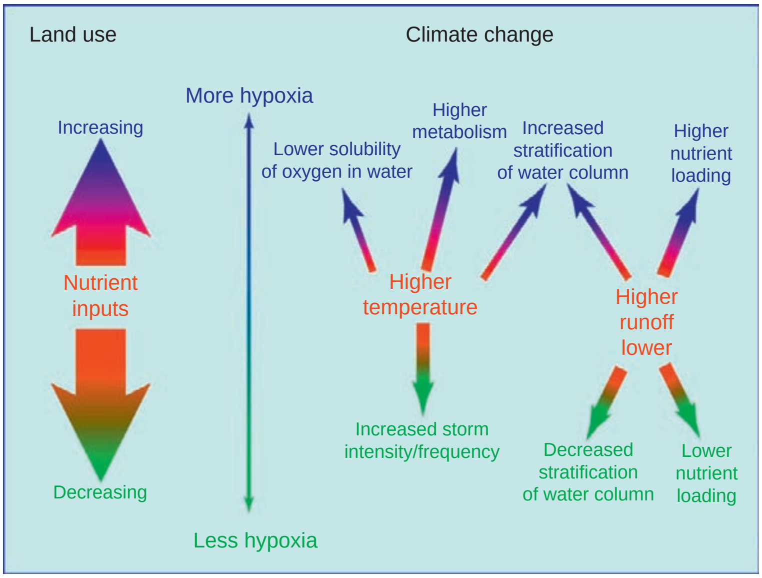

Figure 2 Relative contribution of global climate change and land use to future hypoxia. Thickness of the arrows indicates relative magnitude of effect.

susceptible to the development of hypoxia through direct effects on stratification, solubility of oxygen, metabolism, and mineralization rates.

Glossary

Aquatic surface respiration The phenomenon whereby some fish skim relatively O_2-enriched water at the air–water interface to pass over their gills.

Bohr effect Effect of the proton concentration (pH) on the oxygen affinity of hemoglobin.

Critical P_{O_2} Defined as the environmental P_{O_2} at which fish are no longer able to maintain normal rates of aerobic O_2 consumption.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Pseudobranch A structure present in some fish, it is a reduced gill arch that lies along the inner edge of the opercular flap; its function is largely unknown.

Ram ventilation The process whereby fish are able to ventilate their gills by simply swimming forward with open mouths.

Introduction

Hypoxia, a lowering of the partial pressure of O_2 (P_{O_2}) in the ambient environment (**see also Hypoxia**: The Expanding Hypoxic Environment), occurs in aquatic ecosystems for various reasons including: (1) inadequate mixing of water, (2) vertical stratification of water columns, (3) excessive O_2 consumption in waters densely populated with organisms, and (4) a lowering of barometric pressure as occurs with increasing altitude. Fish might experience aquatic hypoxia continuously (e.g., fish living in a high-altitude lake) or alternatively they might experience hypoxia seasonally or diurnally. Good examples of species experiencing hypoxia on a diurnal basis are fish inhabiting the flood basins of the Amazon.

Depending on the severity of hypoxia, fish respond with an array of behavioral, cardiovascular, respiratory, and metabolic responses aimed at preserving homeostasis (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia, **Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism, **Hypoxia**: Anaerobic Metabolism in Fish, **Bony Fishes**: Crucian Carp, and **Transport and Exchange of Respiratory Gases in the Blood**: O_2 Uptake and Transport: The Optimal P_{50}). Arguably, the most important of these responses is hyperventilation, which is defined as an increase in the volume of water flowing over the gills per unit time (minute ventilation volume, $\dot{V}_w$). Fish can hyperventilate by changing one or both of the variables that determine $\dot{V}_w$, which are breathing frequency (f_V) and stroke volume (V_{SV}). Increasing $\dot{V}_w$, however, comes at a considerable cost owing to the high energetic requirements associated with moving large volumes of water, a dense and viscous medium (at least relative to air). For this reason, there is considerable interspecific variation in the degree of hypoxia required to initiate hyperventilation. Moreover, hyperventilation, while being an appropriate strategy for mild or moderate hypoxia, may be less desirable or even inappropriate when hypoxia becomes so severe that the rising metabolic cost of increasing $\dot{V}_w$ outweighs any benefit.

What Is the Hypoxic Hyperventilatory Response?

Simply put, hypoxic hyperventilation refers to increased breathing associated with a lowering of environmental P_{O_2}. This simple definition, however, does not do justice to the impressive assortment of ventilatory responses exhibited by fish experiencing hypoxia, nor does it adequately explain the varied strategies employed by water breathers, air breathers, and bimodal breathing fish.

Water Breathers

Water-breathing fish ventilate their gills actively through the action of oscillating buccal and opercular pumps, passively by simply swimming through the water with an open mouth (a strategy referred to as ram ventilation), or by some combination of active and ram ventilation. Tunas and some shark species breathe by ram ventilation and upon exposure to hypoxia are able to increase $\dot{V}_{\mathrm{w}}$ by increasing their mouth gape. Thus, in these fish, there is relatively little cost (except that incurred by the increased hydrodynamic drag) associated with hyperventilation. On the other hand, if sufficiently severe, hypoxia will impair swimming capacity and thus $\dot{V}_{\mathrm{w}}$ may be reduced regardless of the gape of the mouth. Although there is great diversity and some exceptions, increases in $\dot{V}_{\mathrm{w}}$ in actively breathing fish are achieved predominantly through increasing V_{SV} and to a lesser extent by elevating f_{V}. This strategy is considered to be energetically less costly than relying predominantly on changes in f_{V}. In some species that normally exhibit periodic (or episodic) breathing (e.g., carp, sturgeon, eel, and zebrafish), hypoxia may cause a switch to continuous breathing (e.g., see **Figure 1**).

In some species, hypoxia may initiate a totally different manner of breathing water, termed aquatic surface respiration (ASR). During ASR, fish rise to the surface and skim the O_2-enriched water at the air–water interface which then flows across the gills. Perhaps owing to the increased predation risks associated with ASR, fish typically exploit this strategy only at severe levels of hypoxia and well after standard hyperventilatory responses are generally initiated. The risk of predation makes it less likely that smaller fish will exploit ASR than larger fish, all other things being equal.

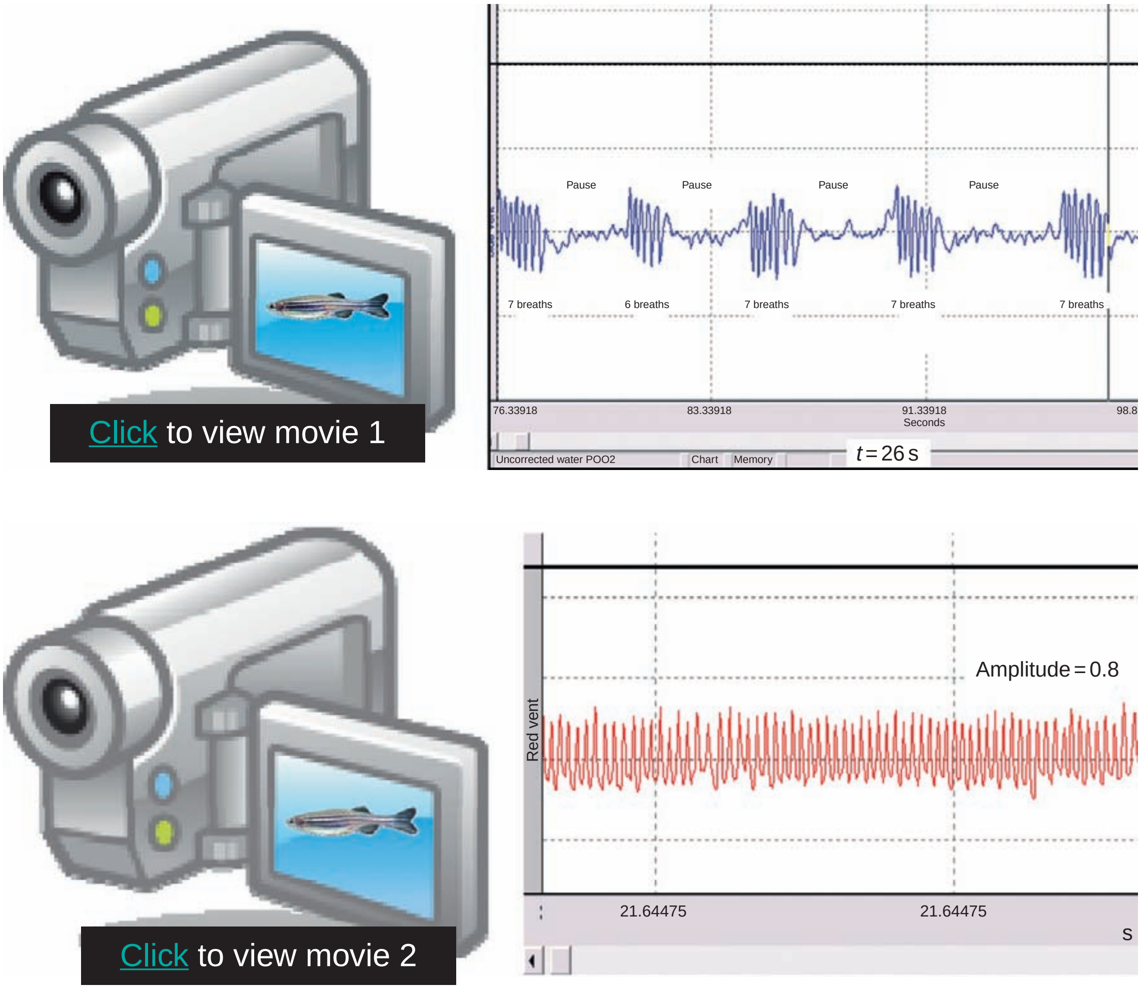

Figure 1 Representative data recordings and accompanying video images (from the same fish) demonstrating markedly different breathing patterns in zebrafish under normoxic or hypoxic conditions. The data recordings represent oscillating voltage changes recorded from the water that are associated with breathing (each peak represents a single breath). Under conditions of normoxia (**Slide 1/Video Clip 1**), zebrafish typically (although not always) display episodic breathing characterized by clusters of breaths separated by distinct pauses or periods of apnea. Under conditions of hypoxia (**Slide 2/Video Clip 2**), zebrafish exhibit continuous breathing which is characterized by a large increase in breathing frequency. These data were provided by Branka Vulesevic (previously unpublished).

Air Breathers

Two strategies for breathing air exist in fish; the facultative air breathers supplement aquatic gill breathing with episodic aerial breathing, while the obligate air breathers must continually breathe air to survive and indeed will drown if denied access to air. Although there is some uncertainty as to the response of obligate air breathers to aquatic hypoxia (i.e., there is evidence both for and against a hypoxic hyperventilatory response), the responses of facultative air breathers are well characterized. In some species (e.g., armored catfish (*Ancistrus chagresi*) and jeju (*Hoplerythrinus unitaeniatus*)), air breathing is normally absent under normoxic conditions but is initiated at levels of aquatic hypoxia usually corresponding to maximal rates of gill $\dot{V}_{\mathrm{w}}$. Similar to ASR, the predation risks associated with air breathing mean that this strategy is exploited only at severe levels of hypoxia, often near the critical $P_{\mathrm{O_2}}$ (**Figure 2**). In other species, the frequency of air breathing, already present under normoxic conditions, is increased by aquatic hypoxia.

What Is the Benefit of the Hypoxic Ventilatory Response?

The ventilatory responses to hypoxia, namely hyperventilation of the gill, ASR, and/or air breathing, represent attempts to maintain O_2 uptake in the face of declining aquatic O_2 levels. The rate of branchial O_2 transfer is governed by diffusivity, convection (ventilation and perfusion), and the blood-to-water $P_{\mathrm{O_2}}$ gradient (the driving force for O_2 diffusion). During hyperventilation, increased water flow across the gill serves to raise the mean blood-to-water $P_{\mathrm{O_2}}$ gradient. Effectively, fewer O_2 molecules can be removed from the water during the shortened duration of transit over the gill, which raises the average $P_{\mathrm{O_2}}$ of the ventilatory water and results in an elevation of arterial $P_{\mathrm{O_2}}$. Hyperventilation during hypoxia therefore serves to minimize the extent of the reduction in arterial $P_{\mathrm{O_2}}$ (and hence arterial O_2 content) that is the inevitable consequence of lowering water $P_{\mathrm{O_2}}$.

Although theory readily predicts a beneficial effect of hyperventilation on raising arterial $P_{\mathrm{O_2}}$, it is more challenging to provide direct empirical data in support especially considering that many protocols or environmental conditions known to elicit hyperventilation may simultaneously influence other factors (e.g., circulating catecholamine levels or blood flow) regulating the rate of O_2 diffusion across the gill. Hence, most experimental protocols cannot easily distinguish between the specific effects of ventilatory adjustments from other factors such as changes in blood-flow patterns and acute changes in functional lamellar surface area. Recently, investigators were able to record continuously in real time, arterial $P_{\mathrm{O_2}}$ and ventilation from goldfish (*Carassius auratus*) experiencing injections of the ventilatory stimulant NaCN into the buccal cavity. These data (**Figure 3**) clearly demonstrate a cyclical rise and fall of PaO_2 that is in phase with the increasing and decreasing $\dot{V}_{\mathrm{w}}$.

The benefit of hyperventilation becomes particularly important as arterial $P_{\mathrm{O_2}}$ approaches the P_{50} value of hemoglobin (the $P_{\mathrm{O_2}}$ at which hemoglobin is 50% saturated with O_2), where the steep slope of the O_2 equilibrium curve means that even small differences in arterial $P_{\mathrm{O_2}}$ can have a

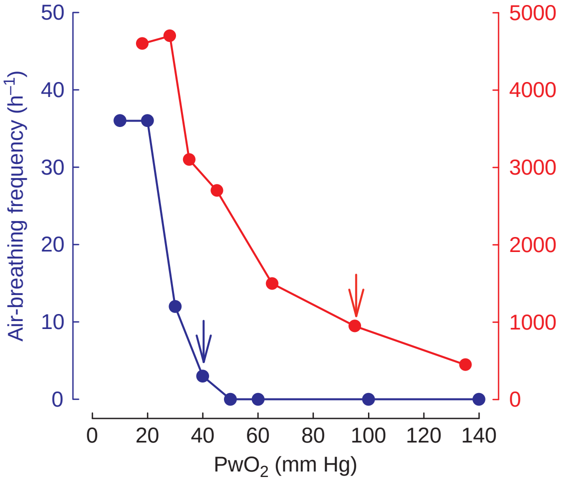

Figure 2 The effects of aquatic hypoxia on gill minute ventilation (*Vg*; red symbols and lines) and air-breathing frequency (blue symbols and lines) in the tropical fish jeju (*Hoplerythrinus unitaeniatus*). The red and blue arrows represent the onset of gill hyperventilation and air breathing, respectively. Air-breathing data are from Perry SF, Reid SG, Gilmour KM, *et al.* (2004) A comparison of adrenergic stress responses in three tropical teleosts exposed to acute hypoxia. *American Journal of Physiology* 287: 188–197, while the gill ventilation data are from Oliveira RD, Lopes JM, Sanches JR, *et al.* (2004) Cardiorespiratory responses of the facultative air-breathing fish jeju, *Hoplerythrinus unitaeniatus* (Teleostei, Erythrinidae), exposed to graded ambient hypoxia. *Comparative Biochemistry and Physiology* 139: 479–485.

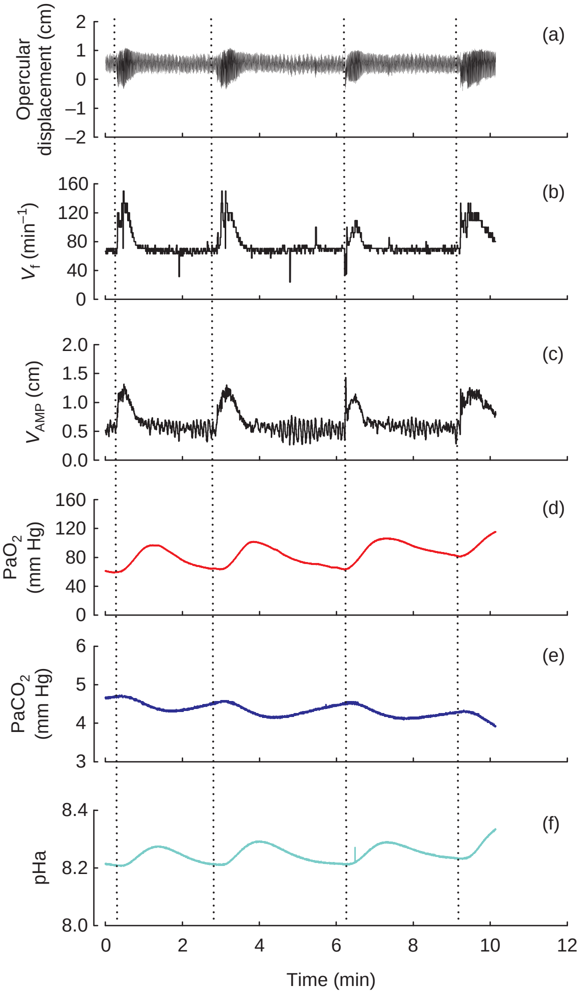

Figure 3 Representative recordings illustrating the effects of four consecutive NaCN injections (indicated by the dotted lines) into the buccal cavity of a goldfish (*Carassius auratus*) on (a)–(c) ventilation parameters and (d)–(f), arterial blood gases. The measured ventilation parameters are (a) linear deflections of the opercular flaps as measured by impedance changes, (b) ventilation frequency (f_V), and (c) ventilation amplitude (V_{AMP}) as determined from the impedance trace. Arterial blood was continuously monitored for (d) P_{O_2} (PaO_2), (e) PCO_2 ($PaCO_2$), and (f) pH (pHa). Note that each bout of hyperventilation associated with NaCN injection caused transient increases in PaO_2 and pHa and decreases in $PaCO_2$. These data were provided by Velislava Tzaneva (previously unpublished).

relatively large impact on arterial O_2 content. In addition to defending arterial P_{O_2}, hyperventilation during hypoxia produces a respiratory alkalosis as arterial PCO_2 is lowered by equilibration of the arterial blood with ventilatory water of lower mean PCO_2. Elevation of red blood cell pH following from the respiratory alkalosis can, in turn, increase the affinity of hemoglobin for O_2 via the Bohr effect, thereby aiding O_2 uptake (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange and Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). The benefit of the hypoxic hyperventilatory response, then, is increased branchial O_2 transfer which contributes to the maintenance of metabolic rate under hypoxic conditions in oxyregulators (fish that maintain a constant metabolic rate during hypoxia).

The trade-off is that more and more water is moved across the gills as less O_2 is removed from the water per unit volume moved. Thus, the downside of hypoxic hyperventilatory response is an increasing energy expenditure on ventilation, the cost of which is high even at rest in water-breathing fish. The maintenance of metabolic rate under these circumstances eventually becomes futile when the cost of increasing ventilation to maintain O_2 uptake from an environment of reduced O_2 availability eventually exceeds the benefits of the O_2 so obtained. The switch to oxygen conforming (the strategy of lowering metabolic rate with reduced ambient P_{O_2}), often with a concomitant reduction in $\dot{V}_w$, will lower the energetic expenditure on ventilation (**see also Hypoxia**: Metabolic Rate Suppression as a Mechanism for Surviving Hypoxia).

What Are the Pathways Mediating the Hypoxic Ventilatory Response?

Unlike birds and mammals, which possess a predominant lone site of O_2 sensing (the O_2 chemoreceptors of the carotid body), fish and other lower vertebrates may exhibit multiple sites of O_2 chemoreception. The O_2 chemoreceptors that initiate hyperventilatory responses are oriented in such a way as to sense changes in both external and internal P_{O_2} levels, although it is unclear whether the receptors comprise a single population of cells positioned to simultaneously sense both environments or separate cell populations each positioned to monitor external (via external receptors) or internal (via internal receptors) P_{O_2} levels (**see also Control of Respiration**: Oxygen Sensing in Fish).

Branchial O_2 Chemoreceptors

The most important site of O_2 chemoreception in fish is the gill with some species exhibiting a preferential distribution of O_2 receptors to the first gill arches. As predicted from the pioneering studies of Pierre Laurent and colleagues, Susanne Dunel-Erb and Yanick Bailly, the O_2-sensing cells of the gill have been identified as neuroepithelial cells (NECs) which are structurally and functionally analogous to the O_2-sensing glomus (type-1) cells of the mammalian carotid body. As many (but, not all) NECs contain an abundance of serotonin (5 hydroxytryptamine (5-HT)), they can be readily identified by immunofluorescence using anti-serotonin antibodies. There are two major populations of branchial NECs (see **Figure 4**): one

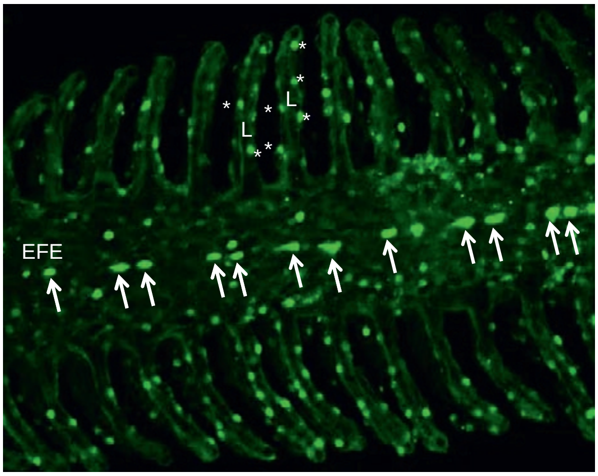

Figure 4 Whole mount immunofluorescence image of a goldfish gill treated with antibodies against serotonin to indicate (green fluorescence) the presence of two populations of neuroepithelial cells. One population (arrows) resides below the efferent filament epithelium (EFE) and above the efferent filament artery, while another (asterisks) can be found on the external surfaces of lamellae (L). This image was provided by Velislava Tzaneva (previously unpublished).

population resides below the efferent filament epithelium and above the efferent filament artery, while another can be found on the external surfaces of lamellae. Thus, it is believed that NECs of the filament are ideally suited to sense both water and blood P_{O_2} while the NECs of the lamellae most likely sense water P_{O_2} only and thus function exclusively as external O_2 chemoreceptors.

The definitive proof that NECs are O_2 chemoreceptors was provided by Michael Jonz studying zebrafish and later corroborated by Mark Burleson studying channel catfish (*Ictalurus punctatus*) (**see also Control of Respiration**: Oxygen Sensing in Fish). Using patch-clamp techniques and cultured cells, it was demonstrated that NECs experience membrane depolarization in response to hypoxia which in turn is related to an inhibition of K^+ conductance through background K^+ channels. The membrane depolarization is the trigger that ultimately leads to neurotransmitter secretion and the downstream efferent neural pathways underlying reflex hypoxic hyperventilation. Interestingly, as in the mammalian carotid body glomus cells, the NECs of zebrafish also respond to elevated CO_2 (hypercapnia) and thus likely play an important role in mediating both hypoxic and hypercapnic ventilatory responses.

Extra-Branchial O_2 Chemoreceptors

The pseudobranch (**see also Role of the Gills**: Morphology of Branchial Ionocytes) is frequently mentioned as an O_2-sensing site on the basis of its morphology and the responsiveness of *in vitro* perfused preparations to hypoxic saline. Yet, neither bilateral sectioning of pseudobranch afferent nerve fibers nor pseudobranch ablation altered the ventilatory response of trout to external hypoxia. In addition, many species known to exhibit robust ventilatory responses to hypoxia lack a pseudobranch (e.g., channel catfish). Thus, at present, there is no solid evidence to implicate the pseudobranch as an extra-branchial site of O_2 sensing. The central nervous system (brain) has also been implicated as a site of O_2 chemoreception largely on the basis of studies performed in the 1970s. More recent studies, however, employing more direct approaches have failed to provide any evidence to support the existence of central O_2 chemoreceptors in fish.

In the absence of any direct data to support a role for the pseudobranch or central nervous system in O_2 sensing, the persistence of ventilatory responses to hypoxia in fish experiencing gill denervation may reflect the presence of extra-branchial receptors within the orobranchial cavity. An alternate and not mutually exclusive hypothesis is that ventilatory responses attributed to extra-branchial O_2 receptors may, in fact, arise from the release of catecholamines (adrenaline and noradrenaline) into the circulation (**see also Hormonal Responses to Stress**: Catecholamines). The principal evidence that led to the theory of a supporting role for circulating catecholamines in stimulating breathing is that these hormones are released into the bloodstream during acute hypoxia, coupled with reports that intravascular injections of catecholamines can evoke hyperventilatory responses in European eel, *A. anguilla*. However, upon analysis of all existing data it is clear that circulating catecholamines do not play a general stimulatory role in the control of breathing during hypoxia, although in certain species it is conceivable that they play a supplementary role at very severe levels of hypoxia when O_2 chemoreceptors may be inhibited. The reader is encouraged to survey the evidence both for and against a role for circulating catecholamines in the control of breathing in comprehensive review articles listed under the section 'Further reading'.

Ontogeny and Plasticity of the Hypoxic Ventilatory Response

Zebrafish respond to hypoxia as early as 2 days post fertilization (dpf), well before the gill lamellae are developed and prior to innervation of the gill filament primordia. At such early life stages, hyperventilatory responses may be driven by O_2 chemoreceptors (perhaps NECs) residing on the external surfaces of the skin. By 7 dpf, the NECs of the developing gill filaments become innervated and this coincides with a sudden increase in the magnitude of the hypoxic ventilatory response. Given the prevailing view that the gill does not play a role in O_2

uptake until about 14 dpf, it begs the question as to the physiological significance of hypoxic hyperventilation in these young fish.

The reflex ventilatory response of adult fish to hypoxia can be markedly influenced by the environmental conditions during a critical period of embryonic and larval development. For example, zebrafish reared under conditions of hyperoxia for the first 7 dpf and then raised 3–4 months in normal water exhibit a blunted ventilatory response to acute hypoxia and the ventilatory stimulant NaCN. This phenomenon whereby adult responses can be shaped by early life experiences is termed 'developmental plasticity'.

In addition to developmental plasticity, the hypoxic ventilatory responses can be influenced by acclimatization. For example, adult zebrafish, maintained under hyperoxic conditions for 28 days, exhibit a reduced capacity to hyperventilate during subsequent acute hypoxia. In contrast to the significant effects of chronic hyperoxia, prior acclimatization of adult zebrafish to hypoxic conditions or rearing them in hypoxic water does not appear to influence subsequent acute hypoxic ventilatory responses. Yet, in catfish, acclimatization to moderate hypoxia for 7 days causes a marked increase in the capacity to hyperventilate during subsequent acute hypoxia. Clearly, it would be premature to draw any general conclusions regarding plasticity of the hypoxic ventilatory response until additional species are examined.

Krebs cycle This is a cyclic pathway located in the mitochondrial matrix that liberates electrons from carbon substrates for donation to the electron transport chain. The Krebs cycle is also known as the tricarboxylic acid cycle and citric acid cycle.

Oxidative phosphorylation A process in the mitochondrion in which the synthesis of ATP (adenosine triphosphate) is driven by (1) the transfer of electrons alone the electron transfer chain to molecular O_2 and (2) coupling to an electrochemical H^+gradient.

Reducing equivalents Molecules derived from vitamins that transfer electrons in redox reactions: mainly NADH and $FADH_2$.

Substrate-level phosphorylation A chemical reaction that results in the formation of ATP by the direct transfer of a phosphate group to ADP from a reactive intermediate.

Introduction

Most biological functions, ranging from powering a membrane-bound ion transporter to the generation of mechanical work through muscle contraction, require the input of metabolic energy in the form of adenosine triphosphate (ATP). ATP is generated by a series of metabolic biochemical pathways that transform the chemical energy stored in food molecules (fats, sugars, and proteins) into usable metabolic energy. The metabolic pathways responsible for this process fall into two broad categories: aerobic metabolism and anaerobic metabolism.

The terms 'aerobic' versus 'anaerobic' provide some initial insight into the differences in these groups of pathways. Aerobic means 'with oxygen', whereas anaerobic means 'without oxygen'. Thus, aerobic generation of ATP via aerobic metabolism, by definition, requires the input of oxygen, whereas anaerobic metabolism does not require any oxygen to generate ATP. This article briefly summarizes the metabolic pathways involved in aerobic metabolism, and then focuses on the biochemical pathways involved in anaerobic metabolism and when in fish these pathways are used.

General Overview of the ATP-Generating Pathways in Fish

Pathways of Aerobic Metabolism

For the most part, fish are similar to other vertebrates in terms of their basic metabolism. Under fully aerobic, resting conditions, more than 95% of the ATP required by a cell is derived from mitochondrial-based aerobic metabolism, referred to as oxidative phosphorylation (**see also Tissue Respiration**: Mitochondrial Respiration and Specializations in Mitochondrial Respiration of Fish). Carbon substrates, usually fats, carbohydrates, and to a lesser extent proteins, are broken down by a series of biochemical pathways whose products ultimately feed into the Krebs cycle, located inside the mitochondria. Fats, in the form of fatty acids, are broken down first by a biochemical pathway called β-oxidation, which liberates acetyl-coenzyme A (acetyl-CoA), which is then transported into the mitochondria and enters the Krebs cycle (**see also Energetics**: General Energy Metabolism). Carbohydrates, as glucose, are partially broken down by glycolysis into pyruvate, which enters the mitochondria and is converted into acetyl-CoA by the enzyme pyruvate dehydrogenase (see **Figure 1**). The pathways involved in amino acid breakdown for energy

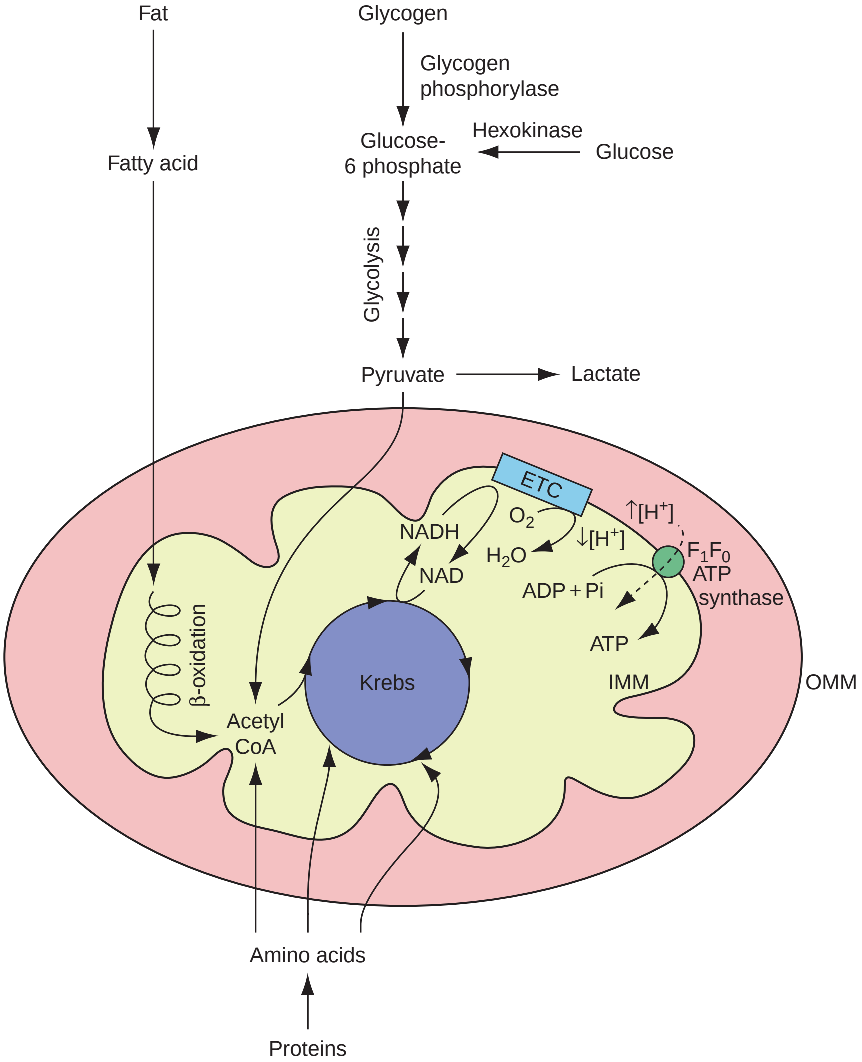

Figure 1 Biochemical map of oxidative phosphorylation and its feeder pathways ETC, electron transport chain; IMM, inner mitochondrial membrane; OMM, outer mitochondrial membrane; Krebs, Krebs cycle. See text for other abbreviations.

are more varied than for fat and carbohydrate oxidation, because depending on the nature of the amino acid that is catabolized, different pathways are used (**see also Energetics**: General Energy Metabolism). Ultimately, however, no matter what pathway is employed in the oxidation of amino acids for energy production, the products of the pathways are delivered to the Krebs cycle either through acetyl-CoA or through other intermediates in the pathways.

The Krebs cycle liberates electrons from carbon substrates and transfers them, as reducing equivalents to molecules such as nicotinamide adenine dinucleotide (NAD) forming reduced NAD (NADH) or flavin adenine dinucleotide (FAD) forming reduced FAD (FADH2). These reducing equivalents, along with electrons stored in the succinate generated by the Krebs cycle, then donate their electrons to a series of proteins embedded in the inner mitochondrial membrane, which are called the electron transport chain proteins (**see also Tissue Respiration**: Mitochondrial Respiration and Specializations in Mitochondrial Respiration of Fish).

As electrons pass along the electron chain proteins, protons are consumed from the inside of the mitochondria and/or transported from the inside of the mitochondria to the outside of the mitochondria. The final electron acceptor of the electron transport chain is oxygen, which accepts electrons while combining with protons forming water. In its simplest sense, the electron transport chain functions to reduce the proton concentration inside the mitochondria (increase pH) while increasing the proton concentration (decrease pH) outside the mitochondria. This generates a proton gradient across the mitochondrial inner membrane, termed the proton motive force, which serves as the driving force for

ATP synthesis. The energy stored within the proton motive force is harnessed for ATP generation though a specific protein called the F_1F_0-ATP synthase, which is an inner mitochondrial membrane-bound protein through which protons can flow. The flow of protons causes the molecular machinery of the F_1F_0-ATP synthase to turn, providing the energy to form ATP from adenosine diphosphate (ADP) and inorganic phosphate. Thus, the energy stored in the proton gradient is used to generate ATP.

The simplified biochemical equation for the aerobic oxidation of glucose by oxidative phosphorylation is

$$C_6H_{12}O_6 + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O + 38\,\mathrm{ATP} \qquad (1)$$

As can be seen from eqn (1), oxygen is an essential part of the oxidative phosphorylation and is the reason it is called 'aerobic'.

Pathways of Anaerobic Metabolism

Anaerobic metabolism, which can be defined as ATP production without oxygen (or in the absence of oxygen), occurs by direct phosphate transfer from phosphorylated intermediates, such as glycolytic intermediates or creatine phosphate (CrP), to ADP forming ATP. This process of direct phosphate transfer from a substrate to ADP forming ATP is termed 'substrate-level phosphorylation' and takes place in the cytoplasm, in contrast to oxidative phosphorylation that takes place in the mitochondria in aerobic metabolism.

Although both processes of ATP generation can occur under any physiological condition, the amount of ATP produced per mole of substrate consumed is approximately 15- to 30-fold lower using substrate-level phosphorylation than if mitochondrial-based oxidative phosphorylation is used to generate ATP.

There are two main anaerobic pathways responsible for ATP production in fish: CrP hydrolysis and glycolysis yielding lactate accumulation.

CrP hydrolysis. To exercise enthusiasts, creatine is a rather well-known compound composed of parts from three different amino acids, including arginine, glycine, and methionine. Creatine can be phosphorylated by the following reaction, which is catalyzed by the enzyme creatine phosphokinase or simply creatine kinase:

$$\text{creatine} + \text{ATP} \rightarrow \text{phosphocreatine} + \text{ADP} + \text{H}^+ \qquad (2)$$

This reaction is reversible. During periods of energy excess, when ATP is not being utilized by other processes at appreciably high rates and oxygen is plentiful (i.e., under normoxic/resting conditions), the creatine kinase reaction favors CrP formation and CrP is maintained at a high concentration in the tissue. For example, in the white muscle of rainbow trout (*Oncorhynchus mykiss*) under resting normoxic conditions, CrP levels up to 45 or 50 mM exist. In contrast, under conditions of where energy demand rapidly increases or oxygen can no longer be supplied to the tissues, CrP serves as a reserve of high-energy phosphates that can be rapidly mobilized; CrP can 'anaerobically' donate phosphate groups to ADP forming ATP. Thus, CrP serves as a kind of phosphate energy buffer in the cell and this role is most commonly observed in muscle. Although CrP levels in fish muscle seem quite high relative to the ATP concentration, which is up to 5 mM in trout muscle, the CrP reserve is rapidly exhausted during periods of intense exercise. Phosphocreatine levels are typically high in skeletal muscle and nervous tissue in fish, which have high and fluctuating energy demands, but low (often less than 5 mM) in other organs.

Glycolysis. The term 'glycolysis' is a combination of the ancient terms 'glycose' meaning sugar and 'lysis' meaning to break. Therefore, quite literally, glycolysis means the breaking of sugar. Glycolysis is a ubiquitous pathway seen in many organisms from yeast, to animals and plants, with few modifications. The main substrate for glycolysis is glucose; however, most cells keep free glucose concentrations relatively low (5 mM). Consequently, tissues that rely on glycolysis to a large extent, store glucose as a carbohydrate polymer called glycogen. Glycogen is a highly branched string of glucose molecules, each of which can be enzymatically cleaved off to feed glucose (as glucose-1 phosphate) into glycolysis.

The simplified biochemical equation for glycolysis is

$$\begin{aligned}&\text{Glucose} + 2\text{NAD} + 2\text{ADP} + 2\ \text{inorganic phosphate}\\&\quad\rightarrow 2\ \text{pyruvate} + 2\ \text{NADH} + 2\text{H}^+ + 2\text{ATP}\end{aligned}$$

Thus, a six-carbon glucose molecule is converted into two-, three-carbon pyruvate molecules plus protons, while simultaneously releasing energy to generate ATP from ADP and store reducing equivalents in the form of NADH.

The specific enzymatic steps of glycolysis are shown in **Figure 2**. Glycolysis is a sequence of 10 enzymatic reactions that can be divided into three stages. In the first stage, often called the preparatory stage, the glucose molecule is phosphorylated (the addition of phosphates) on each of its carbon ends. This process requires three enzymes (hexokinase, phosphoglucose isomoerase, and phosphofructokinase) and yields three metabolic intermediates. In the second stage, the enzyme aldolase splits the six-carbon fructose 1,6-bisphosphate into two-, three-carbon molecules (glyceraldehyde 3-phosphate and dihydroxyacetone phosphate) and then thriose phosphate isomerase converts the dihydroxyacetone phosphate into glyceraldehyde 3-phosphate (isomerase

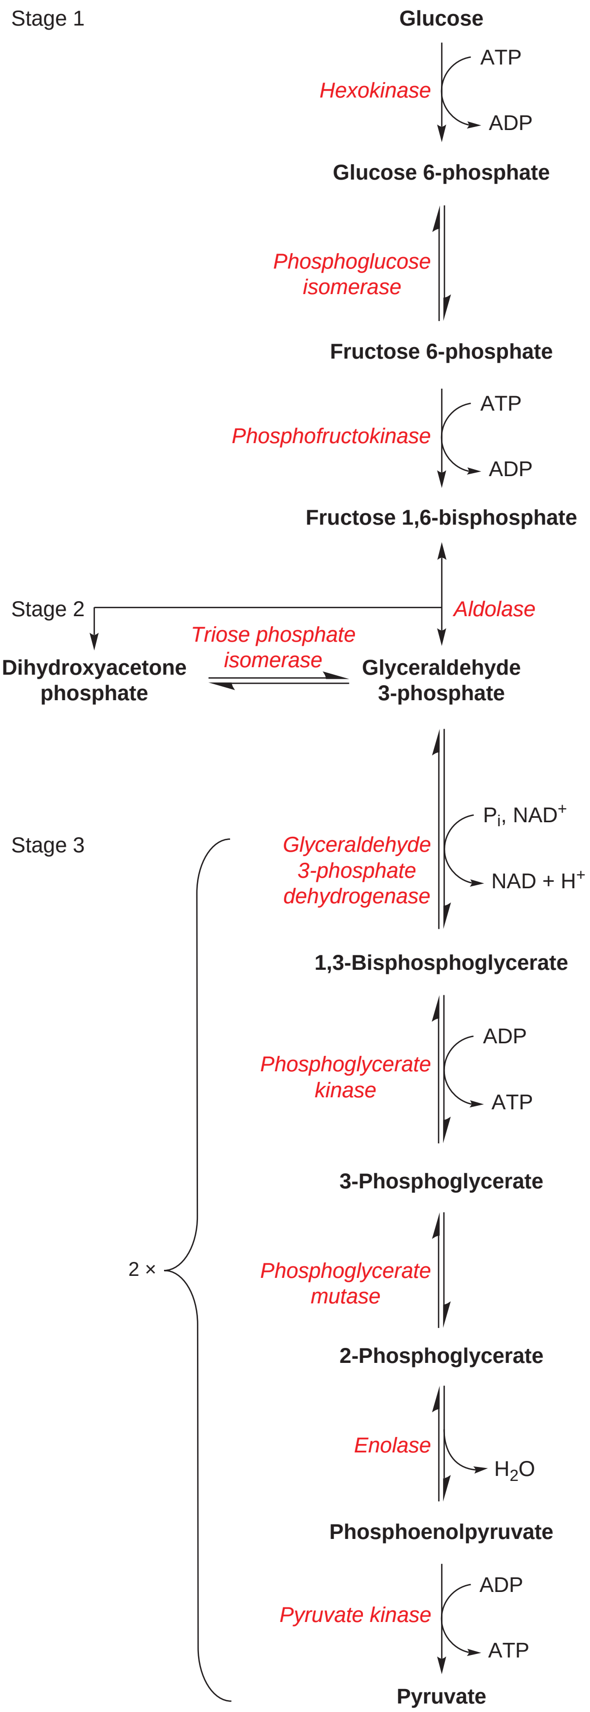

Figure 2 Glycolytic pathway showing the three main stages of glycolysis.

enzymes simply alter the molecular structure without the addition or subtraction of metabolites). Thus, at the end of the second stage there are two molecules of glyceraldehyde 3-phosphate ready to enter into the third stage of the pathway – the payoff stage. In the first step in the payoff stage, another phosphate is added to each glyceraldehyde 3-phosphate forming 1,3-bisphosphoglycerate (a three-carbon molecule phosphorylated at each end) while electrons liberated from the process are stored as NADH. The last four steps of glycolysis generate ATP by direct transfer of the four phosphates onto four molecules of ADP forming ATP.

The Fate of Pyruvate

Under aerobic conditions, the pyruvate generated by glycolysis is transported into the mitochondria through a specific transporter, the monocarboxylate transporter, and enters the Krebs cycle via the enzyme pyruvate dehydrogenase. This enzyme converts pyruvate into acetyl-CoA. At the same time, provided there is ample oxygen available and the electron transport chain is operational, the NADH generated in stage 3 of glycolysis is moved to the inside of the mitochondria through a specific shuttle system that regenerates NAD in the cytosol while supplying electrons to the electron transport chain for ATP generation. This system serves to keep NAD concentrations high and stable in the cytosol, so glycolysis can continue to function.

Under conditions when the mitochondria cannot accept the pyruvate and NADH generated by glycolysis, either because of oxygen limitation (hypoxia; **see also Hypoxia**: The Expanding Hypoxic Environment) or because pyruvate and NADH are being produced at a rate much higher than the mitochondria can accept, a mechanism to recycle NADH into NAD is needed. Without such a pathway for regenerating NAD, glycolysis will grind to a halt. Therefore, cells use the lactate dehydrogenase (LDH) reaction to convert the NADH into NAD, while simultaneously converting pyruvate into lactate, by the following reaction catalyzed by LDH:

$$\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightarrow \text{lactate} + \text{NAD} \qquad (3)$$

The enzyme LDH exists at high levels in most tissues, and especially those tissues that rely heavily on glycolysis for the anaerobic generation of ATP. The tongue muscle of hagfishes is reportedly to have one of the highest LDH activities (**see also Hagfishes and Lamprey**: Hagfishes).

Lactate and Acid

There is a very tight relationship between lactate formation and metabolic acid production (protons or H^+), such that as lactate accumulates during either exhaustive exercise or hypoxia exposure (discussed below), there is a decrease in cellular and blood pH. Because of the use of faulty biochemistry, it has long been thought that this tight relationship between lactate and acid production is a direct one through the formation of lactic acid. However, theoretical analysis performed over the past couple of decades clearly demonstrates that an increase in lactate concentration does not directly cause a cellular acidosis. Lactic acid is not formed because there is no proton to be liberated during lactate formation. In fact, eqn (3) clearly demonstrates that lactate production is a proton-consuming process. The acidosis is actually a product of ATP breakdown to ADP. During ATP hydrolysis, a proton is released:

$$\mathrm{ATP} \rightarrow \mathrm{ADP} + \mathrm{H}^+ + \mathrm{Pi} \qquad (4)$$

Thus, ATP hydrolysis is the primary source of metabolic protons. During periods when ATP hydrolysis is low and met entirely by aerobic metabolism, the protons generated by ATP hydrolysis in the cytoplasm contribute to the generation of the mitochondrial proton motive force through oxidative phosphorylation. During periods of intense ATP hydrolysis, when the mitochondria cannot keep pace with the rate of ATP hydrolysis, the rate of proton production exceeds the buffering capacity of the cell, protons accumulate in the cytoplasm, and acidosis ensues. Both the lactate and hydrogen ions produced can be released into the blood, although not necessarily at the same rates or in the same amount. Therefore, the kinetics of of lactate and hydrogen ions in the blood differ during intense activity although both of them increase considerably in their concentrations.

Why Use Anaerobic Metabolism?

The answer to this question comes in part from a consideration of another question: Under what physiological conditions are anaerobic pathways used over aerobic pathways? Reliance on anaerobic metabolism to support ATP turnover occurs under two conditions, both of which are characterized by a limitation in the capacity of the mitochondria to generate ATP. First, under oxygen-limiting conditions, such as exposure to environmental hypoxia (**see also Hypoxia**: The Expanding Hypoxic Environment), the mitochondria is limited in its capacity to generate ATP because of a lack of its terminal electron acceptor, oxygen. Thus, the only way to generate ATP is to rely on pathways that do not require oxygen. Second, anaerobic metabolism is activated during periods of intense exercise, not because of an oxygen limitation, but because the rate at which ATP must be generated to support intense muscle contraction exceeds the rate at which mitochondria can produce ATP. Consequently, a faster pathway is selected (**see also Ventilation and Animal Respiration**: The Effect of Exercise on Respiration).

There is a large variation in the rate at which ATP can be generated by various metabolic pathways. For example, fatty acid oxidation by β-oxidation and mitochondrial oxidative phosphorylation can only generate ATP at a rate of ~20 μmol-ATP g^{-1} min^{-1} in mammalian muscle (**Figure 1**) The oxidation of glucose through aerobic glycolysis and oxidative phosphorylation generates ATP at a 50% faster rate, ~30 μmol-ATP g^{-1} min^{-1}. The anaerobic generation of ATP via glycolysis alone, yielding lactate production, can generate ATP at roughly twice the rate as aerobic oxidation of glucose, ~60 μmol-ATP g^{-1} min^{-1}. Even faster rates are possible with phosphocreatine hydrolysis, which can generate ATP at a rate somewhere between ~100 and 300 μmol-ATP g^{-1} min^{-1}. As a result, cells select pathways of ATP generation according to the metabolic demands the cell is experiencing (**Figure 3**). In exercising fish, for example, low-intensity exercise is primarily powered by fat oxidation and as exercise intensity increases faster and faster pathways are recruited, but the duration that the exercise can be sustained for decreases. For example, although CrP hydrolysis can generate ATP at a very high rate, it can only do so for a very short period of time because cellular CrP levels are normally kept low. In contrast, fats produce ATP at low rates, but because many fish have very large stores of fats, ATP can be generated for a very long periods of time.

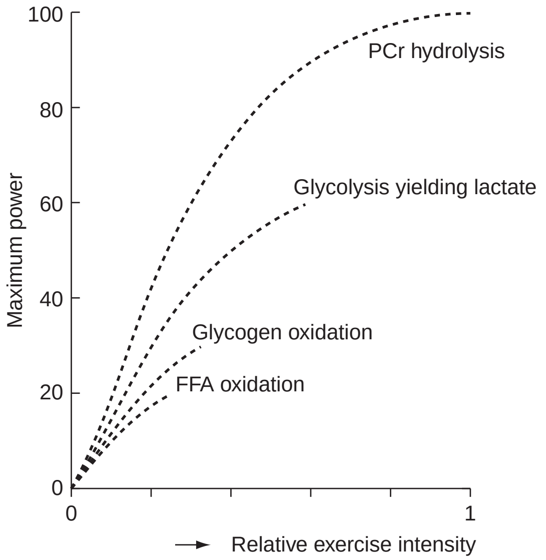

Figure 3 Relationship between relative exercise activity and fuel selection in muscle.

Clearly, the reason for using anaerobic metabolism is because ATP cannot be supplied at a sufficient rate by the mitochondria, no matter how efficient this process is. In the case of oxygen deficiency, mitochondria are shut down; in the case of intense exercise, muscular contractions are consuming ATP too fast for the mitochondria to keep up.

Anaerobic Metabolism and Hypoxia Exposure in Fish

Hypoxia exposure in fish elicits a strong activation of anaerobic metabolism, producing ATP from glycogen and CrP. Endogenous glycogen typically serves as the carbohydrate store for glycolysis. Thus, the levels of glycogen in a tissue are indicative of its capacity to support ATP turnover via glycolysis. Starvation will eventually deplete glycogen stores, limiting the period over which glycolysis can be maintained.

It has been fairly well documented that hypoxia-tolerant animals such as crucian carp (*Carassius carassius*) and goldfish (*Carassius auratus*) typically have higher levels of tissue glycogen relative to animals considered to be hypoxia sensitive (e.g., rainbow trout). Glycogen concentrations tend to be much higher in liver than any other tissues, including the heart, brain, and skeletal muscle. Liver glycogen is thought to serve as a repository of glucose that can be used by other tissues to support glycolytic ATP production during hypoxia exposure. This means that glucose is shuttled from the liver to other tissues during hypoxia, with tissues such as the brain and heart taking priority over the skeletal muscle.

The activity of the glycolytic enzymes can be altered by hypoxic acclimation. For example, in the killifish (*Fundulus grandis*), 4 weeks of hypoxia exposure at ~15% air saturation suppressed glycolytic metabolism in skeletal muscle, while several enzymes involved in glycolysis and carbohydrate oxidation increased in the liver. Fewer changes in glycolytic and glycogen enzymes were observed in the heart and brain compared with the liver and muscle, and those that did change, did so with a smaller magnitude. Interestingly, among the tissues that showed general increases in enzymes within the glycolytic pathway, the enzymes that increased were not always the same enzymes.

A small group of fish, including only the crucian carp, goldfish and bitterling (*Rhodeus amarus*), have the remarkable ability to convert lactate into ethanol and therefore excrete ethanol as their major anaerobic waste. A detailed description of this unique anaerobic end product can be found in **Bony Fishes**: Crucian Carp.

Anaerobic Metabolism and Exhaustive Exercise

Fish, particularly salmonids (e.g., the rainbow trout), have long served as a model for understanding exercise biochemistry. The reason for this popularity is twofold. First, in trout and many fish species, unlike mammals, there is a spatial separation of red and white muscle fibers allowing researchers to examine how different muscle fiber types respond during exercise. Second, methods for exercising fish are well established and there is a well-described gate transition in swimming so that the transition from slow sustainable swimming to burst nonsustainable swimming can be easily quantified. This gate transition, for the most part, is related to the switch from aerobically powered swimming to anaerobically powered swimming (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance).

From a muscle biochemistry perspective, the majority of studies with fish have focused on white muscle metabolism and the metabolic pathways involved in powering exercise and recovery. For the most part, exercising fish adhere to the classical scheme of substrate utilization during high-intensity exercise involving first CrP hydrolysis to power the first few tail flaps, then an activation of glycolysis with lactate accumulation. Over time, swimming intensity must necessarily decrease as muscle glycogen is depleted and metabolic wastes accumulate, and the fish slowly transition to more aerobic metabolism without burst activity. In rainbow trout, intense exercise elicited by chasing in a tank lasts between 1 and 5 min, and at the end of this exercise protocol the fish will have almost completely depleted muscle glycogen content, CrP and ATP content, as well as accumulate high levels of lactate and hydrogen ions, causing a severe acidosis. Numerous authors, however, have noted that wild fish are much better at intense exercise and something like a wild salmon can endure chasing much longer than domestic trout; however, the metabolic profile that characterizes an exhausted fish is not appreciably different.

Recovery from exhaustive exercise in rainbow trout has received considerable attention. During recovery, pathways must be activated to resynthesize ATP, CrP, and glycogen in preparation for another possible bout of exercise. The interesting case within salmonids is that they appear to keep most of the lactate produced in their muscle during exercise and limit the amount that is released into the blood. It is thought that lactate is retained in trout muscle so that it can serve as the direct substrate for glycogen resynthesis, by almost simple reversal of the glycolysis. This is in contrast to how mammals recover from intense exercise; they convert lactate into glucose in the liver and the muscle uses the subsequent glucose for glycogen resynthesis. Regardless of the location of glucose resynthesis, this recovery period of fish and mammals alike is accompanied by excess post-exercise O_2 consumption, which represents a stimulation of oxidative phosphorylation for ATP production to support the metabolic costs of recovery, including the replenishment of ATP, CrP, glycogen, and oxygen stores. It is now fairly well documented that the metabolic costs associated with recovery are fueled by fat oxidation.

Anoxia Complete absence of dissolved oxygen in water.

Critical oxygen tension (P_{crit}) The environmental O_2 tension below which an animal cannot sustain a routine rate of O_2 uptake independent of environmental O_2 tensions. The lower a fish's P_{crit}, the better able it is to maintain normal levels of activity and, therefore, fish with lower P_{crit}'s are believed to be more hypoxia tolerant than those with higher P_{crit} values.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Hypoxia tolerance A relative indicator of an animal's ability to survive hypoxia. A hypoxia-tolerant fish is able to survive more severe hypoxia or a longer time at a set level of hypoxia than a hypoxia-sensitive animal.

Maximal metabolic rate (MMR) The maximum metabolic rate achieved by an animal. If measured as O_2 uptake, it would be termed $\dot{V}o_{2\text{max}}$.

Metabolic rate suppression A reduction in metabolic rate below RMR or SMR values typically induced in response to exposure to environmental stress. Theoretically, the lower the metabolic rate during hypoxia exposure, the longer the organism will survive with its stored fuel.

Routine metabolic rate (RMR) The metabolic rate associated with the maintenance of cellular and whole animal homeostasis as influenced by activity under experimental conditions in which movements are presumably somewhat restricted and the fish is protected from outside stimuli.

Standard metabolic rate (SMR) The minimum metabolic rate of survival. Typically, SMR is measured on resting, unstressed adult animals in the post-absorptive state under normothermic conditions. For fish, normothermic is defined as a temperature well within the species tolerance limits for which the animal has had ample time to acclimate.

Introduction

Periods of environmental hypoxia or even anoxia are extremely common in aquatic systems due to natural causes as well as more recent anthropogenic causes (e.g., eutrophication; **see also Hypoxia**: The Expanding Hypoxic Environment). As a result of these oscillations in dissolved O_2, it is perhaps not surprising that among all vertebrates, fish boast the largest number of hypoxia-tolerant species. In the simplest sense, hypoxia exposure imposes a stress on metabolic energy balance, which elicits a suite of behavioural, physiological, or biochemical responses that either function to enhance O_2 uptake from the environment or permit hypoxia-tolerant fish to defend against the metabolic consequences of O_2 levels that fall below a threshold where metabolic functions cannot be maintained. This article outlines the whole-animal and cellular mechanisms used by fish to suppress metabolic rate during hypoxia exposure with the overall goal of conserving precious metabolic energy.

Defining Metabolic Rate and Metabolic Scope

Roughly 95% of the O_2 consumed by a resting, normoxic fish is used by the mitochondria to generate energy in the form of adenosine triphosphate (ATP), which supports the metabolic costs associated with the maintenance of cellular and whole-animal homeostasis. Overall, metabolic rate can be defined as the total energy turnover within an animal, which is heavily influenced by physiological state. A fish's metabolic rate is normally divided into basal or standard metabolic rate (SMR; basal metabolic rate is normally using only when referring to endotherms) and routine metabolic rate (RMR). SMR is defined as the minimum rate of metabolism determined on a resting, unstressed, adult animal in the postabsorptive state under normothermic conditions. For fish, normothermic can be defined as a temperature well within the species tolerance limits for which the animal has had ample time to acclimate. At the cellular level, SMR is composed predominately of the metabolic costs associated with the maintenance of cellular ion gradients, protein turnover (synthesis and breakdown), and other cellular processes. Based on this definition of SMR, one might expect that it is easy to measure SMR and that SMR is constant for a given animal. However, the minimum cost of survival in fish is highly dependent on environmental condition.

Under most conditions, free-living fish have a higher rate of metabolism than SMR because of the energy expended on physical activity (even if minor), digestion, and reproductive investment, to name a few processes. These are difficult to eliminate in their entirety and can easily double SMR. As a result, measurements of metabolic rate made under these somewhat more natural circumstances are collectively referred to as RMR. The maximal metabolic rate (MMR) of a fish, normally determined as the highest oxygen consumption rate during step-wise increases in swimming, represents the highest metabolic rate achievable by a fish. In this context, MMR is analogous to the $\dot{V}\mathrm{o}_{2\mathrm{max}}$ determined in mammals. The difference between SMR and MMR is aerobic scope or the metabolic scope for activity, with the difference being as much 10-fold. Aerobic scope has been measured in literally hundreds of species of fish and is related to habitat use and ecological success in many, more active species of fish.

Many fish species possess the ability to suppress metabolic rate below RMR or even SMR values as a response to environmental challenge and this is generally referred to as metabolic rate suppression or "turning down the pilot light" as referred to by the comparative physiologist Kjell Johansen. The difference between the lowest measurable metabolic rate and SMR has been referred to as the metabolic scope for survival by the comparative biochemist Peter Hochachka. Theoretically, the greater an animal can reduce its SMR or RMR in a controlled fashion when facing an environmental challenge such as hypoxia, the longer it can survive. Scope then refers to the amount of this reduction. Thus, the capacity to reduce metabolic rate in response to hypoxia/anoxia challenge has emerged as a unifying concept explaining hypoxia survival.

Measuring Metabolic Rate

Metabolic rate cannot be measured directly *in vivo*; therefore, indirect measures must be used. The two most commonly used measures for metabolic rate are O_2 uptake and heat production. Measurements of O_2 uptake are common in the scientific literature; however, O_2 uptake rate measurements only provide insight into metabolic rate under fully aerobic conditions where all of an organism's energy is provided by mitochondrial oxidative phosphorylation and O_2 use. While O_2 uptake and O_2 consumption are often used as interchangeable terms, there is a subtle yet important distinction. Consumption refers to the O_2 used by mitochondria, whereas uptake is typically what is measured in the whole animals and that O_2 is removed from the environment. While the two are equivalent over the long term, they may not be over the short term, as with the depletion or replenishment of O_2 stores following intense anaerobic exercise. Under conditions where anaerobic metabolism is used to provide cellular energy, measurements of O_2 uptake will, in most cases, drastically underestimate metabolic rate. Measurements of O_2 uptake are blind to anaerobic metabolism because this form of energy production is not linked with O_2 consumption. The best indirect measure of metabolic rate, often referred to as direct to emphasize its superiority, is the measurement of heat production by an animal.

Metabolic heat is the inevitable product of energy transduction during ATP turnover and the rate of heat production is directly proportional to ATP turnover rate and hence metabolic rate. Indeed, since about 70% of the energy transfer is lost as heat, the process is often referred to as inefficient, but then this heat is essential for endothermy (**see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks)! Changes in heat production can be interpreted as a change in metabolic rate (increased heat production indicates an increase in metabolic rate and vice versa) and unlike O_2 uptake rates, these measurements are not affected by the mode of cellular energy production and therefore detect changes in metabolic rate no matter whether they are fueled aerobically or anaerobically. They do, however, assume that the efficiency of energy conversion operates at a constant efficiency, which is now known not to be always true. Measurements of heat production are rare in the scientific literature compared with measurements of O_2 uptake.

Hypoxia Exposure Imposes a Metabolic Stress in Animals

The fundamental issue facing fish exposed to hypoxia or anoxia is that of the maintenance of metabolic energy balance. If environmental hypoxia leads to hypoxemia (reduced blood O_2 content) and reductions in O_2 at the mitochondria, then mitochondrial ATP production will be compromised. Under these conditions, ATP can only be generated by anaerobic or O_2-independent mechanisms such as glycolysis (**see also Hypoxia**: Anaerobic Metabolism In Fish).

Although anaerobic metabolism can generate ATP during hypoxia, the total ATP yield is roughly 15 times lower than from mitochondrial processes when the same substrate is used. For example, the full mitochondria-based breakdown of 1 mol of glucose yields ~30 mol of ATP (theoretical ATP yield should be 38 ATP, but the maximum is never quite reached because of proton leak and the metabolic costs of moving substrates across the mitochondrial membrane), while the anaerobic breakdown of glucose, involving only glycolysis, produces 2 mol of ATP, plus partially broken down metabolic wastes (e.g., lactate).

Thus, the switch from aerobic mitochondrial metabolism to anaerobic metabolism during hypoxia exposure imposes at least two metabolic stressors that may limit survival. First, the lower ATP yield from anaerobic metabolism places a substrate-limited cap on the duration of survival during hypoxia. Without O_2, the only metabolic substrates available for ATP production are glycogen and high-energy phosphates and because of the lower ATP yield of anaerobic metabolism, these fuels can be quickly used up. The second issue of relying on anaerobic metabolism is that it produces metabolic waste products such as lactate (plus an associated proton) and its accumulation can have devastating effects on tissues (**see also Hypoxia**: Anaerobic Metabolism In Fish). Overall, the lower ATP yield and accumulation of metabolic wastes during hypoxia exposure present a problem for fish, particularly hypoxia-sensitive fish which quickly succumb to hypoxia due to an inability to maintain cellular energy balance and a loss of cellular ATP.

For all fish, life without O_2 will eventually prove fatal. Thus a fundamental question is: What are the metabolic processes responsible for extending life during hypoxia exposure?

At environmental O_2 tensions where O_2 uptake by the fish is compromised (the point at which O_2 uptake transitions from being independent of environment O_2 to being dependent in terms of the critical oxygen tension or P_{crit}), the duration of survival is dictated by two, interrelated factors:

1. the ability to reduce metabolic demands through a controlled metabolic rate suppression (i.e., have a high metabolic scope for survival) and
2. the availability of substrate for O_2-independent ATP production (**see also Hypoxia**: Anaerobic Metabolism In Fish).

Figure 1 illustrates a conceptual framework to understand the relationship between these two factors. Scenario 1 in **Figure 1**, represents an exquisitely hypoxia-sensitive fish, where at O_2 tensions below P_{crit} the fish attempts to maintain metabolic rate through a large activation of anaerobic metabolism (indicated by long red arrow), which results in the rapid depletion of glycogen and accumulation of lactate and acid. In this case, the length of survival will primarily be dependent on the amount of anaerobic substrate available and the capacity of the organism to deal with the metabolic waste products. At this point, fish, and other animals, are limited in their capacity to store fermentable fuels such as glucose and glycogen because, unlike aerobic fuels such as fat, these fuels must be stored intracellularly and are hydrated. Thus, fermentable fuels occupy a greater space than an equivalent mass of fat. Therefore, without some reduction in metabolic rate, stored fermentable fuels are rapidly exhausted (and deleterious wastes accumulate equally rapidly). On the other hand, scenarios 2 and 3 in **Figure 1** represent increasing levels of hypoxia tolerance, where decreases in metabolic rate limit the need to activate anaerobic metabolism (shorter red arrows in **Figure 1**), extending the time a set quantity of glycogen or other fermentable fuel can support metabolism. The more a fish can reduce its metabolic rate in response to hypoxia exposure, the longer it will live. Of course, reductions in metabolic rate come with consequences in terms of increasing the risk of predation, if the hypoxia environment

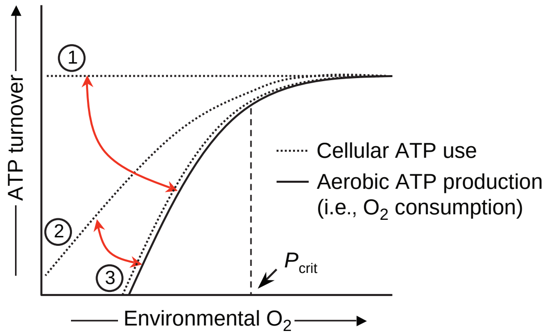

Figure 1 Metabolic responses of fish to changes in environmental O_2. A species' critical oxygen tension (P_{crit}) is the point at which O_2 uptake rate transitions from being independent of environmental O_2 levels (often referred to as O_2 regulation) to being dependent on environmental O_2 (often referred to as O_2 conforming) At O_2 levels below P_{crit}, survival is dependent upon the ability of an animal to suppress metabolic ATP use to limit the extent of the activation of O_2-independent pathways of ATP production. See text for more detail.

does not result in the exclusion of predatory species (**see also Behavioral Responses to the Environment**: Behavioral Responses to Hypoxia).

Metabolic Scope for Survival: Suppression of Metabolic Rate Saves Precious Energy

Decreases in heat production as a response to hypoxia exposure have been measured in many fish species including goldfish (*Carassius auratus*), crucian carp (*Carassius carassius*), tilapia (*Oreochromis mossambiscus*), European eel (*Anguilla anguilla*), zebrafish (*Brachydanio rerio*), and in isolated liver cells from rainbow trout (*Oncorhynchus mykiss*). Interestingly, across this very broad range of fish species, which includes species that are considered extremely hypoxia tolerant (crucian carp, goldfish, and tilapia) and tissues from fish considered to be very hypoxia sensitive (rainbow trout), all species show the capacity to decrease metabolic rate in response to hypoxia exposure.

The precise oxygen conditions that elicit metabolic rate suppression differ between species, but with the limited number of measurements in the literature it is impossible to draw any broad meaningful conclusions about the relationship between hypoxia tolerance and the capacity to suppress metabolic rate. However, generally, the most impressive reductions in metabolic rate occurred in the goldfish, tilapia, and European eel with an ~70% decrease in metabolic rate during hypoxia. Theoretically, and all other things being the same, this reduction in RMR could extend survival time by threefold. The degree of metabolic rate suppression in response to hypoxia exposure in other species appears to be considerably less. These data strongly support the notion that metabolic rate suppression is enhanced in hypoxia-tolerant animals versus hypoxia-intolerant species; however, there is a pressing need to carefully examine the relationship between the metabolic scope for survival in and hypoxia tolerance in multiple species where phylogeny can be taken into account.

Any process that reduces whole animal or cellular energy expenditure during hypoxia exposure will conserve precious ATP and prolong life. Maximal metabolic rate is most sensitive to environmental hypoxia exposure resulting in dramatic decreases in aerobic scope for activity. These decreases in MMR and aerobic scope for activity are likely a consequence of inadequate O_2 extraction from the environment and delivery to muscle, which then imposes a decrease in muscle activity, often manifesting as changes in behavior (reduced swimming activity). Decreases in swimming activity can substantially reduce energy consumption. Fish also reduce RMR through other changes in behavior as well as physiological changes. Equally important, and perhaps more fundamental, are the cellular aspects of metabolic rate suppression and the basic mechanisms that facilitate sometimes-substantial reductions in SMR in response to hypoxia exposure. The remainder of this article outlines the processes, starting from modifications to behavior, physiology, and extending down to the cell and individual proteins that form the basis of turning down the pilot light to the bare minimal levels essential for hypoxia survival.

Changes in Behavior Contribute to Metabolic Rate Suppression

As many fish species are exposed to a progressive decreases in environmental O_2, they often display a suite of behaviors that first serve to seek out better-oxygenated areas but if these cannot be located, shifts in behavior can yield sometimes-substantial savings in metabolic energy. In response to hypoxia exposure, fish have been observed to reduce swimming activity, courtship behavior, and feeding (**Figure 2**). Swimming activity can represent a major component of a fish's energy budget and it seems reasonable to assume that fish exposed to hypoxia will decrease swimming activity to save metabolic energy. Recent reviews of the literature suggest that benthic or demersal fish, those that may experience hypoxia frequently in their natural environment, show reduced swimming activity during hypoxia. For example, in the crucian carp (*C. carassius*) exposed to anoxia, a 50% reduction in spontaneous swimming activity was observed, which is projected to yield up to a 35% decrease in energy use.

However, not all fish species decrease spontaneous swimming activity during hypoxia exposure. Active, pelagic fishes, which likely experience hypoxia in their natural environment far less frequently, attempt to sustain swimming activity and in some cases increase their swimming activity in response to hypoxia exposure. Species of tuna, particularly skipjack tuna (*Katsuwonus pelamis*), show increased swimming speed in response to progressive declines in environmental oxygen. This increase in swimming activity is likely an attempt to escape hypoxia and find better-oxygenated waters. Overall, as might be expected, any single fish species can display both increases and decreases in swimming activity in response to hypoxia exposure and the response is likely dependent upon the degree of hypoxia exposure, the rate of change in water oxygen tension, and the degree of activity in normoxia.

There is also accumulating evidence from behavioral studies that hypoxia exposure can affect courtship behaviors, mate choice, and reproductive efforts in fish and there could be potential metabolic savings from reduced reproductive activity. However, reductions in reproductive efforts, especially in terms of postfertilization parental care, must be counterbalanced with overall reductions in reproductive output.

Figure 2 Contributors to metabolic rate suppression in fish. During exposure to environmental hypoxia of increasing severity or duration, metabolic rate is decreased by a variety of behavioral, physiological, and cellular/biochemical adjustments. At the onset of hypoxia exposure, behavioral adjustments of decreasing muscular activity, reproductive/courtship, feeding, and other voluntary activities facilitate metabolic saving by reducing metabolic rate from a maximum metabolic rate (MMR; thus, reducing aerobic scope) toward a routine or standard metabolic rate (RMR and SMR, respectively). As the environmental challenge persists or grows more intense, physiological adjustments that include reductions in gonadal development, growth, and energy allocated for the maintenance of nonessential physiological functions (e.g., digestive function) reduce RMR toward basal SMR levels. Biochemical adjustments at the cellular level including controlled reductions in Na^+/K^+-ATPase activity, protein synthesis, RNA synthesis, and urea synthesis, to name a few, further decrease overall SMR and enhance survival.

Changes in Physiology Contribute to Metabolic Rate Suppression

There are numerous physiological strategies employed by fish to reduce their metabolic demands during hypoxia exposure, which can generally be described as switching off processes, ranging from the cessation of feeding and digestion, reducing or stopping gonadal development, stopping growth, and shifting metabolic resources from one organ to another depending on the relative importance of each organ system to survival. Although few studies have directly measured the cost-saving measures associated with these physiological shifts, it is not difficult to imagine that these shifts could yield substantial reductions in energy demand and facilitate metabolic rate suppression.

One relevant example is the potential metabolic saving associated with the cost of ventilation in fish. It has been estimated that ventilation in water represents a substantial contribution to SMR and a reduction in the need to ventilate water would facilitate metabolic rate suppression (**see also Hypoxia**: Respiratory Responses to Hypoxia in Fishes). Furthermore, hypoxia in most fish species is known to cause a significant reduction in appetite, which results in reductions in ingested food and reduced growth rate. Reductions in food intake also limit the digestion-associated increase in specific dynamic action, which is the increase in metabolic rate associated with the costs of digestion and nutrient assimilation.

Changes in Biochemistry Contribute to Metabolic Rate Suppression

The biochemical underpinnings of metabolic rate suppression have long fascinated comparative physiologists and biochemists. Unlike humans and many other homeothermic endotherms, which show little or no capacity to reduce cellular SMR or basal metabolic rate, cells from various organs from many fish species possess incredible abilities to reduce their metabolic rate.

In general, the most energetically expensive work a cell does is make proteins and maintain transmembrane ion gradients. Indeed, in an average cell, protein turnover (included synthesis and breakdown) can account for up to 55% of a cell's total ATP demand, and maintenance of ion gradients can account for up to 25% of a cell's total ATP demand. Other processes that contribute to cellular ATP demand include gluconeogensis, urea synthesis, RNA turnover, substrate cycling, and myosine ATPase for intracellular transport. The precise cellular breakdown of the important contributors to cellular SMR will depend on the cell under examination. For example, the percent of cell ATP demand devoted to the maintenance of transmembrane ion gradients will likely be much higher in neurons, whose function is more dependent on membrane ion movements as compared with, say, a liver cell, although these precise measurements have never been made.

As pointed out for the crucian carp or its relatives, the goldfish (**see also Bony Fishes**: Crucian Carp), some fish are capable of reducing their cellular metabolic rate by up to 80%. This overall reduction in metabolic rate is achieved through the dramatic downregulation of Na pumping, protein turnover, urea synthesis, and gluconeogensis. It is now well accepted that the cellular mechanisms underlying metabolic rate suppression are similar across broad taxonomic groups and the mechanisms involved in metabolic rate suppression in carp are very similar to those observed in other species, such as the anoxia-tolerant turtle (*Chrysemys picta*), which can reduce cellular metabolic rate by up to 94% during anoxia exposure. However, there are tissue-specific differences in the use of metabolic suppression among species. For example, in the heart of turtles, anoxia exposure induces metabolic rate suppression resulting in a reduction of cardiac performance to ~5% of its normal level, while in the anoxic crucian carp, heart performance remained close to routine levels because of a large capacity to anaerobic ATP generation. Despite these tissue-specific differences, whole-animal metabolic rate is still suppressed in both the crucian carp and the turtle. Nevertheless, different tissues contribute differently to metabolic rate suppression.

The suppression of protein synthesis has been described in both isolated hepatocytes and fish *in vivo* in species ranging from the crucian carp, goldfish (*C. auratus*), and the Amazonian oscar (*Astronotus ocellatus*). In the oscar, severe hypoxia exposure (10% air saturation) caused tissue-specific decreases in protein synthesis rates that varied from 27% decreases in brain to 60% decreases in heart. In the crucian carp, there is also a substantial decrease in protein synthesis rates in heart, liver, and muscle during anoxia and these decreases were, in part, mediated by decreased RNA transcription rates. In the goldfish, hypoxia exposure (<0.5% air saturation) caused a very rapid (within 0.5 h) decline (~70%) in liver protein translation rate. Combined, it is believed that these decreases in protein synthesis rates are primarily mediated through the specific phosphorylation of eukaryotic elongation factor 2, which halts protein elongation during translation.

Besides protein synthesis rates, few studies have examined how other ATP-consuming processes are modified during hypoxia exposure in fish. Some modifications to ion pumping rates have been noted. In particular, hypoxia-induced decreases in the activity of Na^+/K^+-ATPase were observed in some studies and could represent a substantial ATP savings, but results are conflicting. The crucian carp does not decrease brain Na^+/K^+-ATPase activity during anoxia exposure, despite increases in the inhibitory neuromodulators gamma-aminobuytric acid (GABA) and adenosine. This lack of an effect of anoxia/hypoxia exposure on Na^+/K^+-ATPase activity in the brain of crucian carp is unlike the response observed in turtles, which suppress the activity of Na^+/K^+-ATPase. The differential responses observed in these two champions of anoxia tolerance are probably associated with the simple fact that crucian carp remains active during anoxia exposure, unlike the turtle which becomes comatose. Furthermore, substantial decreases in gill Na^+/K^+-ATPase activity in the oscar exposed to hypoxia (~5% air saturation) have been noted, and it was speculated that this decrease was achieved by a post-translational modification to the Na^+/K^+-ATPase protein. A similar effect of hypoxia exposure was observed in isolated trout hepatocytes, where a hypoxia caused a transient downregulation of Na^+/K^+-ATPase activity and led to speculation that decreases in Na^+/K^+-ATPase activity in response to hypoxia may be accomplished by local changes in reactive oxygen species, but no precise mechanism was given.

Summary

Hypoxia survival in fishes necessitates a metabolic reorganization to reduce ATP consumption through a regulated metabolic rate suppression to match the limited capacity for O_2-independent ATP production. As outlined above, controlled metabolic rate suppression is essential to extend the length of time that can be supported by the limited levels of fermentable fuels. Modifications to behavior, physiology, and cellular biochemistry all contribute to saving precious metabolic energy during hypoxia/anoxia exposure. Thus, it appears reasonable to speculate that the degree of metabolic rate suppression and the quantity of stored fermentable fuel are likely strongly selected for in hypoxia-tolerant fishes. Furthermore, although it has not been explicitly examined, differences between hypoxia-tolerant and hypoxia-intolerant fishes could, along with the noted physiological difference discussed in other articles, be related to their ability to reset SMR to pilot light levels.

Glossary

Anaerobic processes Occurring without the need for oxygen.

Glomerular capsules The site in the kidney where the primary urine is produced as an ultrafiltrate of the blood.

Hypoxia Low partial pressures of oxygen in external or internal environments.

In-series circulation Blood passes first through the gills and then to the systemic vessels, two resistances in series. This contrasts with the divided circulation of birds, crocodiles, and mammals.

Isosmotic Having the same osmotic pressure.

Primitive or derived condition Ancestral trait or one that has evolved more recently.

Osmoconforming Where the osmotic strength of the body fluids matches that of the medium in which an animal lives.

The Fascination and a Few Misconceptions

Hagfishes have long fascinated zoologists because of their unique anatomy and physiology. Often described as the most primitive of the vertebrates, this classification is technically incorrect: hagfishes lack vertebrae, as well as jaws. They are an ancient craniate lineage, diverging from the line that leads to the vertebrates at least 300 mya. Their phylogeny is still unresolved. DNA evidence, both nuclear and mitochondrial, points to a monophyletic origin of hagfishes and lampreys, but many aspects of their morphology and physiology suggest a divergence of the two lines, as does some genetic analysis (**Figure 1**). Whichever way their phylogeny is resolved, the hagfishes remain interesting because of their early separation from the chordate lineage and their potential to shed light on the physiology of the earliest chordates. Limited information from the two described fossils, *Myxinikela* and *Myxineides*, from 305 mya, suggests that they superficially resemble the modern genera. Even so, we need to remember that the hagfishes are an ancient line with relatively few living genera, and it is possible that the living species are not representative of the ancestral forms.

A characteristic of living hagfishes is their low metabolic rate. Hagfishes live on the seafloor, with at least one species recorded at a depth of 5000 m. Abyssal species typically have low metabolic rates, which is presumed to reflect the lack of food at depth. However, even hagfishes found in shallow, productive waters, such as species of the genus

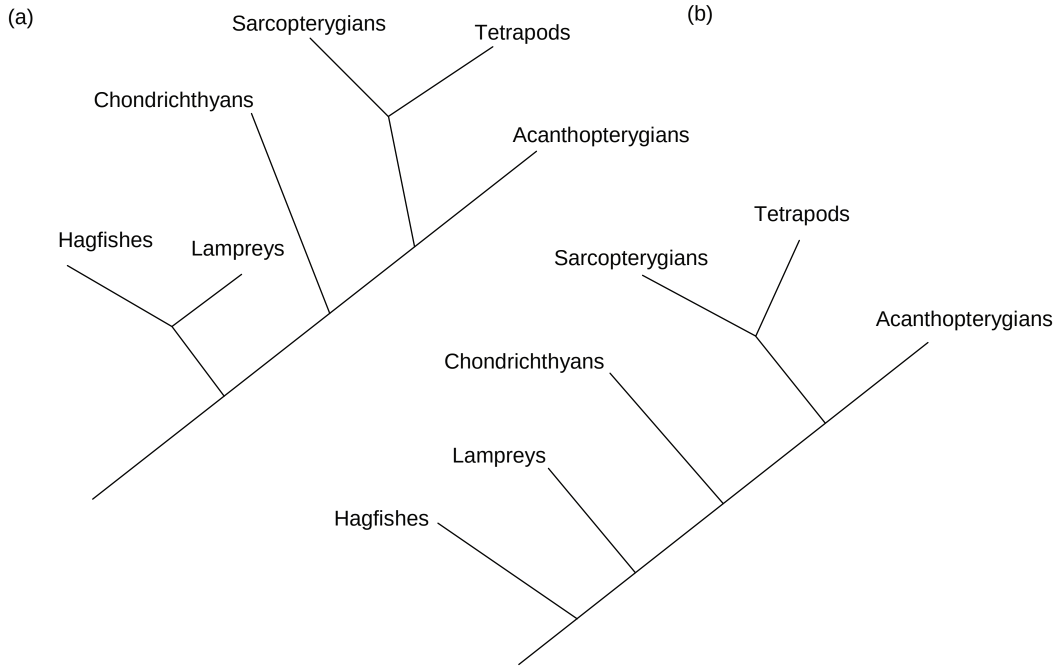

Figure 1 Alternative craniate phylogenies, showing (a) a monophyletic and (b) a diphyletic origin of hagfishes. Scenario (b) would place the hagfishes as the living craniates closest to the ancestral craniate line.

Eptatretus, have very low rates of oxygen consumption. If hagfish gas-exchange systems are efficient (see below), we would expect an animal with a low metabolic rate to tolerate low oxygen partial pressures in its environment, but hagfishes are considered to be unusually tolerant of extreme hypoxia. Early research on modern hagfishes concentrated on *Myxine glutinosa*, which lives in burrows on the Atlantic seafloor and can occur at high densities in cool waters. *Myxine* is extremely tolerant of low oxygen concentrations and is reported to survive when its single nostril is blocked and ventilation prevented. Oxygen is known to be able to enter across its skin, presumably at a rate sufficient to meet the low metabolic demand. This species has also a low body mass and relatively high skin surface area, which would facilitate cutaneous gas exchange. Other species do not live buried in anoxic mud, and one nonburrowing species, *Eptatretus stoutii* (**Figure 2**), has been recently found to survive near anoxic conditions for up to 36 h. Interestingly, and in contrast, a larger species found on the opposite, west side of the Pacific Ocean, *Eptatretus cirrhatus* (**Figure 3**), reacts to waters of low oxygen content by swimming vigorously to escape, although it too can survive hypoxic conditions.

Anaerobic Abilities

The classification of hagfishes and lampreys as jawless fishes (cyclostomes: literally round mouths) does not mean that they are unable to bite their food. Hagfishes have numerous teeth arranged on semicircular dental plates within their mouth, which are everted by the action of a protractor muscle. A large retractor muscle then closes and withdraws the teeth into the mouth, dragging material with it. Hagfishes are capable of consuming food rapidly, although this may exhaust the tongue muscles, which are unusually adapted to function anaerobically, being very poorly supplied with blood vessels. The tongue muscles are capable of accumulating extremely high concentrations of lactic acid, which is trapped, as there are

few blood vessels to carry it away. With a low metabolic rate, it may well be that hagfishes need only to feed at long intervals, allowing the feeding muscles sufficient time to resynthesize glycogen from lactate, ready for the next feeding bout. Their anaerobic abilities may also enable them to burrow through the tissues of their moribund prey (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia).

Interest in exploring the anaerobic capabilities of hagfishes was influenced by the suggestion that the earliest chordates had a well-developed anaerobic swimming ability using fast, but short, bursts of activity to capture prey. However, with an efficient countercurrent exchange of oxygen between the blood and external seawater in its gill pouches, *E. cirrhatus* is capable of fuelling swimming through aerobic metabolism.

The Unique Physiology and Anatomy of Hagfishes

Osmotic and Ionic Regulation

Living hagfishes are exclusively marine, and are unique among the craniates in having extracellular body fluids with an ionic composition similar to seawater, and isosmotic with that medium. They are osmoconformers. All other craniates maintain ionic concentrations in their body fluids approximately one-third of those in seawater, whether they live in the sea, in freshwater, or on land. Maintaining ionic concentrations close to those of seawater may allow hagfishes to reduce their metabolic rate, since it reduces the amount of energy they have to expend on ion regulation. However, hagfishes do regulate divalent ions, such as calcium, magnesium, and sulfate, to plasma concentrations that are significantly less than those in seawater (**Table 1**). The kidneys, liver (bile), and gills are involved in the excretion of divalent ions and the animal can regulate calcium and magnesium concentrations even when external concentrations are raised.

There has been much discussion about the origins of the vertebrates, whether it was in freshwater, brackish waters, or seawater. The high ionic strength of hagfish tissues has influenced this debate, given that they are the surviving craniate group with the longest pedigree. Is the high ionic strength of hagfish blood a primitive or derived condition (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction)? The presence of a kidney in hagfishes has raised interest in the evolution of that organ. If the kidney's primary role is osmoregulation, then what is it doing in hagfishes, which are reportedly highly permeable to water? Any free water the kidney excretes will return passively at the gills and through other external epithelia. The structure of the kidney is also unusual in that it possesses a very few, large glomerular capsules, leading to two apparently undifferentiated archinephric ducts, the homolog of the nephron in other craniates. The tissue surrounding the archinephric duct is lipid filled, suggesting a fuel source for active transport, but to date, we have limited evidence of such processes. There are also some unanswered questions about the mechanisms by which the primary glomerular fluid is formed.

The Blood

The essentially hyperbolic oxygen equilibrium curves (OECs) (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function) of hagfishes demonstrate a very high affinity of their multiple hemoglobins for oxygen (P_{50} values of between 0.5 and 1.8 kPa (**see also Transport and**

Exchange of Respiratory Gases in the Blood: Evolution of the Bohr Effect and Hemoglobin), which might be expected in an animal with a low oxygen demand. A high-affinity hemoglobin will also improve oxygen uptake from hypoxic water.

The hemoglobins of hagfishes are unusual in that they behave as monomers in the oxygenated state, but aggregate as dimers or tetramers as they deoxygenate, which results in increased oxygen unloading. They show a weak Bohr effect. It is cooperativity between the β-chains of the tetrameric hemoglobin of fishes and tetrapods that creates a steep OEC able to unload oxygen at relatively high partial pressures of oxygen (lower affinity). Another unusual feature is that bicarbonate is carried bound to hemoglobin within the red cells of hagfishes, which facilitates carbon dioxide excretion.

The blood volumes reported for three species of hagfishes, ranging from 138 to 187 $\mathrm{ml\,kg^{-1}}$ body mass, are unquestionably the largest within the Craniata. These volumes are 3 times higher than the volume of the primary circulation of teleosts and double that of mammals. However, measurements of plasma volume in hagfishes might be overestimated to some extent, as there are problems finding appropriate indicators that can be retained within the plasma, in what is reportedly a leaky circulation.

An unusual anatomical feature of the hagfish circulatory system is the presence of a large subcutaneous sinus, which lies along the entire length of the animal beneath the dermis of the outer body wall and envelops the musculature and viscera. An astonishing ~30% of the total blood volume has been reported to lie within this sinus, whose significance is not well understood. Furthermore, the hematocrit (packed cell volume) of blood within the sinus is lower than that in the primary vessels. This means that red blood cells do not enter the sinus as readily as does plasma. In 1912, Cole published his observations on the fenestrated papillae on the branchial arteries, which connect to the sinus system, and allow plasma to move to the sinus, but make it more difficult for red cells to leave. This arrangement has parallels with the secondary circulation of bony fishes. Presumably, the low oxygen demand allows the low proportion of erythrocytes reported in the central blood (15% or less of blood volume). Fewer red cells will help keep blood viscosity low, and so reduce the force that the ventricle must develop to generate flow (see below).

Accessory Hearts

There has to be a mechanism to return sinus blood to the central circulation and it is achieved by the action of two accessory pumps. The so-called cardinal hearts are valved structures close to the velum, which are compressed and expanded as the velum beats. As such, their own muscle does not contribute to movement of fluid, which disqualifies them for consideration as hearts. In contrast, the caudal hearts, at the other end of the animal, are muscular, beating structures that empty sinus blood into the caudal vein (**see also Design and Physiology of the Heart**: Accessory Hearts in Fishes).

The Central Circulation

Basic vascular anatomy is similar to that of other fishes, particularly with respect to the branchial circulation. The so-called branchial heart of hagfishes, homologous to that in other craniates, is characterized as a high-volume, low-pressure heart, in that the stroke volume is relatively high, but the force the ventricle develops is remarkably low. Arterial blood pressures in hagfishes are considerably lower than in any other group. Hagfish hearts are only able to generate arterial pressures of up to 20 mmHg (2.7 kPa), less than half the pressure generated in other craniates. The anatomy of the heart prevents rapid, forceful contraction, with the contractile material being relatively sparsely distributed in the cardiomyocytes (**see also Design and Physiology of the Heart**: Cellular Ultrastructure of Cardiac Cells in Fishes). The conduction path for the action potential through the heart is a tortuous one, and, unusually, with the prolonged conduction time of the action potential, atrial repolarization is observed in the hagfish electrocardiogram before the ventricle depolarizes (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping and **Role of the Kidneys**: Histology of the Kidney). This probably explains their low heart rates.

The hagfish heart also lacks a controlling innervation, although it does contain, within its structure, chromaffin cells containing epinephrine and norepinephrine (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes and **Design and Physiology of the Heart**: Cardiac Anatomy in Fishes). Factors controlling the release of these catecholamines and their site of action in living animals are not well understood, although blood vessels in many parts of the circulation, including central veins, can respond to rising concentrations by either contracting or relaxing, depending on the adrenergic receptor type present. It appears that the hagfish circulation can adapt to volume overload by adjusting vascular tone and preventing a large rise in blood pressures that might upset the balance of blood distribution.

Hagfishes have another accessory heart, the portal heart. This pumps blood from the posterior cardinal vein through the liver. It is not clear why hagfishes need an accessory pump to push blood through their livers, and a fully grown specimen has been found that lacked a portal heart. Certainly, the liver is the site of much metabolic activity, but other animals with an in-series circulation, including the teleost fish, have venous blood pressures in the same low range as hagfishes. Perhaps the answer will be discovered in the vasculature of the liver, which might have a greater resistance to flow than in other craniates.

Gill Structure and Ventilation

Both the gill structure and mechanism for ventilating the gills of hagfishes differ considerably from the typical fish arrangement (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy), but it is efficient. Partial pressures of oxygen in the blood leaving the gill exceed 100 mmHg, as high as recorded in other fishes. Hagfish gill pouches are discrete structures. *Myxine glutinosa* has six pairs of them, cranial to the branchial heart (**Figures 4** and **5**).

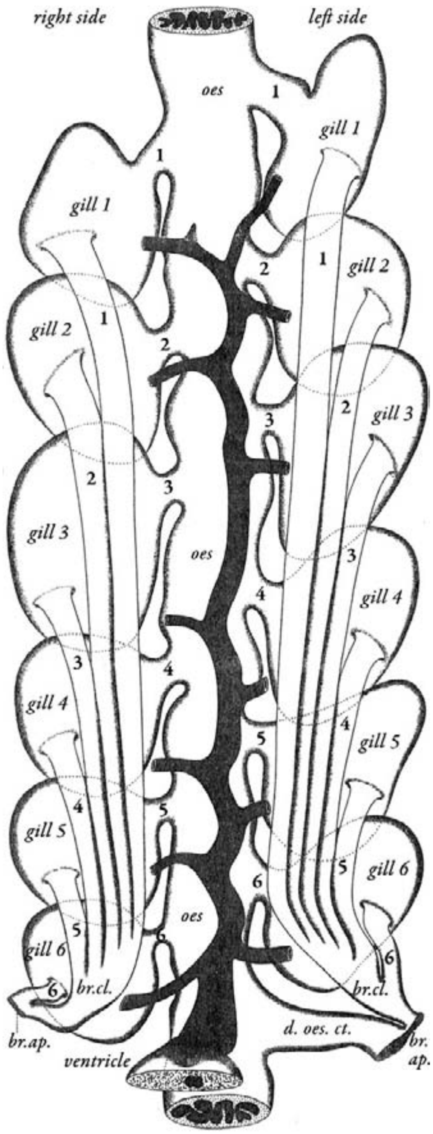

Figure 4 Cole's 1913 drawing of the gill pouches of *Myxine glutinosa*, showing the afferent branchial arteries leading off the single ventral aorta, six pairs of separate inhalant water channels from the pharynx, and the joining of the efferent water ducts of the gill pouches of each side into a single exhalant opening. *Eptatretus cirrhatus* has seven pairs of gill pouches, paired ventral aortas, and a separate efferent gill duct for each gill pouch.

Hagfishes, such as larval lampreys, move water across their gills with a velar pump. The velar chamber, an enlarged portion of the nasopharyngeal duct, bears a cartilage-reinforced membrane that projects ventrally from its roof and ends in paired horizontal membranes or leaves whose free ends lie within the duct. Using red (aerobic) muscles, the leaves can be scrolled and unscrolled. Because of their orientation, water is drawn in through the single nostril and propelled in an anterior-to-posterior direction toward the gill ducts in the wall of the pharynx. Although the gill pouches of hagfishes are muscular and can show contractions and relaxations, it is not thought that they make a major contribution to normal ventilation. Strong contractions of the gill pouch muscles probably help to expel particles, including mucus, when the gill ducts are blocked. In contrast, bi-directional, or tidal ventilation in an adult lamprey is carried out by muscles around their gill pouches that attach to a strong cartilaginous branchial basket, a structure lacking in hagfishes.

Measuring water flow rates across hagfish gill pouches is difficult, as some species do not tolerate the presence of a tube in their nostril, the site where seawater is inspired. Recent measurements suggest that flow rates can be relatively high. However, water pressures associated with gill

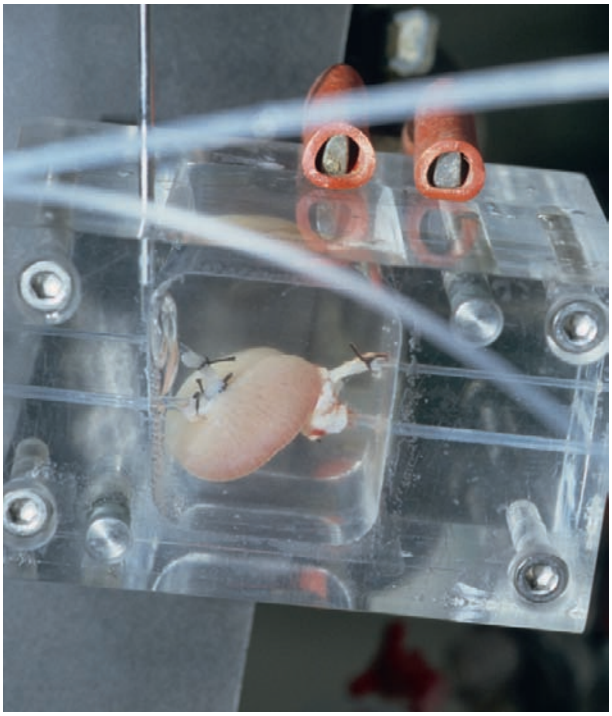

Figure 5 A gill pouch from *E. cirrhatus* with cannulated afferent and efferent branchial arteries and water ducts enclosed in a Perspex chamber. Its discrete nature makes the hagfish gill pouch a potentially useful structure for measuring active and passive exchanges between the blood and water compartments.

ventilation are likely to be low in the absence of a strong muscular pump. As the pharynx has a fixed volume, changes in inspiratory flow must result from an increase in ventilation frequency, which can increase by almost threefold in *Eptatretus* species exposed to hypoxic conditions.

A thin barrier to diffusion between blood and water maximizes gas exchange across gills. The blood-to-water distance in hagfishes is comparable to many teleost fish, being ~1.6 μm at its thinnest point. It is possible that low water pressures within the gill pouches require low blood pressures within the gill lamellae. Otherwise, higher blood pressure in the gill vessels might reduce seawater flow across the gills. This constraint might explain the relative lack of contractile material in the hagfish heart and the presence of auxillary pumps to maintain circulation in a high-volume blood system.

Swimming and Musculature

Muscle accounts for about 40% of body mass, which is not much less than a trout. The lack of a calcified vertebral column probably prevents the hagfish from supporting itself out of water. This contrasts with adult lampreys, for example.

Hagfishes lack a swimbladder, which provides buoyancy in bony fishes, but with a skeleton composed of cartilage rather than bone, they are closer to the density of seawater, which reduces the energy expenditure necessary for maintaining a position high in the water column. However, hagfishes have reasonable stamina, and it can take up to 30 min to exhaust the animals when swimming at 0.5 body lengths per second. Hagfish muscle has a low resting metabolic rate, in common with other tissues in the animal, and it is not known if this compromises its ability to generate force.

Locomotion is eel-like (anguilliform) and involves all muscles posterior to the gills. The hagfish myotome is arranged in a W shape with the two flexures backwardly directed. Within each muscle block, there is some zonation of the white, red, and intermediate fibers, the red being nearer the skin, but the fiber arrangement has been described as a mosaic. This contrasts with the myotome of most teleost fish, for example, where the red muscle is placed superficially under the lateral line. As in mammals, the proximity of anaerobic and aerobic fibers in hagfishes potentially allows the better-vascularized red fibers to process lactic acid produced in the white fibers. From this perspective, the teleost condition is seen as more specialized. Hagfish white fibers are larger, possessing fewer mitochondria and contract more rapidly than their red muscle fibres.

Defense Mechanisms

Hagfishes have a variety of common names. They are called ‘snotties’ or ‘slime hags’ because they can release prodigious quantities of mucins from glands running in two lines down the length of the body. This is sufficient to turn large volumes of seawater into a gelatinous mass. Mucin threads are ejected forcefully from the slime glands. Once outside the animal the threads trap copious quantities of water. Slime production must be an energetically expensive process, with presumed benefits to the animal. Slime can deter attackers. The material, for example, clogs the gills of predatory fish. Interestingly, fishes are not recorded as common predators of hagfishes (**see also The Skin**: Hagfish Slime).

Slime production also creates a potential problem for the hagfish itself, as it might prevent the hagfish’s own ventilation. However, they have a behavior that helps them clear this mucus from their head. This remarkable feature of the hagfish’s neuromuscular system is the animal’s ability to tie itself into a figure-of-eight knot. The animal pushes its tail through a loop it forms in its body near the posterior end. The knot so formed is then moved forward toward the head. In addition to assisting in slime removal, the knotting maneuver might also help the hagfish to withdraw its head and disengage from its food, once burrowed inside it. Alternatively, it could help tear off flesh from its prey, since the knot can be used as an anchor, to apply force.

Acid–Base Regulation

Rapid movement, facilitating prey capture or escape, involves the white muscle cells, generating lactic acid via glycolysis. Lactic acid production has the potential to alter the pH of body fluids. In 1984, Evans first showed that a hagfish, *M. glutinosa*, had the ability to be a net exporter of either acid (H^+) or base, and that these processes depended on sodium and chloride ions, respectively, as the counterions. Since that time, the presence of a sodium–proton exchanger has been confirmed in *M. glutinosa* and *E. stoutii.* In response to injection of either acid or base, hagfishes can rapidly restore the pH of their blood to normal values. Restoration of blood pH following acid injection was associated with increased expression of the sodium–proton exchange enzyme. In this respect, their acid–base regulation is comparable to that of bony fishes. The latter use these same pumps in ionic regulation, but hagfishes are osmoconformers, which suggests that the primary role of the ion-transporting proteins might be in acid–base regulation. Tongue muscle has a high buffering capacity, which contrasts with the blood, which is poorly buffered.

The Digestive System

The food of hagfishes, including dead or dying animals, does represent a high-energy diet. The gut of hagfishes is extremely simple, without a differentiated stomach. Associated with this there is no early acidic phase of digestion, which might indicate that food processing is a prolonged process. Alternatively, decaying flesh may already be partially softened! With their low metabolic rates, they can probably survive months between feeding. In an aquarium, if they are hungry, they certainly feed voraciously and can ingest a large volume of meat. Both *Myxine* and *Eptatretus* spp. are reported to burrow into the bodies of large animals, which indicates that they can tolerate hypoxic conditions at this time.

The control of digestive processes in hagfishes warrants further attention. Hagfishes possess most of the hormones found in other craniates (**see also Hearing and Lateral Line**: Lateral Line Structure, **Integrated Function and Control of the Gut**: Gut Secretion and Digestion, and **Gut Anatomy and Morphology**: Pancreas), although unsurprisingly, their molecular structure often shows differences. Hagfishes are unusual in that the islets of cells secreting insulin and somatostatin are scattered in the gut mucosa, rather than being found within Brockman bodies or a pancreas. Hagfish insulin has been characterized and its secretion rises and falls with blood sugar concentrations, as it does in other craniates.

The Nervous System

Within the chordates, we differentiate the brain from the rest of the spinal cord on the basis of its size and complexity, its anterior position reflecting the forward direction of motion of the animal. Given our anthropogenic tendencies, we imagine an increasing specialization of the brain in evolutionary development from primitive fishes to the anthropoid apes. In this respect, the brain of hagfishes is somewhat remarkable, possessing unusual features. Northcutt and his colleagues have described the telencephalon as massive and complex. The telencephalon (**see also Brain and Nervous System**: Functional Morphology of the Brains of Agnathans and Functional Morphology of the Nervous System: An Introduction) is the most anterior paired region of the forebrain, and includes both the olfactory bulbs, which occupy about 40% of its volume, and the cerebral hemispheres.

Hagfish eyes are very simple structures. They lack a lens and specialized eye muscles. The simple retina is only two cells thick, compared with the three cell layers found in the adult lamprey and jawed vertebrates. The eye probably functions much like the pineal gland of other vertebrates, responsible for sensing light and entraining circadian behaviors rather than detecting external objects. The structure of the eyes of hagfishes argues against a monophyletic origin of the two cyclostome groups.

Given their lack of eyes, we should expect hagfishes to rely heavily on their sense of smell (olfaction) to detect their food. There is a large olfactory organ positioned within a cartilaginous capsule in the dorsal wall of the nasohypophyseal duct, the tube arising from the single anterior nostril, whose current is generated by the pumping action of the velum. Numerous olfactory axons run to two parts of the brain, the olfactory bulbs and the olfactory cortex. That so much of the brain is devoted to olfaction supports the premise that the role of chemoreception is of vital importance to the animals. Experiments with amino acids and steroids demonstrated differing sensitivities to individual molecules at relatively high micromolar thresholds. In contrast to lampreys and jawed vertebrates, hagfishes have been reported to lack taste buds, aggregations of chemosensitive cells (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction), but such structures have been described in the tentacle epithelium of *M. glutinosa*. Hagfishes also have chemosensitive cells in the epithelium of the mouth and pharynx. Unusually, over the outer surface of their bodies, they have 180 000 Schreiner organs, similar in appearance to taste buds. The afferent nerve fibers from these organs occupy about 10% of the terminal field of the brain's medulla oblongata.

Given that a hagfish cannot use vision to orientate itself as it swims, and lacks paired fins for stability and a cerebellum, we might expect the vestibular system would be well developed to compensate. This is the system of semicircular canals in the inner ear, which give humans and other vertebrates information about the body's movement in three planes. Surprisingly, hagfishes have only paired, single semicircular canals rather than three and McVean has demonstrated that they have relatively poor acuity, only triggering a clear sensory nerve response to yawing movements. What other senses assist directed movement in hagfishes? There is a lateral line system around the head region of *Eptatretus* species, but it is lacking in *M. glutinosa*, perhaps reflecting *Myxine*'s burrowing habit. Anyone who handles a live hagfish becomes aware of the acute sensitivity of the skin. Histological evidence suggests the presence of numerous mechano- and proprioceptors in the skin. Clearly, the entire surface of their bodies is involved in sensing stimuli, both mechanical and chemical. Hagfishes are unusual in apparently lacking electrosensitive receptors in their skin. Hagfishes also appear to lack Mauthner neurons in their hindbrains. These neurons are involved in the startle reflex in other craniates and their activation causes withdrawal of the part of the body under potential attack from a predator.

Table 2 Features of their physiology that distinguish hagfishes from other craniates

1. Low basal metabolic rates in all taxa
2. Ionoconformers, to a large degree
3. High blood volumes
4. The subcutaneous sinus
5. Low arterial blood pressures
6. Kidney structure and function
7. Slime glands
8. Lack of a lens in their eyes
9. Single semicircular canals

This brief review has concentrated on the differences between hagfishes and other craniates. While the article has highlighted unique features (**Table 2**), it is important to note that there are numerous features of hagfish physiology that are shared with the vertebrates. For example, the same small peptide molecules and the gasotransmitters that control the rates of processes in higher vertebrates seem to be present in hagfishes, and, with few exceptions, they modulate the same processes. In this respect, the craniates are a conservative group of animals. Hagfishes occupy a pivotal position in our understanding of chordate evolution and we desperately lack information on many aspects of their physiology and development.

Glossary

Ammocoete Alternate name for the larval stage of the lamprey life cycle.

Endostyle A tissue located in the floor of the pharyngeal cavity in lower chordates and larval lampreys that secretes mucus to trap food particles.

Lamphredin A secretion arising from the buccal glands of lampreys that promotes blood and/or tissue feeding due to its anticoagulant and cytolytic properties.

Oral disk The multi-toothed sucker-like structure surrounding the mouth formed during metamorphosis in the lamprey used to attach to prey for feeding, or to hold position to the substratum; also referred to as the sucker or buccal funnel.

Oral hood The anterior-most fleshy organ found on the head of larval lampreys encircling a series of tentacles (oral cirrhi) through which water currents are directed to the mouth.

Suctorial feeding A mode of feeding in which an animal adheres to its prey using suction, and proceeds to extract fluids or tissue for food.

Velum A muscular diaphragm-like organ that generates currents to draw water through the mouth and into the pharynx of larval lampreys, and separates the esophagus from the water tube in post-metamorphic lampreys.

Background

Lampreys (order: Petromyzontiformes), along with hagfishes (order: Myxinidae) (**see also Hagfishes and Lamprey**: Hagfishes), are the only modern-day representatives of the jawless fishes (superclass: Agnatha) that flourished in the extensive seas that covered the earth during the Paleozoic era, approximately 400–500 million years ago (mya). These jawless, scaleless, eel-like fishes have a cartilaginous skeleton and lack paired fins. Often termed ‘cyclostomes’ because of their round mouths, lampreys and hagfishes are best known for their unsavory feeding habits. Parasitic species of lampreys are suctorial feeders, using an oral disk (sucker) to latch onto fish and continuously ingest the blood and/or flesh of their prey (**Figure 1**). Hagfish are scavengers that tear flesh off of carrion, often from the inside out.

Fossil remains of the lamprey-like *Mayomyzon pieckoensis*, *Hardistellia montanensis*, and *Piipiscius zangerli* in North America suggest that lampreys date back to at least the Upper Carboniferous period, approximately 280–300 mya. The more recent discovery of *Priscomyzon riniensis* in South Africa suggests lampreys have existed in their present form at least since the Devonian (approximately 360 mya). *P. rininensis* closely resembles modern (extant) lampreys, possessing a similar body plan and an oral disk with circumoral teeth that strongly suggests that it too used suctorial feeding.

There are 41 species of living lamprey; 37 belong to the family Petromyzontidae and are found in cool waters of the Northern Hemisphere, while four species reside in the Southern Hemisphere belonging to either the family Geotriidae (one species) or Mordaciidae (three species).

Life History of Lampreys

All lampreys have a prolonged, freshwater larval phase followed by a true metamorphosis (**Figure 2**). The protracted larval phase in freshwater streams typically lasts 3–7 years (sometimes longer), during which the larvae (also called ammocoetes) subsist as filter feeders. In this phase, water is directed through an overhanging oral hood to the pharynx by water currents generated by a muscular velum located near the pharyngeal opening (**Figure 3**). Food particles are trapped by mucus (described below), while the water exits the pharynx via the branchiopores (gill slits) after passing over the gills, the main site of oxygen uptake and carbon dioxide

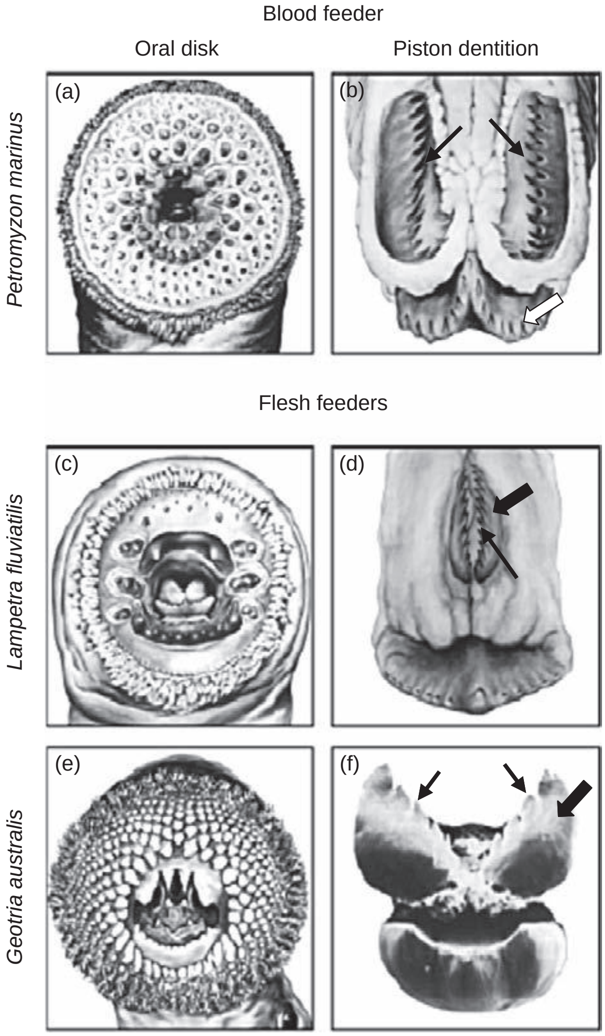

Figure 1 Design and structure of the lamprey oral disk. The multiple, inward (hook-like) facing teeth on the oral disk (a) of sea lampreys (*Petromyzon marinus*) facilitate prolonged attachment to their prey as they ingest the blood of their hosts by piercing the hide with their piston (or piston-like tongue) (b), which is studded with many fine teeth (white arrow) and fine serrations (thin arrows) on the two, widely separated cusps. In contrast, the flesh-feeding river lamprey (*Lampetra fluviatilis*) has fewer teeth studding the oral disk (c), and the piston (d) contains two large, serrated (thin arrows), cusps (thick arrow) that can interlock, allowing the animals to gouge flesh from their prey. The oral disk of pouched lamprey (*Geotria australis*) has many backward-oriented teeth (e), allowing the animal to slide along its prey as it removes chunks of flesh via a scissor action of the two, large, serrated cusps on its piston (f). Modified from Renaud CB, Gill HS, and Potter IC (2009) Relationships between the diets and characteristics of the dentition, buccal glands and velar tentacles of the adults of the parasitic species of lamprey. *Journal of Zoology* 278: 231–242.

excretion in lampreys and most fishes (**see also Hagfishes and Lamprey**: Lampreys: Environmental Physiology).

At the end of the larval phase, the ammocoetes undergo a metamorphosis that is characterized by the appearance of the eyes, and a switch from a unidirectionally ventilated to a tidally ventilated gill in which water is actively pumped in and out of gill pouches. The most notable change is the formation of the multi-toothed oral disk and a toothed piston-like tongue, which facilitates the ingestion of blood and/or tissues of fishes (**Figure 1**). Following the 8–24-month parasitic phase, sexually mature adults migrate up freshwater streams, spawn, and then die. All nonparasitic lamprey species are thought to have evolved from an identifiable parasitic lamprey ancestor, but bypass the feeding period following metamorphosis.

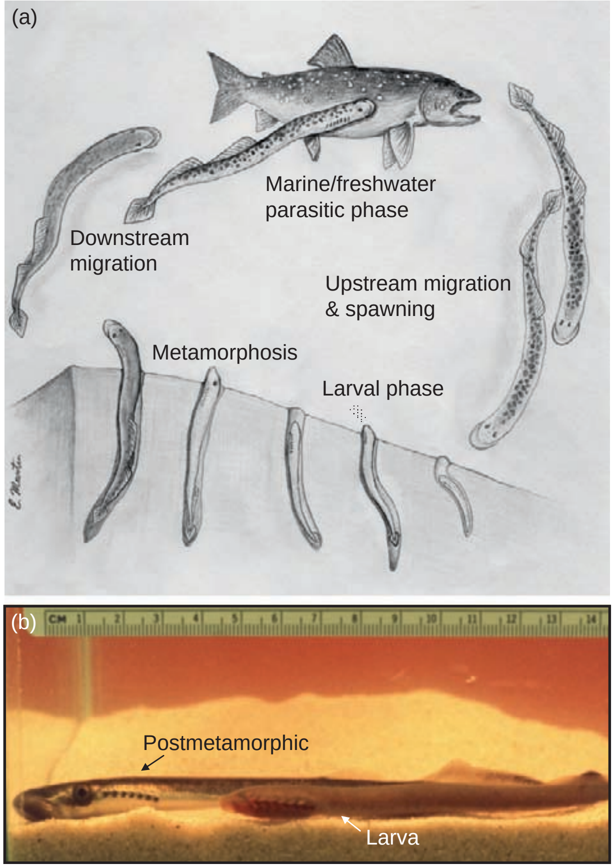

Figure 2 Life history of a parasitic species of lamprey. (a) The life history of lampreys begins with a prolonged, relatively sedentary, filter-feeding larval stage (ammocoete), followed by a 3–4-month period of metamorphosis preparing them for the more active parasitic phase which is usually 8–24 months (depending upon species). The terminal spawning phase takes place in freshwater rivers/streams. (b) Comparison of sea lampreys (*Petromyzon marinus*) in the larval (foreground) and postmetamorphic stages (background). Photo by MP Wilkie.

Locomotion and the Skeletal-Muscle System

Like other fishes, the skeletal muscle is arranged in overlapping W-shaped myotomes running the length of the body. Swimming is anguilliform, achieved by sending

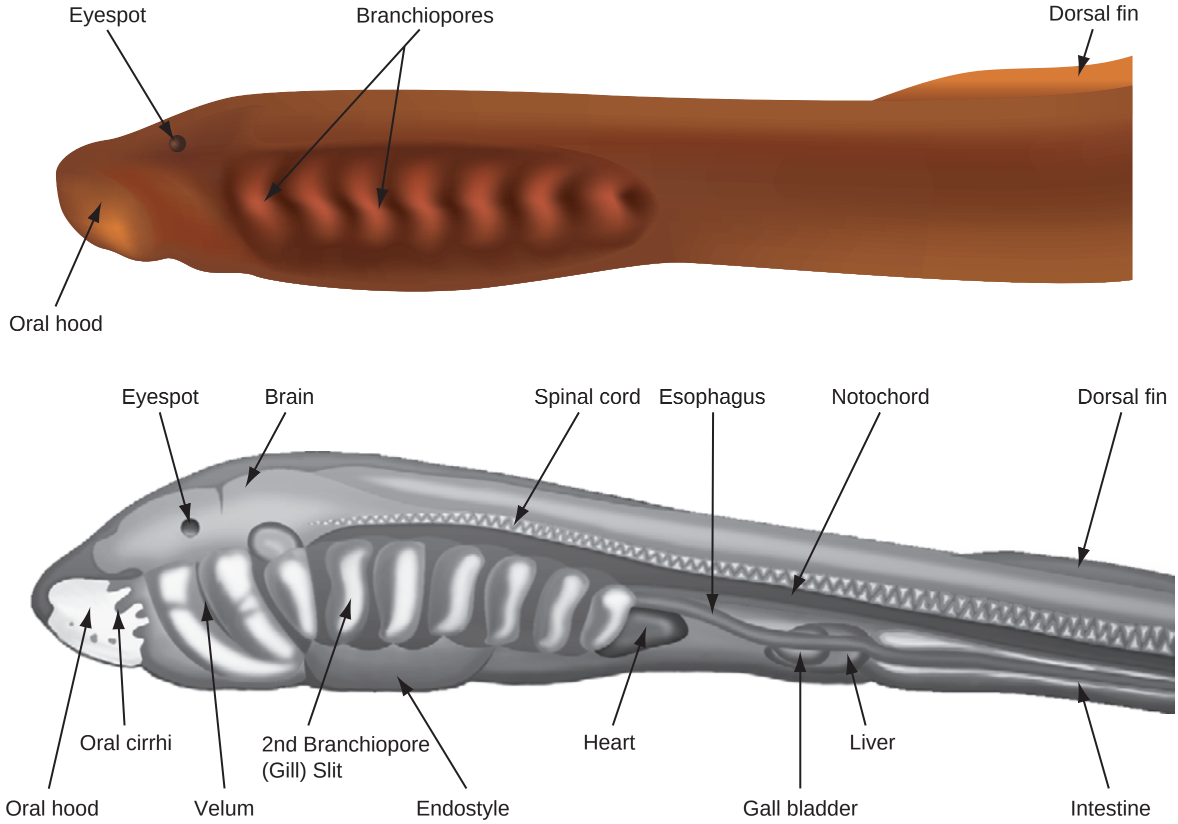

Figure 3 Longitudinal views showing the external and internal anatomy of larval lampreys. Redrawn from Hardistry MW and Potter IC (1971) The behaviour, ecology and growth of larval lampreys. In: Hardisty MW and Potter IC (eds.) *The Biology of Lampreys*, vol. 1, pp. 85–125, London: Academic Press.

alternating waves of contractions down either side of the body that result in eel-like swimming. However, this mode of locomotion generates lateral forces that impede forward momentum, which likely explains the lower critical swimming speeds (U_{crit}) of upstream-migrant sea lampreys (*Petromyzon marinus*; 1.1–1.4 body lengths s^{-1}) versus comparably sized salmonid fishes (>2 body lengths s^{-1}) that use the more efficient carangiform or subcarangiform swimming modes (**see also Buoyancy, Locomotion, and Movement in Fishes**: Experimental Hydrodynamics and Undulatory Swimming). Although the maximum burst swimming speed attained by an adult, upstream-migrant sea lamprey is up to 390 cm s^{-1} and is comparable to speeds attained in salmonids, such bursts can only be sustained for short periods (a few seconds). Accordingly, upstream-migrant sea lampreys navigate against fast-flowing currents using brief bursts of swimming, followed by rest intervals lasting several minutes during which they attach to the substrate using their oral disk.

Lampreys, such as the pouched lamprey (*Geotria australis*), the Pacific lamprey (*Entosphenus tridentata*), and likely other species, use their oral disks to climb over rocky obstacles and waterfalls as they swim upstream. Indeed, the Pacific lamprey has been observed scaling the vertical inclines of man-made dams! In laboratory experiments, upstream-migrant Pacific lampreys can traverse inclines as steep as 45°. Climbing is achieved by sending undulations down either side of the body, culminating in a powerful flicking of the tail. The lamprey then straightens its body while simultaneously detaching and then reattaching the oral disk to the substrate to inch itself forward and upward (see **Video Clip 1**).

Burrowing, which allows larval lampreys to occupy niches with abundant food and few predators, is initiated by large lateral whip-like undulations of the body driving the head vertically into the substrate. Unlike swimming, the amplitude and the duration of undulations are greater due to the need to generate greater forward momentum to overcome the greater resistance of the substrate (usually silt, sand, or fine gravel) compared to water. Because the muscle contractions involved in burrowing are at least as intensive as those associated with vigorous swimming, burrowing is likely energetically costly.

The skeletal muscle of lampreys has a high anaerobic capacity with high amounts of phosphocreatine that are used to temporarily sustain adenosine triphosphate (ATP) supply during brief bursts of activity. High muscle glycogen stores, along with relatively high activities of lactate dehydrogenase (LDH), indicate that lampreys also have a high glycolytic capacity to fuel intense activity when ATP supply does not match ATP demand (**see also Hypoxia**: Anaerobic Metabolism In Fish). Although post-exercise recovery can take several hours in fishes such as salmonids, larval lampreys and upstream-migrant lampreys can restore phosphocreatine and glycogen stores, as well as correct accompanying acid–base disturbances, within 1 h, quickly preparing them for additional bursts of burrowing or swimming.

The rapid recovery of larval lampreys from exercise is related to an ability to increase postexercise oxygen consumption by up to sixfold. Unlike the trunk musculature of salmonids, which is mainly fast-twitch (glycolytic or white muscle) fibers, the trunk of lampreys is a mosaic of overlapping slow-twitch oxidative (red) and fast-twitch (white) fibers, which may promote shuttling of lactate from white to red muscle and immediate lactate oxidation for ATP production or glycogen replenishment during or following exercise.

Unlike teleosts, lampreys do not have a swimbladder (**see also Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes). There was likely little selective pressure for buoyancy control in burrow-dwelling larvae, or in parasitic stage animals that often latch onto fish. When not attached to fish/substrate, or during upstream migration, lampreys likely have to continually swim to avoid sinking. The relatively light cartilaginous skeleton (specific gravity ~1.1) and the large lipid (specific gravity ~0.8) reserves that accumulate during the parasitic phase likely provide some buoyancy (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes) after metamorphosis.

Metamorphosis

When larval lampreys have accumulated sufficient lipid, and other environmental and endocrine factors are suitable, they enter metamorphosis. Lipid is an essential fuel reserve because lampreys cease feeding during metamorphosis. The gradual accumulation of thyroid hormone in the blood (both thyroxine (T4) and triiodothyronine (T3)) during larval life is also critical because a sudden drop in thyroid hormone concentrations following peak T3 and T4 concentrations triggers metamorphosis. A preceding rise in water temperature is also needed, but photoperiod does not appear to be important (**Figure 4**).

Seven stages of metamorphosis are recognized, mainly based on changes in the appearance of the eye, and the development of the oral disk (**Figure 5**). The gills also become tidally ventilated following metamorphosis. Greater metabolic rates, an increased height of the one or two dorsal fins, and a more elaborate lateral line system are associated with the more active life style following metamorphosis. Body coloration also changes from light or dark brown to a silvery to blue-black sheen in many species (**Figure 2**).

The major reorganization of internal organs also occurs, including the intestine and liver, which reflects the switch from a filter-feeding phase to a blood-feeding

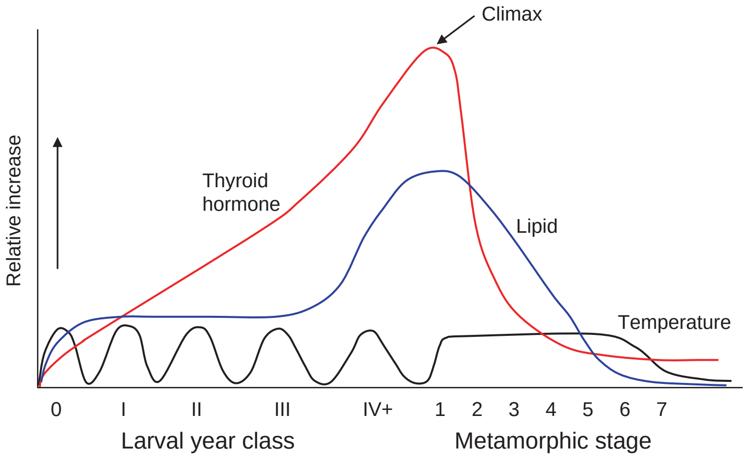

Figure 4 Prerequisites for the initiation of metamorphosis in the lamprey. Prerequisites include the gradual accumulation of thyroid hormone (solid red line) and lipid (blue line) throughout larval life, and fluctuations in ambient temperature (solid black line). Metamorphosis is initiated when thyroid hormone (T3 and T4) concentrations peak (climax), and then precipitously drop. Reproduced from Youson JH (1994) Environmental and hormonal cues and endocrine glands during lamprey metamorphosis. In: Davey KG, Peter RE, Tobe SS (eds.) *Perspectives in Comparative Endocrinology*, pp. 400–408. Ottawa: National Research Council of Canada, with permission from National Research Council of Canada.

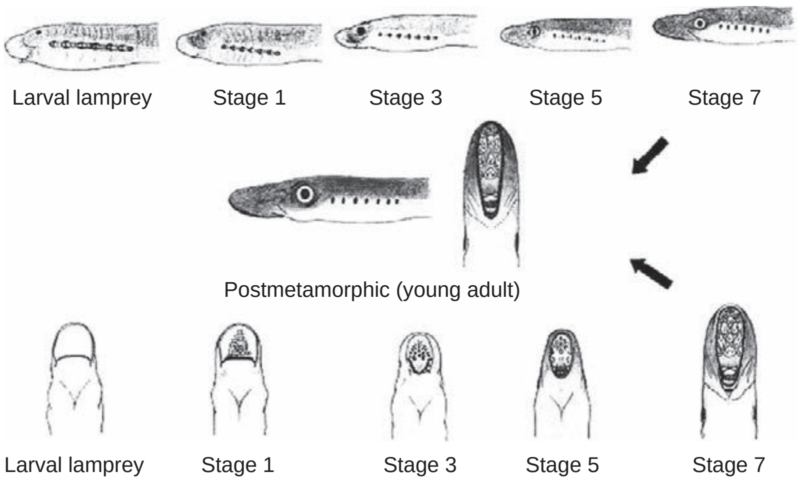

Figure 5 Lamprey metamorphosis. Lateral (upper row) and ventral views (lower row) of larval, metamorphic (stages 1, 3, 5, and 7) and postmetamorphic (juvenile adult) stages in sea lamprey showing the key changes that take place in the structure and organization of the head and feeding structures of lamprey during metamorphosis. Modified from Youson JH and Potter IC (1979) A description of the stages in the metamorphosis of the anadromous sea lamprey, *Petromyzon marinus* L. *Canadian Journal of Zoology* 57: 1808–1817.

phase of the parasitic species. A perplexing observation is the loss of the hepatic bile ducts (biliary atresia), leading to the accumulation of bile pigments (biliverdin and bilirubin) in the liver. Due to the switch from filter to suctorial feeding, the velum is no longer needed to generate feeding or respiratory water currents and is remodeled to serve as a valve to prevent food from entering the pharyngeal (water) tube, which is internally connected to the gills. The endostyle is replaced by follicles of thyroid tissue (follicular thyroid) rather than becoming the distinct thyroid gland of higher vertebrates. The conversion of the oral hood of the larva to the multitoothed oral disk is accompanied by the formation of the serrated, piston-like tongue used for piercing the hide of hosts/prey and the development of buccal glands, which are the source of a salivary secretion called lamphredin (discussed below). Pancreatic tissue, more appropriately called an enteropancreas, is comprised of a series of follicles in the ammocoete that form larger masses of pancreatic tissue following metamorphosis. The larval kidney completely degrades in the mid-posterior region of the body before being replaced by an adult structure (**see also Hagfishes and Lamprey**: Lampreys: Environmental Physiology).

Upstream Migration and Reproduction

Anadromous upstream-migrant lampreys do not home to their natal streams as migrating salmon do (**see also Fish Migrations**: The Biology of Fish Migration and Pacific Salmon Migration: Completing the Cycle). Instead, they use a most suitable river strategy in which appropriate rivers/streams are identified through the detection of bile salts secreted by resident larval lampreys. In sea lampreys, these bile salt pheromones (petromyzonamine disulfate, petromyzosterol disulfate, and petromyzonol sulfate) are very potent and can attract lamprey at extremely low (picomolar) water concentrations. Upstream-migrant male sea lampreys secrete another pheromone, 3-keto petromyzonol sulfate, which triggers aggressive mate seeking by ovulating females. The most suitable river strategy of lampreys may have co-evolved with the parasitic habits of the anadromous lampreys, which undergo wide geographic distribution while attached to their hosts during the marine phase of their life cycle.

Spawning takes place over redds, constructed by the males in gravelly to rocky riffles. The females of parasitic species are highly fecund, sometimes with >100 000 eggs, depending upon the species and their size. Egg production is lower in smaller nonparasitic species. Spent male and female lampreys die within days of spawning.

Feeding

Larval lampreys filter-feed on suspended matter in the water column, which is mainly detritus, but includes diatoms, algae, and other microorganisms. The velar pump draws water into the pharynx via the oral hood that overhangs the oral cavity. Initial filtration is by the fringe-like oral cirrhi that guard the mouth, but smaller food particles are subsequently trapped in the pharynx by tangles of mucus secreted by the endostyle and by the lateral walls of the pharynx. The food is subsequently diverted to the esophagus and intestines, while the water exits the pharynx via the branchiopores (**Figure 3**).

Parasitic lampreys may begin feeding as juvenile adults shortly after metamorphosis is completed, often as they migrate downstream. Their diet consists of blood, tissue, or both, depending upon the species. The serrated, piston-like tongue of blood feeders is equipped with many fine teeth for piercing the hide of hosts/prey. Flesh feeders contain a few stout cusps for gouging tissue (**Figure 1**). The velar tentacles are also larger in number and size in flesh feeders, presumably to prevent chunks of tissue from clogging the branchiopores (**Figure 1**). Both blood- and flesh feeders secrete lamphredin from the paired buccal glands. Lamphredin contains cytolytic enzymes and an anticoagulant to break down tissue and to prevent blood clotting, respectively, but the secretion may also have anesthetic properties.

In freshwater, parasitic lampreys attack a variety of teleosts; large salmonids such as lake trout are preferred in the Great Lakes. Less is known about marine feeding, where prey includes Atlantic salmon and Pacific salmon, swordfish, eel, mackerel, herring, and cod. Sea lampreys have been sited attached to North Atlantic right whales, and to a variety of shark species including sandbar, dusky, tiger, Greenland, and basking sharks (**Figure 6**; see **Video Clip 2**). Although actual feeding on sharks was considered doubtful due to the shark's thick dermal denticle armor, the high urea excretion rates measured in lampreys removed from a basking shark confirmed that feeding had taken place (**Figures 6**(**b**) and **6**(**c**)). Because lampreys have low urea production rates, most of the postremoval urea excreted must have originated from the shark, which retain high concentrations of urea in their blood and tissues as a counterbalancing osmolyte as in all marine elasmobranchs (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts).

Upstream-migrant lampreys do not feed, but are able to survive for months by subsisting on endogenous lipid stores and, in the final stages of their life, the proteolysis of tissue protein. Remarkably, the Pacific lamprey undergoes natural starvation for up to 14 months during its spawning migration up large rivers in British Columbia.

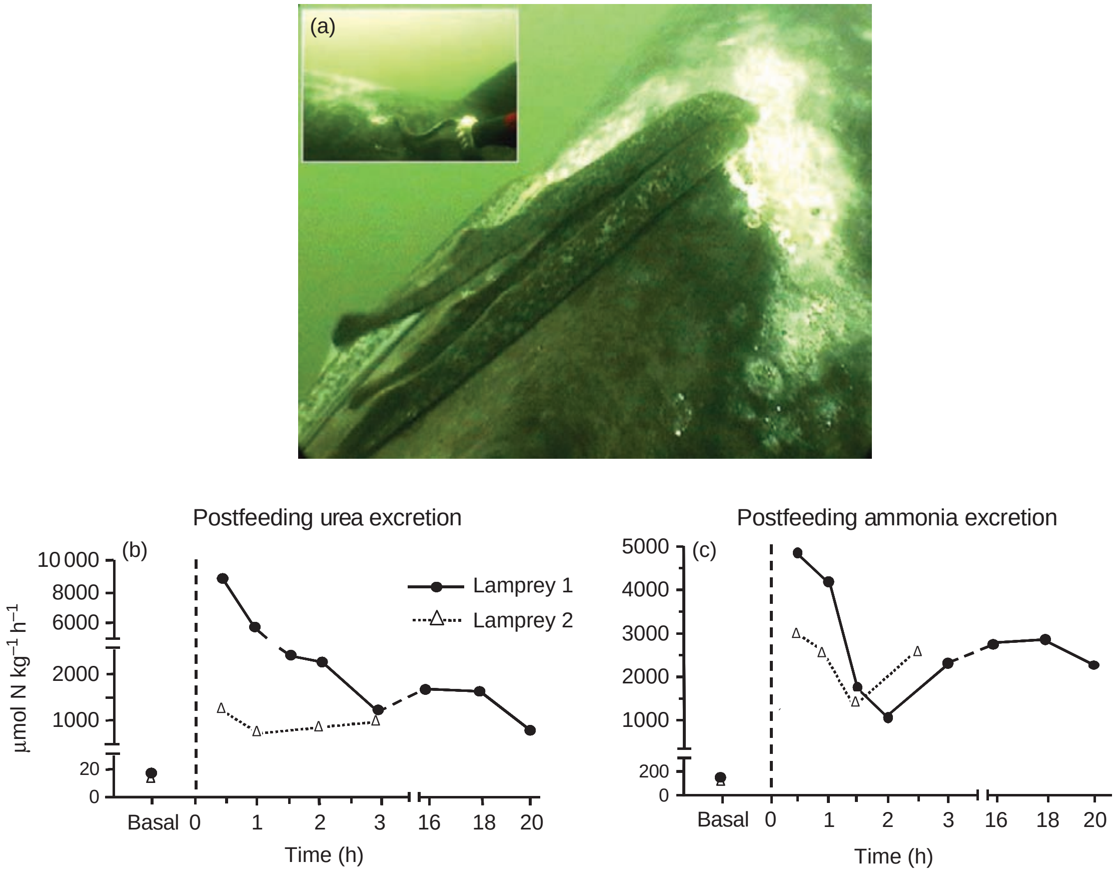

Figure 6 Sea lamprey parasitism of sharks. Sea lamprey feeding upon a basking shark (*Cetorhinus maximus*) in the Bay of Fundy, New Brunswick, Canada (a). Feeding was confirmed by marked elevations in urea (b) and ammonia (c) excretion measured immediately following the removal of lampreys from the sharks. Reproduced from Wilkie MP, Turnbull S, Bird J, *et al*. (2004) Lamprey parasitism of sharks and teleosts: High capacity urea excretion in an ancient vertebrate relic. *Comparative Biochemistry and Physiology, Part A* 138: 485–492.

Growth and Metabolism

The low nutritive value of their food and slow rates of assimilation are associated with low metabolism and slow growth, which result in the prolonged larval stage compared with other metamorphosing vertebrates (e.g., amphibians). Growth is greatest in early midsummer, when food supply is abundant, but before waters become too warm, which impairs digestion and lowers assimilation efficiency. Glycogen concentrations are maintained at relatively high concentrations in the muscle, likely to fuel burst swimming or burrowing (see above). Glycogen is also substantially higher in the meninges of the brain than in other fishes, supplying glucose to the nervous system. Glycogen stores in the very small liver (<1% of wet body mass) and the nephric folds (kidney plus surrounding adipose tissue) are limited, or in the case of muscle glycogen, unavailable for glucose homeostasis.

The fall and winter preceding metamorphosis is one of arrested growth for sea lampreys, when they stop increasing in length but continue to gain mass as they accumulate the lipid needed to endure the nontrophic (nonfeeding) metamorphic phase. An arrested-growth phase is not seen in other species of parasitic or nonparasitic lampreys, such as the pouched or American brook lamprey, which gradually accumulate lipid throughout larval life. Lipid accumulates in the nephric folds and the fat columns surrounding the notochord, with lesser amounts accumulating in the intestine, beneath the skin and among the viscera. While the liver stores lipid, its overall contribution is likely minimal due to its small size. The progressive reductions in kidney and liver triacylglycerol and other lipid stores indicate that these are main lipid fuel depots during metamorphosis. Amino acid catabolism increases when lipid stores are nearing depletion as metamorphosis is completed.

The parasitic phase is associated with rapid growth. At the completion of metamorphosis, when anadromous sea lampreys begin their downstream migration, they are less than 20 cm long and weigh a few grams. When they return to freshwater up to 24 months later to migrate upstream, they may be over 80 cm long and weigh approximately 900 g. Landlocked sea lampreys and other species are generally much smaller at this age.

During the parasitic phase, lipid re-accumulates in the nephric folds and liver. In addition, glycogen increases in the muscle, likely to fuel the bursts of swimming needed to pursue prey or evade predators. The very high concentrations of glycogen in the meninges of the brain (>100 mmol kg^{-1} wet tissue) may provide a critical glucose reserve for the nervous system when lampreys starve for long periods in the parasitic phase, or during upstream migration.

Glycogen and lipid synthesis in parasitic juvenile lampreys at sea clearly comes from protein-rich blood. Blood is ingested at high rates, 2–16% of their dry body mass per day, which can result in a nitrogenous waste (mainly ammonia and lesser amounts of urea) load up to 5 times of that reported in intensively feeding hatchery-reared salmon (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia). Postmetamorphic increases in the rates of nitrogenous waste excretion and the activities of the amino acid catabolizing enzymes, such as glutamate dehydrogenase (GDH) in sea lampreys, suggest that juvenile lampreys have a high capacity to use amino acids for glycogenesis and lipogenesis when ingesting large amounts of protein-rich blood.

Like salmonids (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle), migrating lampreys rely on stored lipid to satisfy their basal energy requirements. Between the onset of migration and spawning, whole-body lipid stores decrease 50% in both males and females. Proteolysis becomes important in the terminal phase of migration just before or following spawning, when available lipids are likely nearing depletion. Not surprisingly, fat and protein content in male and female gonads are not reduced, even after periods of starvation lasting several months or more. Spawning is accompanied by further depletion of energy reserves including muscle glycogen, which likely fuels the final bouts of burst exercise associated with redd building and the spawning act. While the reduction in fuel reserves associated with the upstream migration and spawning is severe, it does not approach those levels observed immediately following metamorphosis. Thus, death following spawning is not likely the result of energy depletion in lampreys, but one of general senescence.

The Great Lakes Invasion by Sea Lampreys

Much of the original interest in lamprey physiology was due to the devastating effects that sea lamprey had on fisheries in the Great Lakes of North America. There are likely two populations of sea lampreys in North America, an anadromous population found along the Atlantic coast, and a landlocked population now thought to be indigenous to Lake Ontario, based on recent microsatellite genotyping analysis.

Niagara Falls posed an insurmountable barrier to sea lamprey entry from Lake Ontario into Lake Erie and beyond, until a deeper and wider Welland canal was constructed in mid-1800s that eventually allowed invasion of Lake Erie and the upper Great Lakes. By the 1940s, sea lamprey predation of Great Lake fishes, along with overfishing, had wiped out many economically important fishes; lake trout populations were near collapse.

In response, Canada and the United States formed the Great Lakes Fishery Commission (GLFC), a binational body given the mandate to eradicate the sea lamprey.

Sea lampreys were never eradicated from the Great Lakes. Instead, the GLFC developed and implemented an integrated pest-management plan to control sea lamprey populations. The measures include

1. *Physical barriers*. The use of traps and barriers to block the upstream migration of sea lampreys into rivers and streams that are suitable for spawning and the nurturing of larval sea lamprey.
2. *Sterilizing techniques*. Captured males may be treated with a compound (bisazir) that renders them sterile. The sterilized males are then released onto spawning beds to mate with females, without fertilizing the eggs.
3. *Pesticides*. The most widely used, and successful, method of sea lamprey control is the pesticide, 3-trifluoromethyl-4-nitrophenol (TFM), which is applied to lamprey-infested streams, sometimes in combination with low amounts (1–2%) of niclosamide, a molluskcide. TFM selectively targets larval sea lampreys, which have a low capacity to detoxify TFM compared to other resident fishes and invertebrates. By interfering with oxidative phosphorylation in the mitochondria, TFM reduces ATP production rates and eventually depletes fuel stores leading to death. TFM also undergoes rapid photodegradation, minimizing environmental persistence and reducing its nontarget impact on aquatic ecosystems. In recent years, a better knowledge of sea lamprey growth, metamorphosis, and metabolism has made it possible to predict from length and weight measurements when sea lampreys start metamorphosis. This permits targeted TFM applications in streams containing larval sea lampreys most likely to enter metamorphosis the following summer.
4. *Attractants*. The recent recognition that upstream-migrant sea lampreys rely on bile salts (pheromones) secreted by larval sea lampreys to locate suitable spawning habitat has made it possible to develop attractants that can more effectively trap upstream-migrant lampreys or divert them into unsuitable habitat.

As a better knowledge of lamprey physiology develops, more effective means of sea lamprey control will follow. However, an improved understanding of lamprey physiology might also contribute to the conservation of vulnerable lamprey species. Unfortunately, populations of these living fossils are threatened in many parts of the world.

Glossary

External branchiopore One of seven external openings found on either side of the lamprey head through which exhalent water currents pass after irrigating the gills.

Gill pouch One of seven pairs of tidally ventilated gill chambers in post-metamorphic lampreys in which exhalent water is forced across the gills by active compression of the gill basket, and inhalant water is drawn into the chamber due to the elastic recoil associated with branchial muscle relaxation.

Glomus A bundle of capillaries across which primary urine (filtrate) is produced, and subsequently taken up by one of several associated kidney (renal) tubules via the renal (Bowman's) capsule.

Internal branchiopore One of seven internal openings that connect the water tube (branchial duct) in lampreys to the gill pouches.

Opisthonephros The functional kidney found in the posterior trunk of larval and post-metamorphic lampreys, which replaces the early larval pronephros.

Pronephros A kidney formed from the anterior nephric ridge during development that is comprised of a glomus that services several kidney tubules, but gradually degenerates during larval lamprey life and during embryonic development in higher vertebrates.

Velum A muscular diaphragm-like organ that generates currents to draw water into the pharynx of larval lampreys, and separates the esophagus from the water tube in post-metamorphic lampreys.

Introduction

Lampreys likely face a range of environmental challenges during their complex life cycle (**Figure 1**; **see also Hagfishes and Lamprey**: Lampreys: Energetics and Development). Larval lampreys may have to deal with fluctuations in O_2 and temperature within their burrows in the silty substrate of streams, and the increased metabolic demands and reorganization of the respiratory and circulatory systems during metamorphosis may explain why transforming lampreys move to faster-flowing, better-oxygenated waters. Anadromous parasitic-phase lampreys must also acclimatize to seawater, while upstream-migrant lampreys have to re-acclimatize to freshwater, navigate around obstacles, and/or swim against fast-flowing waters prior to the terminal, spawning phase of their life cycle. Despite such challenges, lampreys have proven very resilient, having survived in their present form since at least the Devonian (~360 million years ago (mya)). Much of the lamprey's success may be related to a variety of respiratory, cardiovascular, and renal adaptations that allow them to cope with a wide range of environmental challenges.

Gas Exchange and Cardiovascular System

Respiration

Respiration primarily takes place across the gills (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics and O_2 Uptake and Transport: The Optimal P_{50}). An extensive dermal capillary network in the adults of some species, however, may allow some gas exchange to take place across the skin. A dermal capillary network is absent in larvae, but the subcutaneous tissue below the thin dermis is well vascularized, and perhaps sufficient to allow limited cutaneous O_2 and CO_2 exchange. Migrating adults of the pouched lamprey (*Geotria australis*), Pacific lamprey (*Lampetra tridentata*), and likely other species emerge from water during upstream migration. The skin could become important for respiration if gill function is compromised under such conditions. In fact, *G. australis* can survive emersion for many hours in moist environments, but it is unclear if this is due to cutaneous respiration or a resistance to collapse of the gill pouch (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

Figure 1 Summary of the life cycle of a parasitic lamprey species.

There are seven gill slits or pores (branchiopores) leading into branchial pouches through which water passes when the gills are irrigated. The gills themselves are comprised of gill filaments studded with numerous thin, plate-like lamellae, the probable site of gas exchange, as in the teleost fishes (**see also Role of the Gills**: Morphology of Branchial Ionocytes). Unlike in teleost fishes, however, the gills are supported by a lattice-like cartilaginous skeleton (branchial basket). The outer margins of lamellae from adjacent filaments come into close contact with one another, forming a sieve-like barrier through which exhalent water flows. Blood flow through the lamellae is counter to water flow – a similar countercurrent arrangement to that of elasmobranch and teleost fishes that maximizes O_2 uptake by ensuring a steady partial pressure diffusion gradient is maintained along the length of each lamella (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics and **Transport and Exchange of Respiratory Gases in the Blood**: O_2 Uptake and Transport: The Optimal P_{50}). It is likely that blood flow through the lamellae is controlled by neural and humoral factors, but experimental studies are lacking.

Irrigation of the larval gill is unidirectional, but unlike teleosts which use a buccal–opercular pump to irrigate the gills, larval lampreys generate respiratory currents via contractions of a muscular velum (velar pump) and the branchial musculature, which is anchored to the branchial basket (**Figure 2**(**a**)). Upon inspiration, medial flaps of the velum seal together and contract in a caudal direction, increasing the volume and decreasing the pressure in the oral cavity, drawing water into the mouth (**Figure 2**(**b**)). As the velum continues to contract (velar stroke), the branchial muscles contract, squeezing the pharyngeal chamber and forcing water across the gills, and out the branchiopores. Relaxation of the velar and branchial musculature leads to elastic recoil of the pharyngeal chamber and closure of the branchial valves guards against flow reversal. The corresponding decrease in intrapharyngeal pressure continues to draw water into the pharynx via the oral cavity and the process repeats (**Figure 2**(**b**)).

Ventilation is primarily tidal after metamorphosis, which allows lampreys to breathe while attached to their prey or the substratum with their oral disk. The velum is also remodeled, primarily serving as a valve to ensure that ingested blood/tissue is directed to the esophagus, and away from the branchiopores (**Figure 3**(**a**)). During respiration, contraction of the branchial musculature forces water out of the gill pouches. Subsequent relaxation of the branchial musculature leads to elastic recoil (expansion) of

Figure 2 (a) Lateral view of the head region of a larval sea lamprey. Water containing O_2 and food is drawn into the oral cavity and pharynx (pharyngeal tube) via contractions of the velum before passing across and exiting via the branchiopores. Mucus secreted by the endostyle, traps food in the pharynx, which is then directed to the esophagus. (b) The velar pump. Contraction (solid arrows) of the velum initiates the velar stroke (II) which expands the volume of the oral cavity generating inward water flow (open arrows) but reduces the volume of the branchial chamber forcing water across gills. Near the end of the velar stroke (III), contraction of branchial musculature ensures continued flow across gills. Elastic recoil and relaxation of the velum (IV) results in expansion of the branchial chamber and continued unidirectional water flow, while closure of the branchial valves prevents backflow across gills. Internally, the gill pouches are connected via internal branchiopores to the water tube (branchial duct). (b) Schematic representation of ventilation in post-metamorphic lamprey gills. Contraction of branchial musculature forces water across the gills and out the external branchiopore, followed by elastic recoil which expands branchial pouch to draw in water. Redrawn with modifications from Randall DJ (1972) Respiration. In: Hardisty MW and Potter IC (eds.) *The Biology of Lampreys*, vol. 2, pp. 287–306. London: Academic Press.

the branchial basket, creating suction to draw water into the gill pouches during inspiration (**Figure 3**(**b**)).

To promote gas exchange, more active or fast-growing fishes tend to have larger lamellar surface areas and thinner lamellae compared to more sedentary species. Despite a 2- to 2.5-fold increase in O_2 consumption following metamorphosis, the blood–water diffusion distance across the lamellar epithelium and the total gill surface area change little in lampreys. In fact, total gill surface area (14–27 $cm^2\ g^{-1}$ body mass) is comparable to that of many active teleosts (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics). Such findings might explain the relatively high metabolic scope of lampreys. Although larval lampreys have very low resting metabolic rates when burrowed, they can increase their mass-specific O_2 consumption by 5–6 times following exercise, which is comparable to measures made in salmonid fishes (**see also Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming).

Circulation

Deoxygenated blood is pumped by a heart into the ventral aorta, which subdivides into paired afferent branchial arteries. The blood then flows from the branchial arteries to afferent arterioles and then lamellar capillary beds. The blood leaves each lamella via an efferent arteriole, subsequently draining into an efferent branchial artery and the dorsal aorta, which subdivides into vessels that provide the head and trunk with oxygenated blood. Although the number is different, the branchial vessels have a similar arrangement as in teleosts (**see also Circulation**: Circulatory System Design: Roles and Principles).

Most O_2 is transported bound to hemoglobin, which is comprised of an iron-containing heme group to which O_2 reversibly binds. Unlike most vertebrates (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin), lamprey hemoglobin dissociates to form monomers (single globin chains) when oxygenated. Upon deoxgenation, however, the hemoglobins associate to form dimers (two globin chains) or oligomers (<2 chains). The O_2 affinity of the oxygenated monomer is higher than that of the oligomers, as characterized by hemoglobin-O_2 dissociation curves that are parabolic in shape with low P_{50} values (**Figure 4**(**a**)). This serves to maximize O_2 uptake by the animals, especially when O_2 is limited. In contrast, the formation of dimeric or oligomeric hemoglobin with deoxygenation is characterized by a more sigmoidal O_2-dissociation curve which is shifted to the right (**Figure 4**(**a**)). This association may promote hemoglobin-O_2 unloading at the tissues by lowering the hemoglobin-O_2 binding affinity (higher P_{50}) when O_2 is abundant in the water. Depending on the species, O_2 unloading is markedly enhanced by acidification of the blood (Bohr shift; **see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function) arising from the production of metabolic acid and CO_2.

Carbon dioxide loading at the tissues is facilitated by a pronounced Haldane effect, which increases the blood's CO_2-carrying capacity through the carbonic anhydrase (CA) catalyzed hydration of CO_2 to HCO_3^- and H^+ within the red blood cell (RBC; **Figure 4**(**b**)). Unlike higher vertebrates (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion and Carbonic Anhydrase in Gas Transport and Exchange), lampreys retain most of this HCO_3^- within the RBC (as opposed to the plasma) because they lack an erythrocytic Cl^-/HCO_3^- exchange protein. The H^+ associates with the hemoglobin, to facilitate O_2 offloading at the tissues via the Bohr effect. At the gills, oxygenation leads to the release of H^+ from the hemoglobin, leading to the CA-mediated dehydration of HCO_3^- to CO_2. The resultant increase in the P_{CO_2} diffusion gradient allows CO_2 to be excreted across the gills (**Figure 4**(**b**)).

The unique characteristics of their hemoglobin gives lampreys the dual ability to efficiently offload O_2 during vigorous exercise (e.g., swimming or burrowing) when O_2 is abundant, and to maximize O_2 uptake when O_2 is limited (hypoxia). It is difficult to establish when free-swimming, parasitic or upstream-migrant lampreys might encounter hypoxic conditions, but larval lampreys certainly face O_2 limitations at the sediment–water interface or within their burrows. In fact, larval lampreys survive indefinitely at O_2 tensions below 10 mmHg and for up to 36 h at 3–5 mmHg in cold (5 °C) water. They cannot survive anoxia. When the river lamprey (*Lampetra fluviatilis*) becomes hypoxic, hemoglobin-O_2 affinity increases due to RBC swelling, which dilutes the hemoglobin leading to less globin chain interaction. Hypoxia-induced increases in RBC pH also cause a leftward Bohr Shift and increased O_2 affinity (**Figure 4**(**a**)). Larval lampreys likely have a higher basal hemoglobin-O_2 affinity than post-metamorphic lampreys as indicated by their 80–90% lower P_{50} values.

The hypoxia tolerance of lampreys is also related to their ability to lower metabolic demands as demonstrated by marked decreases in ventilation during hypoxia. The presence of blood sinuses in the lamprey circulatory system contributes to a high venous O_2 reserve in the event of hypoxia. Despite relatively low concentrations of liver glycogen, the glycogen reserves are very high in the meninges of the brain (<100 mmol kg^{-1} wet wt), particularly in parasitic and upstream-migrant lampreys, which may provide an anaerobic energy source for the nervous system during hypoxia or glucose reservoir during prolonged starvation.

Osmoregulation

Freshwater

The body fluids of larval lampreys, landlocked post-metamorphic lampreys, and upstream-migrant lampreys are hyperosmotic to their freshwater habitats, resulting in large outward ion gradients and inwardly directed osmotic gradients (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction).

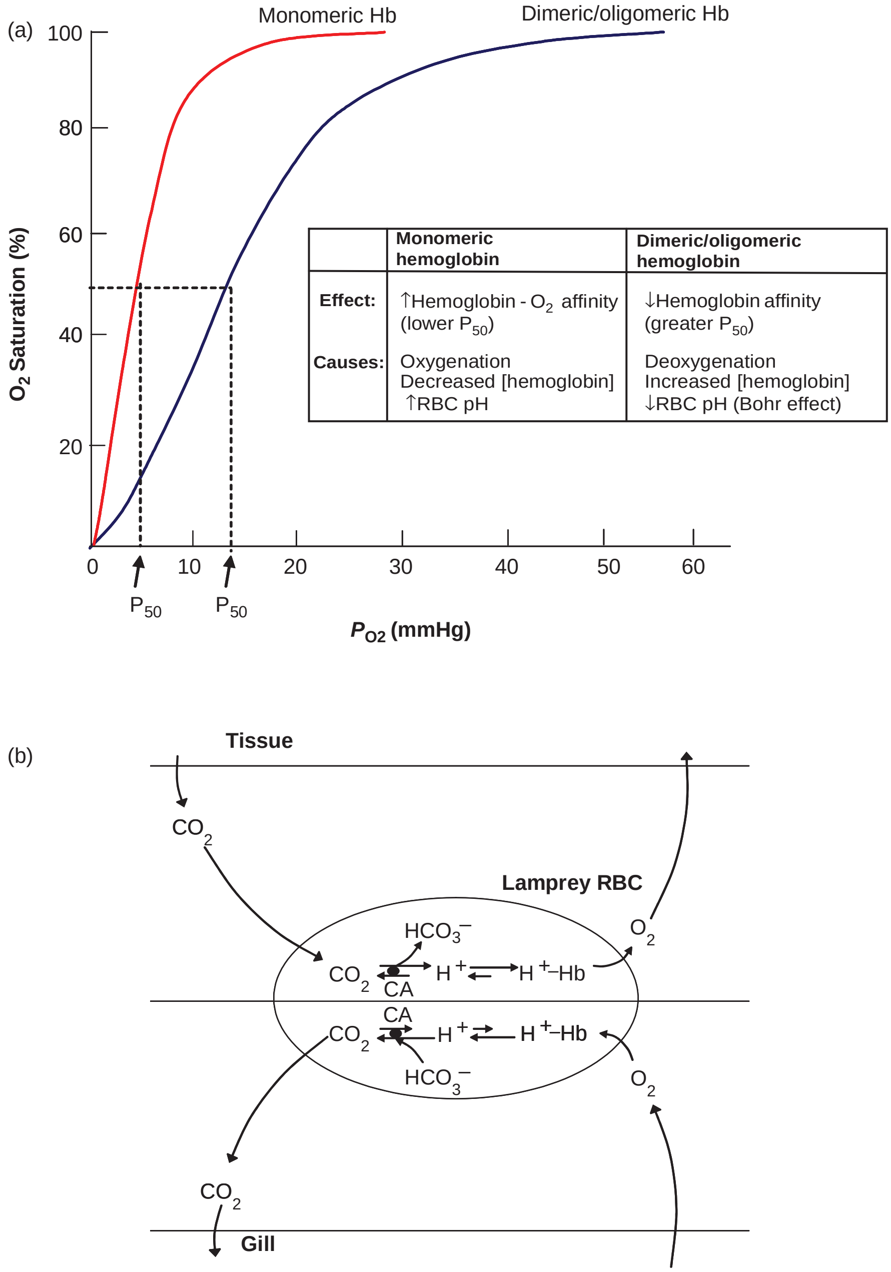

Figure 4 (a) Hemoglobin-oxygen dissociation curves of lampreys. Lamprey hemoglobin contains only a single heme group to which O_2 binds. Oxygenation causes hemoglobin to aggregate resulting in the formation of dimers or oligomers of hemoglobin, and a corresponding rightward shift in the hemoglobin-oxygen dissociation curve (greater P_{50}). (b) Carbon dioxide transport by lampreys. At the tissues (top half of figure) CO_2 diffuses into red blood cells (RBCs) down P_{CO_2} gradients maintained by the carbonic anhydrase (CA) catalyzed hydration of CO_2 to HCO_3^- and H^+ leading to H^+-hemoglobin associations that promote O_2 unloading to the tissues by decreasing hemoglobin-O_2 affinity (Bohr shift). H^+-hemoglobin association also increases intracellular pH, promoting greater HCO_3^- generation, increasing the blood CO_2-carrying capacity (Haldane effect). The HCO_3^- is retained in the RBC due to an absence of Cl^-/HCO_3^- exchange across the plasma membrane of the RBC. At the gills (lower half), the opposite occurs, where the loss of CO_2 across the gills leads to HCO_3^- dehydration and further CO_2 generation and unloading from the RBC. (b) Reproduced from Nikinmaa M, Airaksinen S, and Virkki LV (1995) Haemoglobin function in intact lamprey erythrocytes: Interactions with membrane function in the regulation of gas transport and acid–base balance. *Journal of Experimental Biology* 198: 2423–2430, with permission from Company of Biologist.

To counterbalance diffusive and renal ion losses, ions are extracted from blood as it is filtered at the kidneys and ions are taken up by the gills. There may also be some intestinal Na^+ and Cl^- uptake in larvae.

Larval lampreys have a pronephric kidney located in the anterior body, whichgradually atrophies before being replaced by a pair of opisthonephric (mesonephric) kidneys in the posterior two-thirds of the body. In both the pronephros and opisthonephros, blood is filtered across a glomus, which is a single, compact bundle of capillaries invested by several renal (Bowman's) capsules to form a renal corpuscle. The primary urine filtrate, comprised of small organic molecules (e.g., glucose and amino acids), nitrogenous wastes (ammonia and urea), and ions (Na^+, Cl^-, and Ca^{2+}), passes from the capsule into the proximal and the distal tubules, before draining into a common collecting duct and a urinary (archinephric) duct leading to the cloaca, the final site of urine excretion. The proximal and distal tubules are arranged in a loop that superficially resembles the loop of Henle in mammalian nephrons, but the functional significance, if any, is unknown (**Figure 5**(**a**)).

In freshwater, the kidneys excrete copious amounts of dilute urine to counter continual influxes of water across the gill and body surface (**see also Role of the Kidneys**: The Kidney and **Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). Urine flow rates (UFRs) in larval lampreys and post-metamorphic lampreys range from 150 to 350 ml kg^{-1} d^{-1}, higher than in freshwater teleosts (~100 ml kg^{-1} d^{-1}). Thus, the gills and/or tegument of lamprey likely have high water permeability. Glomerular filtration rates

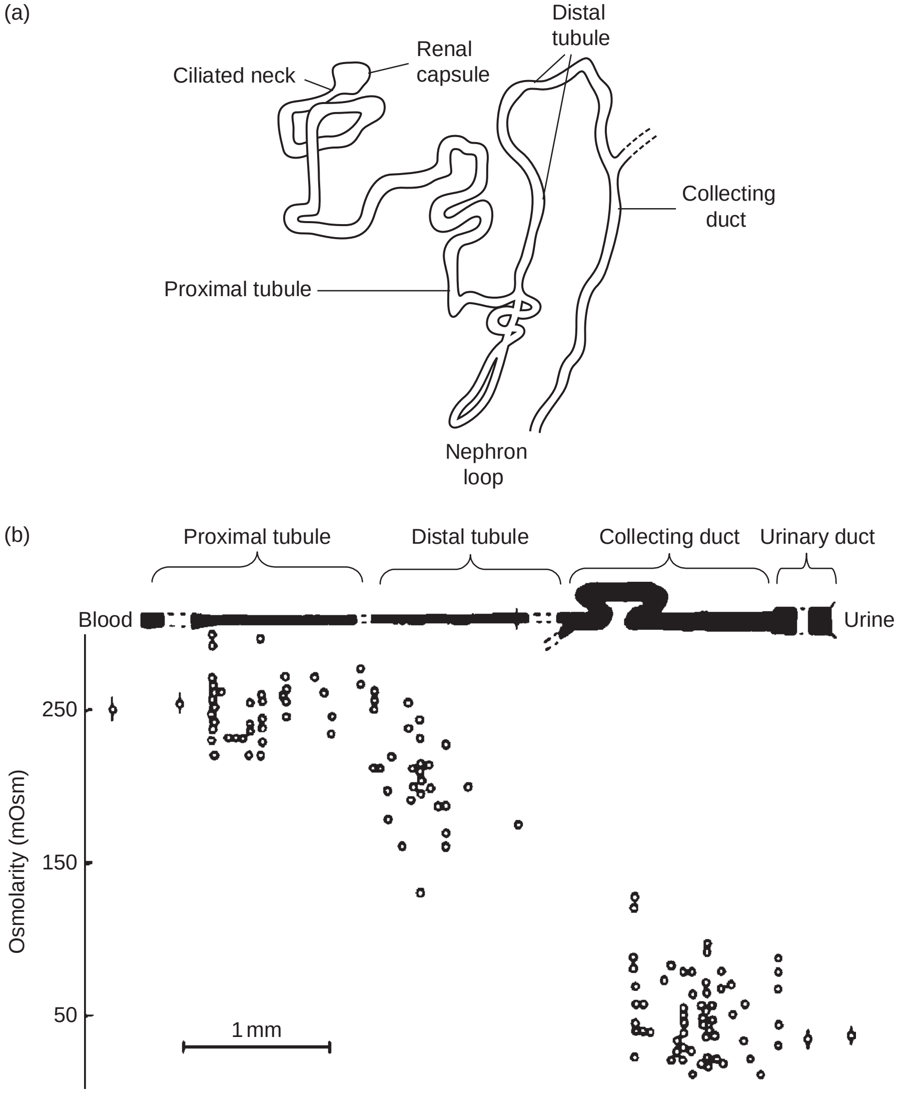

Figure 5 Lamprey renal tubule (opisthonephros) design and urine production. (a) Illustration of the lamprey renal tubule. Note the nephron loop, which superficially resembles the loop of Henle seen in the mammalian kidney. (b) Urine production in freshwater lampreys begins with formation of the primary filtrate at the renal capsule (Bowman's capsule) which empties into the proximal tubules of several renal tubules. The majority of ion reuptake in freshwater takes place at the distal tubule and the collecting segment resulting in a copious dilute urine. Reproduced from Logan AG, Moriarty RJ, and Rankin JC (1980) A micropuncture study of kidney function in the river lamprey, *Lampetra fluviatilis,* adapted to fresh water. *Journal of Experimental Biology* 85: 137–147, with permission from Company of Biologist.

(GFRs) are also high, approximately 5–7 times greater than teleost values. The dilute urine of freshwater lampreys has low concentrations of Na^+, Cl^-, and K^+ due to highly efficient renal tubular reuptake of these ions, which mainly (< 90%) takes place across the distal and collecting segments (**Figure 5(b)**). Radio-tracer studies (^{22}Na and ^{36}Cl) indicate that net urinary ion (Na^+ and Cl^-) loss is compensated by ion uptake by the gills.

As in the jawed fishes, the gills are a major site of osmotic and ion regulation, acid–base regulation, and nitrogenous waste excretion. The lamprey gill epithelium is comprised of mucus cells, pavement cells (PVCs), and mitochondrion-rich (MR) cells. There are three classifications of MR cells: ammocoete MR cells (AMRs) are found in larval lampreys (**Figure 6(a)**); intercalated MR (IMRs) cells are between PVCs in both ammocoetes and post-metamorphic lampreys (**Figure 6(b)**); and chloride cells (CC) appear after metamorphosis and disappear in upstream migrants (**Figure 6(c)**). Branchial ion uptake likely takes place via the MR cells, as in teleosts. However, the type of MR cell involved is unresolved. Because the morphology, surface area, and density of AMRs do not change following acclimation to more dilute or saline waters, their role in ionoregulation may be minimal. The IMRs (also referred to as ionocytes and ion uptake cells) have more extensive surface ornamentation and a complex tubular network in the apical region of the cell supporting a role in ion transport. The IMRs also exhibit ultrastructural alterations and increased surface area in response to altered water chemistry, further suggesting that they are sites of ion uptake. The CCs appear following metamorphosis (see below), when the AMRs are lost, but the IMRs are retained.

Immunohistochemical and molecular analyses indicate that Na^+ uptake is likely similar to that proposed for teleosts **Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes) in which Na^+ crosses the apical membrane via epithelial Na^+ channels (eNac) via electrochemical gradients generated by an apical vacuolar H^+-adenosine triphosphatase (ATPase) pump and the basolateral Na^+/K^+-ATPase. The H^+-ATPase pumps H^+ across the apical membrane,

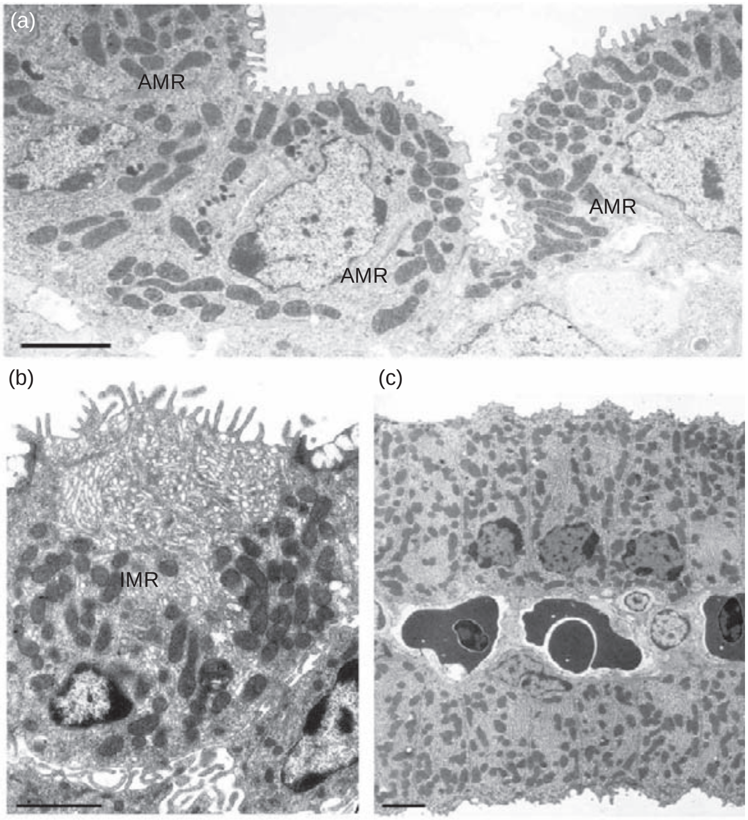

Figure 6 Ultrastructure of lamprey mitochondria-rich cells. (a) Ammocoete MR cells (AMR) cell from sea lamprey larvae, and (b) Intercalated MR (IMR) cell and (c) rows of chloride cells (CC) on either side of blood space in downstream migrant pouched lampreys. Note the extensive ornamentation and a complex tubular network in the apical region of intercalated MR cells and CCs which mediate ion uptake and ion excretion in freshwater and saltwater acclimated lampreys, respectively. Scale = 2 μm (a, b), 3 μm (c). Reproduced from Bartels H and Potter IC (2004) Cellular composition and ultrastructure of the gill epithelium of larval and adult lampreys: Implications for osmoregulation in fresh and seawater. *Journal of Experimental Biology* 207: 3447–3462, with permission from Company of Biologist.

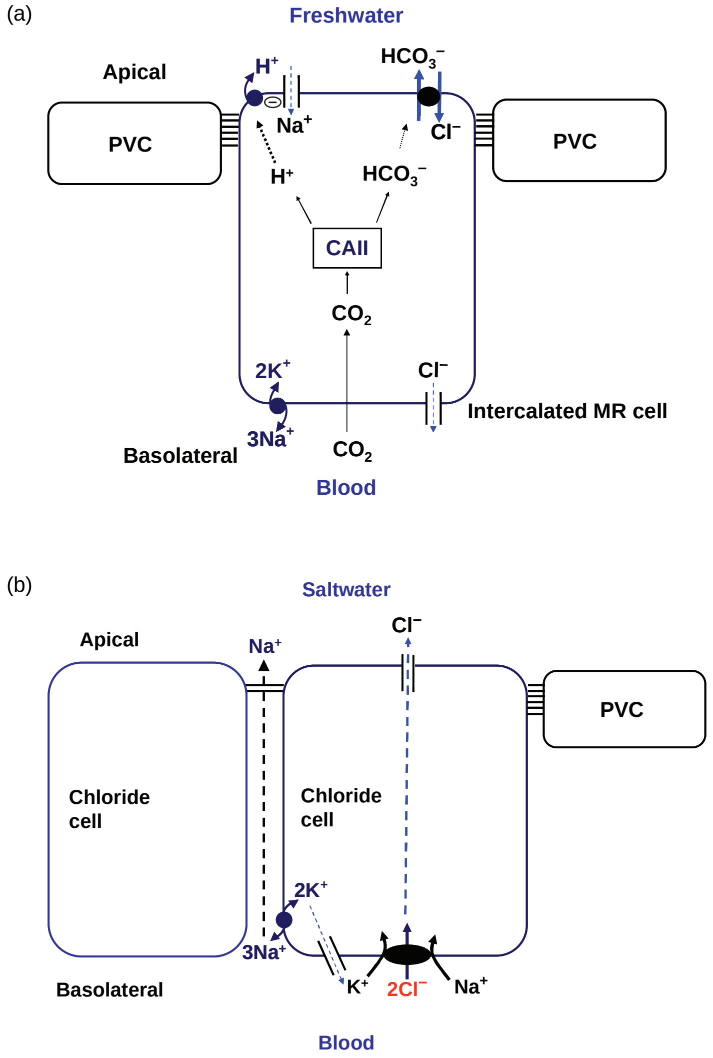

Figure 7 (a) Gill-mediated ion uptake in fresh water. The site of ion uptake is thought to be via intercalated mitochondria-rich (IMR) cells, though the precise mechanisms need confirmation. The pavement cells (PVCs) predominate in the gill but their role in ion exchange is presently thought to be minimal. (b) Gill-mediated ion uptake in saltwater. Higher rates of Na^+/K^+-ATPase activity in saltwater likely concentrate Na^+ in the paracellular spaces between adjacent rows of chloride cells (CC), generating electrochemical gradients that favor Na^+ extrusion across leaky tight junctions. Chloride excretion involves basolateral Na^+:K^+:$2Cl^-$ (NKCC) co-transport, leading to buildups of intracellular Cl^- that likely favor Cl^- excretion via apical Cl^- channels. From Bartels H and Potter IC (2004) Cellular composition and ultrastructure of the gill epithelium of larval and adult lampreys: Implications for osmoregulation in fresh and seawater. *Journal of Experimental Biology* 207: 3447–3462.

creating an electrical gradient to draw Na^+ into the cell before it is transported to the blood via the oubain-sensitive basolateral Na^+/K^+-ATPase (**Figure** 7(**a**)). The presence of CA within the gill ICF promotes the H^+ generation needed to drive the H^+-ATPase and the HCO_3^- needed to drive Cl^- uptake, possibly via an apical anion exchange protein (Cl^-/HCO_3^- exchange) (**Figure** 7(**a**)).

Seawater

Metamorphosis prepares anadromous lampreys for their seaward migration, in addition to their parasitic lifestyle. Like anadromous teleosts (**see also Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation), sea lampreys drink seawater from which water absorption takes place in the anterior intestine down osmotic gradients generated by the uptake of Na^+ and Cl^-. UFR is reduced by more than 90% in saltwater due to decreases in GFR, and increased water uptake across the distal and collecting tubules. The urine has relatively low Na^+, suggesting that most of the Na^+ that enters the blood is excreted by branchial CCs. Yet, the urine is slightly hyperosmotic to the blood due to high concentrations of Cl^-, and toxic divalent ions such as Mg^{2+} and SO_4^{2-}.

The mode of Na^+ and Cl^- excretion by the CC is similar to marine teleosts (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts), and likely involves a basolateral Na^+:K^+:$2Cl^-$ (NKCC) co-transport system, which moves Na^+, K^+, and Cl^- into the cytosol of the CC (**Figure 7**(**b**)). The very high activities of Na^+/K^+-ATPase, on the tubular system and basolateral membranes of CCs, move the Na^+ into the paracellular spaces between the rows of adjacent CCs which likely generates an outwardly directed electrochemical gradient for Na^+ extrusion via leaky tight junctions. The K^+ passes back into the extracellular fluid (ECF) via basolateral channels. Chloride is proposed to exit the gills via apically located Cl^- channels, which have been isolated from gills of teleosts but not yet lampreys.

Hormonal Regulation

There is a lack of data on the hormonal regulation of osmo- and ionoregulation in lampreys. As in teleosts, arginine vasotocin (AVT) and the renin–angiotensin system appear to be involved. AVT injection in upstream-migrant river lampreys results in increased urinary Na^+ and K^+ excretion, and a greater UFR suggests that AVT might be involved in freshwater acclimation. Angiotensin-converting enzyme and angiotensin I have been isolated from river lamprey, indicating the presence of a renin–angiotensin system in lampreys. Angiotensin I and II injection increases blood pressure in lampreys, and the system may stimulate drinking behavior in seawater-acclimated lampreys, but this possibility requires further investigation.

Acid–Base Regulation

Because lampreys retain HCO_3^- in the RBC due to the lack of RBC Cl^-/HCO_3^- exchange, lampreys have a low capacity to buffer acid–base disturbances in the plasma (**Figure 4**(**b**)). This is compounded by a low nonbicarbonate (protein) buffering capacity, making the lamprey particularly prone to wide fluctuations in pH as a result metabolic H^+ production during exercise or environmental disturbances (e.g., low pH). Despite their vulnerability to plasma (extracellular) acid–base disturbances, larval and upstream-migrant sea lampreys quickly correct exercise-induced acidosis via a high-capacity H^+ excretion system. The presence of branchial MR cells suggests that the gills may be able to modulate H^+ excretion in response to internal and externally induced acid–base disturbances. Nothing is known about renal acid–base regulation in lampreys.

Nitrogenous Waste Production and Excretion

Ammonia

The breakdown of excess amino acids generates highly toxic ammonia (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia). At physiological pH, most ammonia is in the NH_4^+ form due to its relatively high dissociation constant (p$K \sim 9.5$ at 15 °C) which can be described by the following equation:

$$NH_3 + H_2O \leftrightarrow NH_4{}^+ + OH^-$$

Blood and tissue ammonia concentrations in lamprey tissues are comparable to measurements made in other fishes. However, larval sea lampreys are ammonia tolerant and can withstand blood ammonia concentrations (< 2 mmol L^{-1}) fatal to many other fishes. High ammonia tolerance could suit the burrow-dwelling life style of larval lampreys, where decaying organic matter could cause fluctuations in water ammonia.

Urea

In terrestrial and semiterrestrial vertebrates, ammonia is converted to less toxic urea. Most fishes (**see also Nitrogenous-Waste Balance**: Ureotelism), including lampreys, excrete urea, but it only constitutes 10–20% of the total nitrogenous waste excreted (ammonia plus urea excreted). Lampreys only increase urea excretion rates slightly when exposed to high ammonia; therefore, urea production does not likely explain the high ammonia tolerance of larval sea lampreys. Basal urea production in lampreys is primarily via the catabolism of purines via the process of uricolysis in the liver. In mammals, amphibians, and a few unique teleosts (**see also Nitrogenous-Waste Balance**: Ureotelism), urea is primarily produced using the ornithine urea cycle (OUC) to detoxify ammonia. Urea is also produced via the OUC in elasmobranchs, but retained in the blood and tissues as an osmolyte to maintain water balance in seawater.

Urea production by the OUC entails the conversion of ammonia or glutamine to carbamoyl phosphate via carbamoyl phosphate synthetase III (CPSase III), followed by a series of intermediate steps leading to arginine, which is then hydrolyzed to urea via the enzyme arginase. Although all enzymes of the OUC were detected in parasitic-phase sea lampreys, the low activities of key enzymes (e.g., CPSase III) suggest that urea production by the OUC is physiologically irrelevant. Regardless, these observations do support a long-standing hypothesis that the components of the OUC were likely present in an ancestral jawless vertebrate. Because the ability to detoxify ammonia to urea using the OUC was considered a prerequisite for the invasion of land by vertebrates, these findings support a long-standing hypothesis that this critical metabolic machinery was present at an early stage in vertebrate evolution.

Parasitic lampreys markedly increase urea excretion rates (10- to 15-fold) after feeding on teleosts, and by a remarkable 75- to 450-fold after being removed from basking sharks (*Cetorhinus maximus*) (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development). Thus, lampreys likely possess specialized mechanisms of urea transport in the gill and/or kidneys. In elasmobranchs, urea transporters in the gills are used to retain urea, but urea transporter genes have also been isolated in the gills of the gulf toadfish (*Opanus beta*) and the Lake Magadi tilapia (*Alcolapia grahami*), fishes that normally produce and excrete high amounts of urea (ureotelism) (**see also Nitrogenous-Waste Balance**: Ureotelism). Because urea concentrations in shark tissue are two to three orders of magnitude greater than in lampreys (**see also Chondrichthyes**: Physiology of Sharks, Skates, and Rays), lampreys may need to rid their body of urea due to its potential to perturb proteins and/or disrupt osmotic balance. While sharks have adaptations to cope with high concentrations of internal urea, lampreys may not be able to as effectively deal with urea's potentially toxic effects. Elasmobranchs retain high concentrations of trimethylamine oxide (TMAO) in their blood and tissues, which counteract some of urea's perturbing effects, and may confer some protection to lampreys that ingest shark blood but this needs to be examined.

Concluding Remarks

While not as extensively studied as some teleost fishes, a surprising volume of research has been conducted on the environmental physiology of sea lampreys. Despite diverging over 500 mya from the gnathostomes, in many ways the physiology of modern-day lampreys is remarkably similar to bony fishes. While clear differences certainly exist, there are fundamental similarities in the modes of respiration, ion- and acid–base regulation, and nitrogen excretion used by extant lampreys and teleost fishes. It remains to be determined whether or not these similarities were the result of convergent evolution, or whether or not they represent traits that were present in a common ancestor to the lampreys and the gnathostomes.

Glossary

Gymnovarian Naked ovaries with ovarian folds open to the peritoneal cavity from where the eggs ovulate.

Hypercapnia High levels of carbon dioxide in blood.

Hypometabolic rate Decreased metabolic rate.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Iteroparous Capable of reproducing more than once (usually many times) in a lifetime.

Normocapnia Dissolved carbon dioxide levels in the environment that are at, or very near, air-saturated levels.

Normoxia Normal levels of oxygen in water or arterial blood.

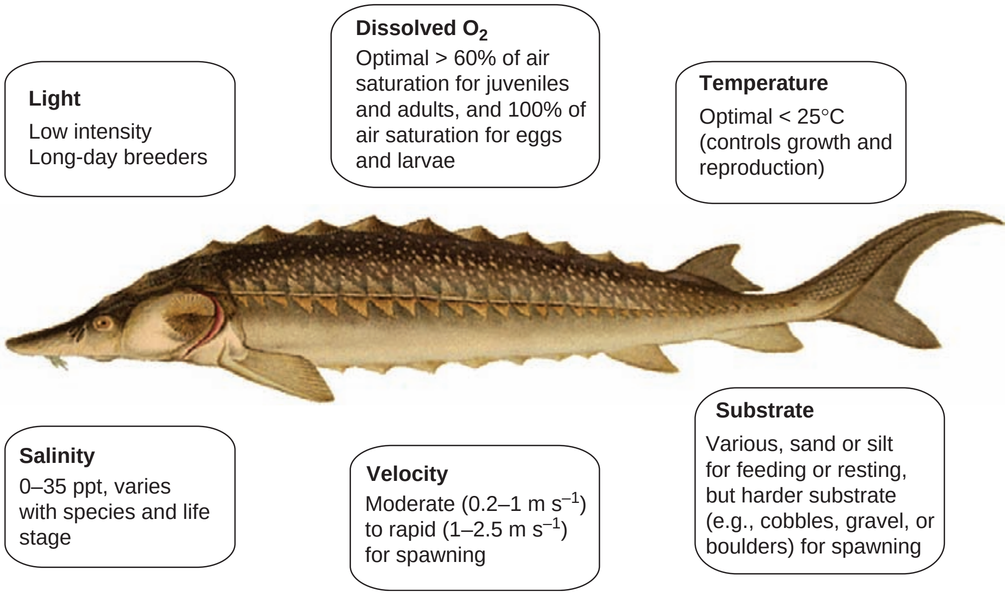
Oxyconformer Organisms that allow their metabolic rate to fall as the environment becomes progressively hypoxic.

Oxyregulator Organisms that maintain their metabolic rate as the environment becomes progressively hypoxic.

Introduction

Sturgeon and paddlefish (order Acipenseriformes) are a phylogenetically ancient clade of ray-finned fish, with fossil evidence from the Jurassic Period ($\sim 1.5-2.0 \times 10^6$ years ago). There are 25 extant species of sturgeon and two species of paddlefish living in the fresh- and saltwaters of Northern Hemisphere. Most of them are subjected to many environmental challenges and are endangered (i.e., on the verge of extinction). The lure of caviar, one of the most-expensive food products, played a major role in the dramatic decline of overfished sturgeon stocks. Today (2010), most sturgeon stocks in North America are protected from the impacts of commercial fisheries. However, they represent only a small fraction of their historic abundance, and their recovery is hampered by human impacts on their reproductive habitats.

Physiology is the science that investigates mechanisms in living organisms. It is the study of key performance pathways between an organism's phenotypic design (structure) and its patterns of resource use and survival that determine its evolutionary fitness. Sturgeon, as well as other animals, must use their (inherited and developed) structural and design (morphological and genetic) characteristics through biochemical and physiological mechanisms to achieve performance (e.g., reproduction, tolerances and adjustments to environmental changes, growth, and locomotion) levels, to survive (e.g., fighting off pathogens or evading predators), and use needed available resources (e.g., O_2, food, mates, and living and nesting spaces). The interactions between performance and patterns of resource use are often expressed in a bioenergetic relationship using energy as its currency (**see also Energetics**: General Energy Metabolism). Changes in environmental conditions (e.g., temperature, dissolved gases, and salinity) often elicit physiological responses, which may affect fishes' performance levels. **Figure 1**



Light
Low intensity
Long-day breeders

Dissolved O_2
Optimal > 60% of air saturation for juveniles and adults, and 100% of air saturation for eggs and larvae

Temperature
Optimal < 25°C (controls growth and reproduction)

Salinity
0–35 ppt, varies with species and life stage

Velocity
Moderate (0.2–1 m s^{-1}) to rapid (1–2.5 m s^{-1}) for spawning

Substrate
Various, sand or silt for feeding or resting, but harder substrate (e.g., cobbles, gravel, or boulders) for spawning

Figure 1 Some environmental requirements for a generalized sturgeon.

shows some environmental requirements for a generalized sturgeon. Whereas low-level or short-duration changes are dealt with via slight adjustments, stress-inducing water-quality changes (e.g., increased temperature, low dissolved O_2 (hypoxia), high dissolved CO_2 (hypercapnia), and increased salinity) challenge fishes, including sturgeons, and may activate a suite of metabolically costly physiological countermeasures. Understanding the time frames and limits of these responses and their potential costs (e.g., in redirecting energy from growth or reproduction to other energy-conversion categories) may help meet conservation, management, or commercial goals for protection and use of sturgeon resources. This article provides a brief overview of sturgeons' reproductive physiology and their physiological responses to hypoxic, hypercapnic, and saline environments and makes comparisons with some more-derived teleosts, which have been studied more extensively.

Reproduction

Reproduction, including sexual maturation, spawning, and early development, is a most sensitive part of sturgeons' life cycles. All sturgeons require a much longer time to reach sexual maturity than do modern teleostean fishes. The median age at first spawning varies between 10 and 20 years in most sturgeon species. Although all sturgeon are iteroparous (i.e., spawn several times during their lives), the breeding intervals, particularly in females, can be as long as 8–10 years, compared to the annual interval in the majority of the temperate-zone teleosts. In spite of their high number of eggs (up to 1 million in Atlantic sturgeon *Acipenser oxyrhynchus*) produced per spawning by a female sturgeon, late sexual maturity and long breeding intervals contribute to low overall reproductive rates in sturgeon and make them very vulnerable to overfishing and environmental changes in their reproductive habitats. Finally, all Acipenseriformes reproduce in rivers and require specific conditions for successful spawning and for the survival of their embryos: current velocity 1–2 m s^{-1}, hard spawning substrate, moderate turbidity, and river temperature ranging from 10 to 18 °C, in most species.

Sturgeon are gymnovarian (i.e., have naked ovaries with ovarian folds open to the peritoneal cavity where the eggs ovulate). Ovulated eggs are transported via the heavily ciliated Müllerian funnel into the mesonephric duct, acting as a Wolffian duct, in sturgeon females. Lake sturgeon *A. fulvescens* continued laying eggs over an 8–12-h period, with the eggs released in 1000–1500-egg batches, and their spawning behavior was polygamous, with several males fertilizing the eggs of a single female. The fecundity (number of eggs produced at single spawning) varies in different species from approximately 50 000 to more than 1 000 000, depending on the fish size and that of the ovulated eggs. For example, the average fecundity of the anadromous Atlantic sturgeon from the Hudson River, USA, was 500 000, and the eggs were 2.5 mm in diameter (smallest eggs in North American acipenserids). In contrast, the anadromous green sturgeon *A. medirostris* of the Pacific Coast had a fecundity of 160 000 with an egg diameter of 4.4 mm (largest eggs in North American acipenserids).

The spawning periodicity in the wild stocks is usually inferred from observations on tagged fish. Analysis of multiyear observations on paddlefish (*Polyodon spathula*) in the Missouri River (USA) watershed indicates breeding intervals of 2 years in males and 3 years in females. Somewhat similar intervals were observed in lake sturgeon in Lake Winnebago, USA. The most common estimates from studies of cultured sturgeons are 1 year in males and 1–3 years in females. Our observations on cultured white sturgeon *A. transmontanus* strongly suggest that endogenous reproductive cycles in fish born and reared in captivity are annual in males and biennial in females. All sturgeon species reared in modern aquaculture exhibit a dramatic acceleration of growth and early sexual maturation (e.g., approximately half of the time required for maturation, compared with wild fish).

Endogenous and Environmental Regulation of Reproduction

Puberty (i.e., the acquisition of the capacity to reproduce and the onset of the first reproductive cycle) is recognized in sturgeon by the increase in plasma concentration of sex steroids, proliferation of spermatogonia in males, and the start of vitellogenesis in females. Body size and accumulated energy play important permissive roles in the onset of the first reproductive cycle, when energy is diverted from somatic growth to reproduction. The onset of puberty and the reproductive cycle is orchestrated by environmental signals (such as photoperiod) and secretion of two pituitary gonadotropins: follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The system is regulated by a complex feedback of the gonadal sex steroids and growth factors and is linked with other endocrine pathways. Pubertal age of wild sturgeon varies from 5 to 15 years in different species, but farmed sturgeon exhibit early puberty (3–6 years), because they are fed, continuously, on a high-energy diet and are grown at relatively high temperatures (e.g., 18–24 °C).

The endogenous regulation of the reproductive cycle in sturgeon includes hormones of the hypothalamic–pituitary–gonadal reproductive axis. In general, it is similar to the reproductive axis of modern teleosts (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction). Brain peptides and neurotransmitters play the key roles in puberty and the reproductive cycle, but their functions have not been studied, systematically, in sturgeon. Gonadotropin-releasing hormone (GnRH) of sturgeon is identical in molecular structure to mammalian GnRH-1, and is effectively used as a synthetic agonist GnRHa for the induction of ovulation and spermiation in sturgeon aquaculture. The functional role of another GnRH form found in the sturgeon brain (i.e., chicken GnRH2) has not been determined. As in teleosts, two pituitary gonadotropins regulate the reproductive cycle in sturgeon. They were first described in farmed white sturgeon as stGTH1 and stGTH2, and later confirmed as molecular and functional homologs of mammalian FSH and LH in Siberian sturgeon *A. baeri*, Russian sturgeon *A. gueldenstaedti*, and Chinese sturgeon *A. sinensis*. Plasma concentrations of FSH are elevated from the onset of puberty and during gonadal growth and vitellogenesis, whereas the plasma concentration of LH rises significantly during the spawning season of sturgeon.

The FSH and LH secretions control the synthesis and secretion of gonadal sex steroids: androgen, estrogen, and maturation-inducing steroids (MISs). Biosynthesis of sex steroids takes place in the ovarian theca and granulosa cells and testicular Leydig cells. Sex steroids, in turn, control germ-cell development, sexual behavior, and secretion of GnRH, FSH, and LH via feedbacks to the brain and pituitary. Gonadal steroids with known or assumed functions in sturgeon are testosterone (T), 11-ketotestosterone (11-KT), estradiol-17β (E_2), and MIS 17,20β-dihydroxy-4-pregnen-3-one (17,20β-P). All of these hormones are present in the circulation in both sexes, but in different concentrations. Testosterone provides the substrate for synthesis of 11-KT and E_2, and a positive feedback to the sturgeon pituitary. The 11-KT is believed, largely by analogy with teleosts, to control spermatogenesis. The E_2 stimulates secretion of the yolk precursor (vitellogenin) in the liver and is required for the maintenance of ovarian follicles in the late phase of oogenesis. The MIS 17,20β-P was found in high concentrations in ovulating females and spermiating males. Two other candidates for the MIS, progesterone (P_4) and 17,20β,21-trihydroxy-4-pregnen-3-one (20β-S), have been proposed in sturgeons. All of the different MISs, including P_4, are highly potent in stimulating egg maturation *in vitro*. Knowledge of growth factors participating in sturgeon gametogenesis is limited to recent studies on insulin-like growth factor (IGF-1) and its receptors in the sturgeon ovary, showing the important roles of IGF-1 in the differentiation of granulosa cells and regulation of vitellogenesis.

The endogenous reproductive cycle is synchronized by environmental cues, such as photoperiod and temperature. Similar to salmon, some sturgeon species have different spawning ecotypes distinguished by timing of spawning migrations and spawning seasons. Most sturgeon species spawn during the spring and summer (i.e., the long-day breeders) but some, such as Chinese sturgeon in the Yangtze River, spawn in the fall. There is some indication that the endogenous reproductive cycle can override the effect of photoperiod. For example, the majority of white sturgeon females farmed in California and reared in outdoor tanks under natural photoperiod reaches full sexual maturity during March–June, but some females reach maturity in October–November. To our knowledge, the regulatory role of photoperiod in sturgeon reproduction has not been studied in an experimental setting.

Seasonal temperature plays an important role in the gametogenesis and spawning of sturgeon. For example, maturing white sturgeon females and males undergo gonadal regression (ovarian follicular atresia and phagocytosis of sperm) if they are exposed to temperatures above 15 °C during the winter months before the spring spawning period. The fact that elevated pre-spawning temperatures induce dramatic decreases in concentrations of plasma T and E_2 before the onset of gonadal regression suggests that seasonal environmental temperature is a regulatory factor in sturgeon gametogenesis and spawning. A better understanding of the role of temperature as an environmental regulator of sturgeon reproduction is particularly important for the conservation of sturgeon.

Growth

The semi-anadromous white sturgeon (*Acipenser transmontanus*) and the anadromous green sturgeon (*A. medirostris*) are native to eastern North Pacific waters. In California, there is a coastal and inland white-sturgeon sportfishery and a growing commercial (freshwater) white-sturgeon culture industry. Because some poorly circulated inland systems may become warm and hypoxic and some high-density culture systems hypercapnic, some physiological responses, including growth rates, of these sturgeon to these environments have been measured.

As temperature increased from 15 to 20 °C, under normoxic conditions, juvenile white sturgeon specific growth rate significantly increased from 1.6% to 2.6% body weight d^{-1}. In contrast, a further temperature increase to 25 °C resulted in only a slight, nonsignificant increase (to 2.9% body weight d^{-1}). Further, mildly hypoxic conditions (at 58% of air-saturated conditions) significantly decreased growth at all temperatures. This hypoxia-induced decrease in growth appeared to result from decreased food-consumption rates. Sympatric striped bass (*Morone saxatilis*) of the same size showed growth-rate increases with each increase in temperature under normoxia, including at 25 °C, where the fastest rates of growth were shown (3.2% body weight d^{-1}). Instead of ascribing these temperature-related growth differences to evolutionary lineage, historical habitat differences constitute the more likely explanation. Striped bass were introduced to California waters in the late 1870s, and their significant growth rate increase with the 5 °C increase to 25 °C probably reflects the warmer conditions of Chesapeake Bay on the USA's Atlantic Coast, where they evolved. Growth of the young striped bass was also sensitive to hypoxia, although not significantly so at the lowest temperature (15 °C), where its growth rate is the lowest. Finally, growth rates of young juvenile green sturgeon (0.10 g wet mass) increased with an increase in temperature (to 24 °C), compared with fish at 19 °C, as long as sufficient food and oxygen were available.

White sturgeon growth performance was significantly decreased in the hypercapnic conditions (1.17% wet body mass increase d^{-1}), compared with normocapnic conditions (2.86% body mass d^{-1}). As in the growth experiment with hypoxia, the decreased growth was apparently due to a decreased food-consumption rate. In a sham treatment using HCl, the decreased pH (simulating the hypercapnic pH) did not affect growth, implying that the decreased appetite and decreased growth rate seen in the hypercapnia treatment were due to the high CO_2, but not due to the resulting pH decrease. Hypercapnia (50–60 mg L^{-1}, pH: 6.15–6.30) also decreased growth of rainbow trout (*Oncorhynchus mykiss*) after a 330-day chronic exposure. Sophisticated, high-density white-sturgeon culture systems may become hypercapnic. Such high densities of fish are possible with the carefully metered addition of pure oxygen into the water inflows, increasing the quantity of dissolved O_2 for the fish to respire. However, the high respiring biomass of the sturgeon produces much CO_2. Because CO_2 is 25–30 times more soluble in water than O_2, depending on the temperature, the CO_2 tends to stay dissolved, producing hypercapnic conditions.

Respiratory Metabolism

The respiratory metabolic rates (**see also Energetics**: General Energy Metabolism) of three ontogenetic stages of juvenile white sturgeon were examined at stage-appropriate environmental temperatures. Expressed as mg O_2 consumed per gram body weight per hour, small (0.2 g body weight at 10 °C), medium (1.9 g at 16 °C), and large (63 g at 20 °C) white sturgeon all displayed significant decreases in mean oxygen consumption (i.e., aerobic metabolic) rate with exposure to mild (51% of air-saturation levels) hypoxia. Analysis of videotapes of the experimental fish showed that hypoxia also significantly decreased activity. Therefore, the significantly decreased metabolic rate of juvenile white sturgeon was at least partially due to decreased activity. The juvenile white sturgeon did not show a compensatory increase in oxygen-consumption rate when returned to normoxic conditions, after exposure to hypoxia. This response is consistent with the hypometabolic (decreased overall metabolic) response to hypoxia, in part due to decreased activity levels in the juvenile white sturgeon, seen also in white sturgeon adults. This response may serve white sturgeon well in natural habitats where decreased activity would decrease oxygen demand, thereby conserving oxygen resources in hypoxic habitats until conditions improved. This response differs from that seen in Siberian sturgeon, which do not decrease oxygen consumption rate during hypoxia and show a compensatory rate increase after return to normoxia. This compensatory rate increase repays the oxygen debt associated with anaerobic contributions to overall metabolism (**see also Swimming and Other Activities**: Energetics of Fish Swimming). This distinctly different pattern, compared with white sturgeon, may stem from habitat-related differences in the Siberian sturgeon's life history. Finally, Adriatic sturgeon *A. naccarii* exhibited a linear decline in oxygen consumption (i.e., 'oxyconformer') with significant decreases in arterial oxygen content and increases in plasma (lactate) when exposed to progressive hypoxia under static conditions. However, when these sturgeon were allowed to swim at a low sustained speed, they could regulate oxygen consumption (i.e., 'oxyregulator') down to 37 mmHg partial pressure of oxygen (P_{O_2}). At moderate levels of hypoxia, these swimming fish exhibited no significant changes in either arterial blood oxygen content or plasma lactate.

Blood-Oxygen Affinity

Increasing CO_2 decreased white-sturgeon blood-O_2 affinity, from the arterial-type CO_2 levels, through low- and high-hypercapnic levels we would associate with the high-density white sturgeon culture (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin and O_2 Uptake and Transport: The Optimal P_{50}). This Bohr effect-type shift (**see also Design and Physiology of the Heart**: Cardiac Cellular Length-Tension Relationship) results in higher P_{50} values (i.e., lower blood-oxygen affinities) at increased P_{CO_2} values. Note that although low hypercapnic conditions (30.4 mmHg P_{CO_2}) dramatically decreased the oxygen affinity (increased P_{50}), compared with normocapnic conditions at each temperature, further P_{CO_2} increases (to 76 mmHg P_{CO_2}) do not decrease blood-O_2 affinity substantially further (P_{50} only increases by 3 and 5 mmHg at 15 °C and 20 °C, respectively). Thus, white sturgeon in high hypercapnic conditions at 15 or 20 °C are able to adequately saturate their blood with oxygen for respiratory purposes under high hypercapnia, almost as much as under low hypercapnia. Studies on rainbow trout do not show this pattern, albeit at lower P_{CO_2} levels (up to 11 mmHg P_{CO_2}). Finally, juvenile green sturgeon blood-oxygen equilibria data over the 11–24 °C range indicate that these fish tolerate moderate environmental hypoxia, moderate aerobic activity, low-to-moderate hypercapnia, and moderate temperature changes in their environment.

Acid–Base Balance

Arterial CO_2 conditions directly reflect those in the water in hypercapnia-exposed fishes. Hypercapnic exposure induced stress in white sturgeon, as shown in significantly increased plasma catecholamines (norepinephrine and epinephrine) and cortisol concentrations. Ventilatory frequency consistently increased (hyperventilation) under hypercapnia, compared with the normocapnic controls. Arterial oxygen tension showed either no difference or a slight increase in the hypercapnic fish, presumably due to the hyperventilation. As expected, arterial (plasma) pH significantly decreased in the hypercapnic fish. However, after about 2 days, arterial pH started to show a compensation toward that of the normocapnic sturgeon, due to the significant accumulation of bicarbonate ion. This response parallels that in most teleosts studied, but the white sturgeon's response (~35% of pH restoration) was more limited and slower. For example, an ~91% arterial pH restoration after a 7-day hypercapnic exposure in rainbow trout has been reported, and the marine teleost, *Conger* sp., recovered 92% of its initial pH depression only after a 30-h hypercapnic exposure. Similarly, juvenile green sturgeon show a decreased accumulation of plasma (lactate), compared with that in rainbow trout, following severe chasing stress.

Gut Blood Flow

If hypercapnia exposure decreases digestive efficiency from decreased gut blood flow, growth may be limited in high-density white-sturgeon-culture tanks. Blood flow to the splanchnic organs typically decreases in unfed exercising or struggling teleosts. Although hypercapnic exposure did not affect gut blood flow in white sturgeon, the associated struggling significantly decreased it. An increased number of struggle events occurred when white sturgeon were exposed to hypercapnia, compared to when they were exposed to normocapnia. Thus, the stress associated with hypercapnia could increase struggling, with consequent decreases in gut blood flow, under hypercapnic culture conditions. Interestingly, the relative gut blood flow (% of cardiac output) measured in white sturgeon was approximately half of that measured in Atlantic cod (*Gadus morhua*), indicating a possible reduced splanchnic perfusion scope in white sturgeon, compared with Atlantic cod.

Osmoregulation

Because of the anadromous green sturgeon's threatened-species status, physiological aspects of the juveniles' acclimation to seawater have been studied to assist in its protection. Semi-anadromous shortnose sturgeon (*A. brevirostrum*) and anadromous European Atlantic sturgeon (*A. sturio*) juveniles apparently move into low-salinity areas, and in the latter case, move into seawater after several years. Similarly, juvenile Atlantic sturgeon (*A. oxyrhinchus*) have been reported to move into estuaries and eventually to the ocean after 2–6 years. The timing of seawater entry in juvenile green sturgeon is unknown, although physiological studies and field-based evidence indicate that fish move into seawater between 6 months and 3 years of age. Laboratory-based studies showed that green sturgeon can osmo- and ionoregulate in seawater for long periods of time from as young as 6 months of age, with fish becoming better adapted with increasing age and body-size. Juvenile green sturgeon may not experience high salt concentrations prior to direct entry into seawater (e.g., because of seasonal sandbar occurrences across the mouths of spawning rivers), suggesting that these juvenile fish must be physiologically prepared to hypo-osmoregulate prior to oceanic entry.

In many salmonids (e.g., *Oncorhynchus* species), physiological preparative changes for a seawater-based existence occur prior to actual exposure to hyperosmotic salinities. Using trace-element analysis, laser ablation-inductively coupled plasma-mass spectrometry, to analyze differences in freshwater and seawater elemental signatures between calcified growth zones of pectoral fin rays, it was determined that juvenile green sturgeon from the Klamath River move into seawater between the first and second growing seasons (6–18 months of age). After the initial movement into seawater, the juvenile green sturgeon appear to remain there for at least 5 years, as indicated by the constant high Sr/Ba ratio concentrations in growth zones 2–6 of the fin-ray sections. Although field data are limited, few green sturgeon between 3 and 13 years of age are found in the Klamath estuary. Long-distance migrations are known to occur in green sturgeon, and, perhaps, juveniles move along the coast, remaining primarily in seawater.

After 7 weeks' acclimation to three salinities (<3, 10, and 33), anadromous green sturgeon (of three ages: 100, 170, and 533 days posthatch), Na^+, K^+-ATPase activities increased in the gills and decreased in the kidneys with increasing salinity, consistent with the change from ion reabsorption to excretion seen in many teleosts. Gill mitochondria-rich cells (MRCs) increased in size and decreased in relative abundance with fish size/age. Gill MRC Na^+, K^+-ATPase content (e.g., ion-pumping capacity) was proportional to MRC size, indicating greater abilities to regulate ions with size/age. In the gastrointestinal tract (GIT), Na^+, K^+-ATPase activities increased fourfold in the pyloric ceca, presumably due to increased drinking rates and salt and water absorption. The increased GIT fluids, solids, and ion concentrations were similar to those found in teleosts in hyperosmotic conditions, along with the very low fluid volumes in isomotic and hyposmotic conditions. However, a greater proportion of base (HCO_3^- and $2CO_3^{2-}$) was found in intestinal precipitates, rather than in fluids, which is different from teleosts. Overall, green sturgeon, and likely other sturgeon species, osmo- and ionoregulate with similar mechanisms to more-derived teleosts, although acclimation to hyperosmotic salinities may be more dependent on body size.

Swimming Performance

Swimming performance (e.g., as measured in cm s^{-1}, in a laboratory flume) generally increases with increasing body size as juvenile sturgeon grow. An interesting exception was noted in anadromous green sturgeon when they reached the size required for seawater tolerance (i.e., ~30 cm total length (TL)). During a critical (autumnal) season after reaching this size, the critical swimming velocity (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance) decreased with further increases in size for a period of several weeks. If their (decreased) swimming performance did not match the increased river velocities associated with autumnal rains, juvenile green sturgeon of sufficient (seawater-tolerant) size would drift downstream, presumably migrating to the ocean. Juveniles of the same size tested later (winter) failed to show this decline in swimming performance with increasing size, and these fish may not migrate out of the rivers until a later time. Interestingly, this pattern is similar to that reported in some migrating salmon juveniles (smolts). At the other end of the body-size spectrum, adult white sturgeon can burst-swim up to 2.5 m s^{-1} to ascend a prototype fishway.

Stress Responses

Overall, the physiological stress responses in sturgeon seem similar to those in teleostean fishes that have been studied. Plasma catecholamines and cortisol concentrations typically increase in fish exposed to net-confinement, air-exposure, or chasing-type stressors. Increased plasma lactate and decreased plasma pH also accompany struggling or high-activity-type stress responses in both teleosts and sturgeons. However, the freshwater sturgeon of the genus *Scaphirhynchus* show reduced stress responses, compared with teleostean species that have been investigated. Juvenile green sturgeon subjected to chronic stress for 28 days show an increased maintenance metabolic rate and a decreased scope for activity, compared with unstressed control fish.

Glossary

Antibody Proteins found in blood that are used to neutralize foreign disease organisms (e.g., bacteria, viruses, and protozoa) as part of the immune defenses of an animal.

Basolateral The part of a cell or layer of cells lying closest to the blood supply faces the internal environment.

Batoid The group of cartilaginous fish commonly known as skates or rays.

Cone The sensory cell type in the eye (photoreceptor) involved in color vision and bright light conditions.

Countercurrent Flowing in opposite directions. Used for an arrangement of vessels (e.g., blood vessels or kidney tubules) such that fluid flows in one direction in one vessel that lies close to another vessel in which the flow is in the opposite direction. This arrangement allows the transfer of molecules or heat from one vessel to another in such a way as to maintain a gradient along the countercurrent vessels.

Ketone bodies Four carbon molecules produced by the incomplete oxidation of fats or from a few specific amino acids.

Lipids Group of naturally occurring hydrophobic compounds including fats, oils, waxes, phospholipids, and others.

Na^+/K^+-ATPase (NKA, the sodium pump) This is a major ATP-consuming ion pump that, directly or indirectly, drives many ion-regulatory processes, including maintaining sodium and ion gradients across cell plasma membranes and being present at high levels in ionocytes.

Osmoconformer An organism that maintains the total concentrations of all the small molecules in its body fluid compartments similar to that of the environment.

Osmolyte Small highly soluble molecules used to control the osmotic pressure of body fluid compartments.

Paracrine A cellular signal like a hormone that is released by a cell and acts on nearby cells.

Pharynx The part of the digestive tract between the mouth and the esophagus.

Pheromone A molecule that is released outside the body to signal other members of the same species.

Proprioception The ability to sense the positions of one's own body parts.

Sphyrnid Members of the family Sphyrnidae – the hammerhead sharks.

Tympanum Ear drum.

General Overview

The sharks, skates, and rays (hereafter referred to as the elasmobranchs) belong to one of the most ancient fish groups, first appearing in the fossil record perhaps as early as the late Silurian or early Ordovician 420–450 million years ago. They represent the most ancient extant jawed fishes. Although mostly known as large predatory animals, this only encompasses a few of many species of elasmobranchs. Currently, there are about 1000 known species of elasmobranchs divided into 48 families, indicating their diversity of form. They include the largest fish in the world (the filter-feeding whale shark, *Rhincodon typus*), warm-bodied fast-swimming predators such as the great white shark (*Carcharodon carcharias*), flattened bottom dwellers (the skates), and deep-sea and freshwater species.

Elasmobranchs, in general, are long-lived species that mature late and produce few offspring. Morphologically, they are relatively simple. They have no swimbladder for buoyancy. They lack a plate covering the gills and they have a skeleton composed entirely of cartilage rather than bone. They have several novel structures such as a rectal gland for salt secretion, a spiral-valve intestine for digestion, and specialized organs for producing cells of the immune system. They are reputed to be remarkably resistant to cancer but the veracity of this has not been established. The existing forms have many physiological features that may be considered primitive and some that are almost unique. Physiologists have long regarded elasmobranchs as good models for the study of certain aspects of physiology. For example, the rectal gland has been studied for decades as a model for salt excretion. Elasmobranchs also have many unique aspects in their internal biochemistry. A defining feature of this group is the use of urea for osmotic support and this has widespread consequences for their metabolic organization. As fish with many primitive features, they can give us insights into the evolution of vertebrate physiological systems.

Sensory Biology

Elasmobranchs use one of the widest arrays of senses available to any organism. They have available all of the senses that humans have, in addition to being able to sense electrical fields, magnetic fields, and vibrations using specialized sensing cells. These senses differ in the distance at which they can gather information from the environment. This allows for long-distance detection of prey and closer fine-tuning to locate prey precisely. The brain regions involved contribute to the relatively large brain:body size ratios of elasmobranchs (**see also Brain and Nervous System**: Functional Morphology of the Brains of Cartilaginous Fishes).

Olfaction

The olfactory organs of elasmobranchs are found in sacs in the nostrils (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction). The sensitivities of these to L-amino acids such as lysine and valine are similar to those of other fishes (10^{-6}–10^{-8} M), while sensitivity to L-serine is much higher (10^{-14} M). This allows gathering information about chemical sources from great distances. The part of the brain involved in processing this information is largest in those relying most on this sense. The great white shark has the largest (18% of the total brain mass), indicative of its need to detect colonies of its prey (marine mammals). The detection of sex pheromones for reproduction also relies on these organs. Elasmobranchs are well known for being able to track minute amounts of blood from long distances.

Taste

The taste buds of elasmobranchs are structurally similar to those of other vertebrates and occur in the epithelium of the mouth and pharynx (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction).

Audition

Although sharks are not known to make sounds, they can detect low-frequency sounds (20–1000 Hz) helped in part by a connection (fenestra ovalis) of the posterior semicircular canal to the tympanum not found in other vertebrates. Although they lack a swimbladder, used in other fishes to amplify sound and detect pressure changes, some parts of the inner ear can respond to pressure change (**see also Hearing and Lateral Line**: Auditory System Morphology and The Ear and Hearing in Sharks, Skates, and Rays).

Electro- and Magnetoreception

The ability to detect low-frequency electrical events is made possible by specialized electroreceptors found below the skin (**see also Detection and Generation of Electric Signals**: Active Electrolocation and Detection and Generation of Electric Signals in Fishes: An Introduction). These are called the 'ampullae of Lorenzini' and can detect impulses as low as 5 nV cm^{-1}. They are thought to be used in detecting planetary magnetic fields for navigation and prey detection (**see also Sensory Systems, Perception, and Learning**: Magnetic Sense in Fishes). These organs have also been implicated in sensing thermal gradients due to their extreme sensitivity to temperature.

Mechanoreception

As in other fishes, the lateral-line system provides the mechanoreception needed for localizing the moving objects and currents. These are important for schooling, prey detection, and mating. The basic component of the lateral-line system is the neuromast, a group of sensory hair cells covered by a gelatinous cupola. The lateral-line system can extend over the entire body with denser arrays in the head region. Some types of neuromasts are used for proprioception.

Vision

Elasmobranchs have well-developed eyes with a nearly complete (360°) visual field found in all species (**see also Vision**: Adaptations of Photoreceptors and Visual Pigments). Relative to body size, benthic batoids and sharks have the smallest eyes, while pelagic sharks have the largest eyes. In addition to an upper and lower eyelid, a protective nictitating membrane is found in carcharhinids and sphyrnids. Most elasmobranchs have a reflective tapetum lucidum that improves sensitivity in low-light conditions. The lens shape is highly variable among elasmobranchs. Elasmobranchs have both rods and multiple cones and thus can see color. The visual pigments are adapted to the wavelengths found in the habitats of each species. Deeper-water species have pigments adapted for better reception of blue-green wavelengths. Skates have a single cell type in the retina that functions as a rod at low-light intensities and as a cone at higher intensities.

Balance and Motion Detection

Elasmobranchs may have been the first vertebrates to employ three semicircular canals for the balance and perception of motion.

Muscle Physiology and Swimming

The myotome is arranged in a cone-shaped bundle that can be isolated intact, easily, making it an excellent model for studies of muscle physiology. The muscles consist of red and white fibers as in other fish (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance and **The Skeleton**: Cartilaginous Fish Skeletal Anatomy, and Cartilaginous Fish Skeletal Tissues). The pectoral fins of sharks have limited mobility and do not play a role in propulsion, while batoids use their pectoral fins for most of their propulsion. The skin of elasmobranchs is designed to reduce drag, using scale-like denticles to minimize turbulence and turbulent shear stress. The size, shape, and spacing of the denticles are correlated with the swimming speed of the fish.

Electric Organs

In addition to sensing electric fields, some elasmobranchs can produce electricity to a significant extent. There are two types of electric organs known in elasmobranchs (**see also Detection and Generation of Electric Signals**: Electric Organs and Generation of Electric Signals). One involves the production of weak electric fields by organs along the tail for communication and prey detection. This is found exclusively in skates (Rajoidei). Another involves the production of much stronger electric impulses for confusing or immobilizing prey and perhaps for defense. This is found in members of the order Torpediniformes containing four families and about 40 species. These have appropriately named genera such as *Torpedo*, *Narcine*, and *Hypnos*. In these species, the electric organ is derived from the modified gill muscles that occupy about one-sixth of the body mass.

Buoyancy Regulation

Elasmobranchs have no gas-inflated swimbladder and must rely on a variety of factors to reduce their density and hence their energy expenditure to maintain their position in the water column (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). The lack of substantial calcification of the skeletal system (bone) eliminates a major factor in reducing buoyancy. The use of density-lowering organic solutes (urea and methylamines) in high concentrations reduces the density of the various fluid compartments. These molecules act by reducing the packing of water molecules surrounding them, resulting in negative partial molal volumes in aqueous solution. Because of this, plasma density and presumably density of most tissues are less than that of seawater.

A third major contributor to buoyancy is the large fatty liver. The liver of elasmobranchs is unusually large in deep-water species (**Figure 1**). In general, the larger the liver the more fat (oil) it contains with some species having livers with 80% oil by weight. Elasmobranchs' liver oil contains triacylglycerols (TAGs), alkyldiacylglycerols (DAGEs), wax esters, and squalene. Deep-water species tend to have either high DAGE (up to 89%) or high squalene (up to 79%) (**Figure 1**). Shallow-water pelagic and benthic species mostly use TAG (**Figure 1**). The most buoyant liver lipids (DAGEs) are spared during periods of starvation and are synthesized if needed to increase buoyancy.

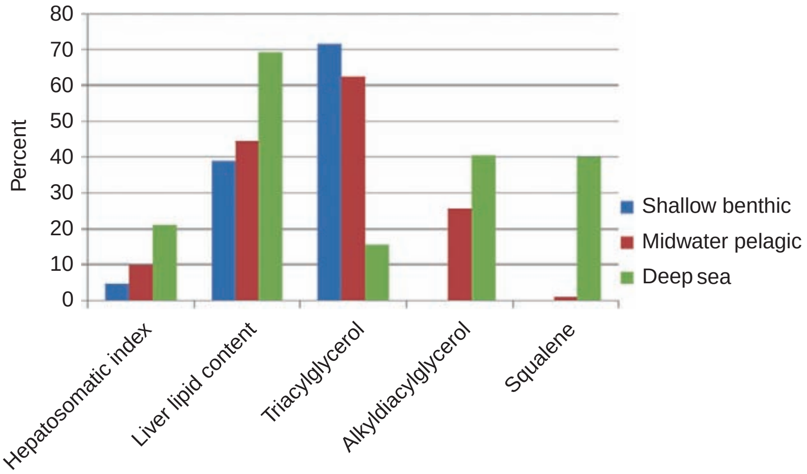

Figure 1 Hepatosomatic index (liver weight as % of body weight), liver lipid content (lipid weight as % of liver weight) and percentages of specific lipids (% of liver lipids) in shallow-water benthic, shallow-water pelagic, and deep-sea elasmobranchs. Values are estimated from multiple sources.

Deep-Water Elasmobranchs

While many elasmobranchs exist over a wide range of depths, some spend most of their lives at great depth. Adaptations to deep water include higher lipid content in the liver, higher proportions of diacylglycerols and squalene in liver lipids, and altered proportions of methylamines and urea. The altered liver lipids help maintain neutral buoyancy to reduce the energy requirements of locomotion. Higher levels of trimethylamine-*N*-oxide (TMAO) and lower concentrations of urea have been observed and these may help offset the detrimental effects of high pressure on proteins and membranes. Enzyme activities of deep-water elasmobranchs are lower than those of their surface counterparts.

Freshwater Elasmobranchs

Only a small percentage (less than 5%) of elasmobranchs can live in freshwater compared to 40% of teleost species. The basis for this has been speculated upon and may relate to the urea requirement of proteins. Some species such as the bull shark (*Carcharhinus leucas*) enter and leave freshwater while others such as some African (e.g., African freshwater stingray, *Dasyatis garouaensis*) and Southeast Asian (e.g., white-edged freshwater whipray, *Himantura signifer*) species spend their entire lives in freshwater. All of these species undergo reductions of urea levels in tissues but still maintain relatively high concentrations (80–200 mM). This may be necessary to maintain the function of urea-requiring proteins. Only one group, the members of the family Potamotrygonidae of South America, resides entirely in freshwater and maintains negligible urea levels. This group has lost the capacity for urea synthesis and those parts of the kidney responsible for urea retention. The rectal gland is also reduced or absent in this group (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes).

All freshwater elasmobranchs give birth to live young ones perhaps to avoid the osmotic challenges faced by external eggs in freshwater.

Sensory traits also evolved for life in freshwater. For example, optimal detection of electrical signals in freshwater is associated with shorter canals in the ampullae of Lorenzini. These have been termed ‘miniampullae’ as found in *H. signifer* or ‘microampullae’ as found in the Potamotrygonidae.

Because of the reduced need to direct nitrogen to urea via glutamine synthetase, levels of this enzyme are lower and glutamate dehydrogenase levels are higher in liver of freshwater species than in marine species. The reduced need for urea allows amino acids to be deaminated via glutamate dehydrogenase (GDH) and the ammonia to be eliminated. Ammonia excretion rates of freshwater elasmobranchs are higher than those of marine species (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia).

Respiration

Elasmobranchs have from five to seven gill slits, with seven being the ancestral condition. The gills have a typical countercurrent flow of blood against the water to optimize gas exchange. The popular perception that all sharks need to swim continuously to breathe is a myth. Some elasmobranchs do ram-ventilate or force water through the gills by swimming, but others including the skates and rays use muscles in the head region to pump water across the gills and do not need to swim to breathe. Under hypoxic conditions, ram-ventilating species swim faster to improve oxygen uptake. In skates and rays with mouths that are located ventrally, water enters and may exit via the spiracle.

The metabolic rates of elasmobranchs are comparable to those of teleosts when factors such as temperature and lifestyle are similar. Blood flow to the gills can be increased or decreased as needed for improved ventilation as in other fishes.

Circulation

The circulation of elasmobranchs is similar to that of the other fishes, with deoxygenated blood first going to the gills where it picks up oxygen and loses carbon dioxide (**see also Circulation**: Circulatory System Design: Roles and Principles). The oxygenated blood then flows to the rest of the body and returns to the heart. The heart has four chambers: the sinus venosus, the atrium, the ventricle, and the conus arteriosus (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping). The sinus venosus receives deoxygenated venous blood and delivers it to the atrium. Contraction of the atrium moves blood into the muscular ventricle that contracts forcing the blood into the conus arteriosus and thence to the gills. The ventricle has a compact outer layer and a spongy inner layer. There are coronary arteries supplying the conus and ventricle with oxygenated blood from the gills (**see also Design and Physiology of the Heart**: The Coronary Circulation).

Reproduction

All elasmobranchs employ internal fertilization and display one of the two types of reproduction (oviparity, i.e., egg laying, and viviparity, i.e., live birth) (**see also Social and Reproductive Behaviors**: Sexual Behavior in Fish). The male has two external intromittent organs called 'claspers' with grooved surfaces to introduce sperm into the female. Seawater is used by the muscles of the claspers to pump sperm into the female. In egg-laying species, a tough leathery egg case is deposited around the egg, and this is released to the environment soon after fertilization. Among livebearers (55% of all elasmobranch species and 100% of freshwater species), there are further two reproductive types (placental and aplacental). The embryos of aplacental forms rely on yolk reserves or eat unfertilized eggs or other embryos. Placental embryos either feed on placental milk produced by a placental analog (uterine epithelium) or form a true placenta with the maternal and embryonic tissues in close contact.

In all cases of viviparity, the embryo is released in a highly developed state and no further maternal care is given.

Osmo- and Ionoregulation/ Osmoconformation

As osmoconformers, marine elasmobranchs use an unusual combination of organic solutes to balance osmotically (actually slightly hypertonic) with seawater. Urea accounts for 40% of osmotic support, and methylamines and/or amino acids another 20% with inorganic ions making up the rest (**Figure 2**). Urea is a small molecule that diffuses almost as rapidly in water as do the water molecules themselves. This may facilitate rapid osmotic adjustment within the various body fluid compartments. Rapid movement of urea and water across membranes requires pores such as aquaporins, and these have been found in elasmobranchs (**see also Osmotic, Ionic and Nitrogenous-Waste**

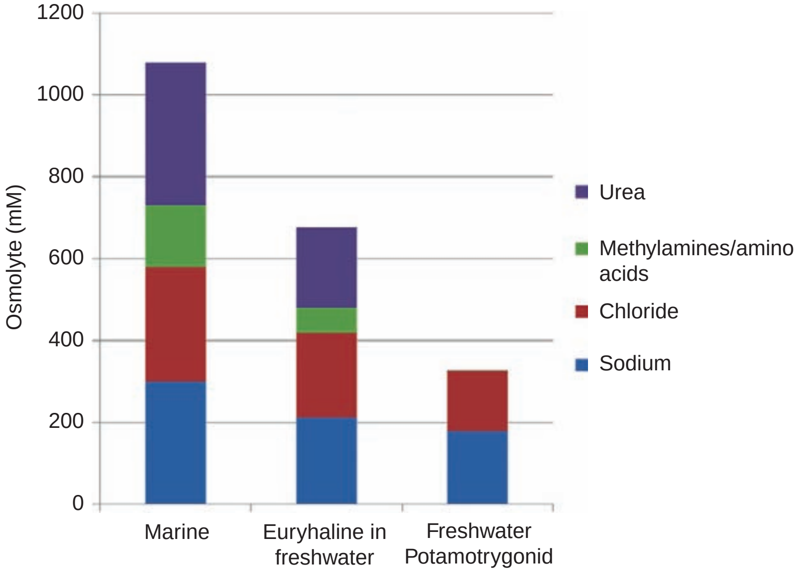

Figure 2 Major solute concentrations in plasma of marine, and freshwater elasmobranchs.

Balance: Water Balance and Aquaporin). The slightly hypertonic condition means elasmobranchs do not need to drink seawater to replace water losses. This reduces but does not eliminate the intake of salt (Na^+ and Cl^-). The activities and abundance of Na^+/K^+ adenosine triphosphatase (ATPase) in gills of marine elasmobranchs are an order of magnitude lower than those of teleost fish. Unlike teleost fishes, salt excretion is accomplished primarily by the rectal gland, instead of the gills. The rectal gland is a finger-shaped structure with a lumen emptying into the rectum (**see also Role of the Gut**: Dogfish Rectal Gland). The mechanism of action is similar to that of the chloride cells of teleost fishes. This involves lowering intracellular sodium by the action of a Na^+/K^+-ATPase on the blood side causing sodium to enter with K^+ and Cl^- via an Na^+/K^+2Cl^- symporter (**Figure 3**). The transepithelial potential generated causes Na^+ to move between the cells into the lumen. Chloride follows through a chloride channel on the lumen side. The secretion is regulated at several levels by nervous, hormonal, and paracrine signals. The fluid produced contains levels of sodium and chloride similar to that of seawater. Since marine elasmobranchs do not drink seawater, they must bring in ions such as Mg^{2+} and Ca^{2+} from food in the gut (**see also Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation).

Digestion

As carnivores, elasmobranchs take in mainly protein and lipid. They rely on many of the same enzymes for digestion as do other vertebrates. The elasmobranchs are the most ancestral extant vertebrates capable of acid secretion in the stomach (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion). Acid proteases, such as pepsin, act to initiate digestion of protein. Gastrin or gastrin-like peptides are the signals for acid secretion. Chitinases are found in species feeding on crustaceans. In the intestine, alkaline phosphatase, elastase, carboxypeptidases, trypsin, colipase, alpha-amylase, saccharase, and dipeptidase are secreted from the pancreas stimulated by secretin and cholescystokinin (CCK).

Lipid digestion involves bile salts and pancreatic lipase as in other vertebrates. Pancreatic colipase activates the lipase in the presence of bile salts. Bile is used for lipid solubilization using bile acids that form alcohol sulfate esters. The two main bile alcohols are chimaerol and scymnol. Bile release is induced by gastrin and CCK-related peptides. The pancreatic lipase acts primarily on the 1 and 3 positions of TAGs. This enzyme may also be involved in hydrolysis of wax esters. Digestion of a range of carbohydrates also occurs with the appropriate enzymes and many of these are localized not only in the digestive tract but also in the tissues of the immune system (spleen, Leydig's organ, and epigonal organ) for digesting bacteria. Food takes longer to pass through the gut of elasmobranchs, compared to that of teleosts, due to the relatively inefficient spiral valve intestine.

Intermediary Metabolism

The intermediary metabolism of elasmobranchs is different from that of the other vertebrates in several ways. These include aspects of nitrogen, lipid, and ketone body metabolism. All of these differences can be attributed to the heavy reliance on urea for osmotic support.

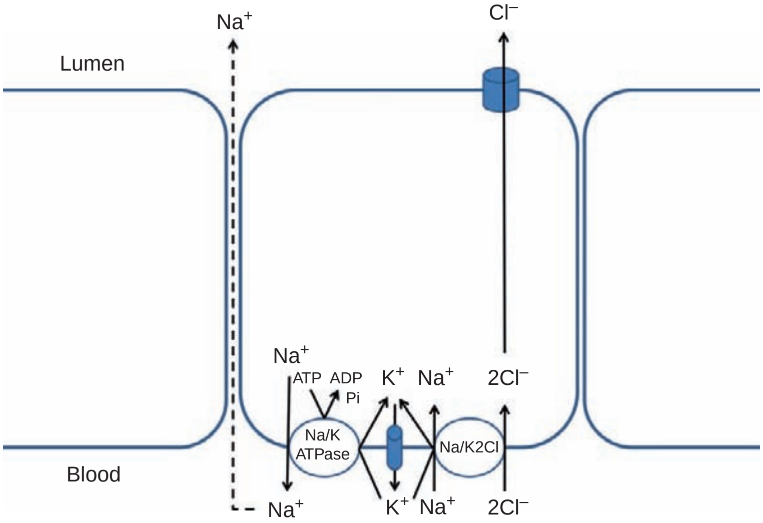

Figure 3 Ion movements for salt secretion in rectal gland of a marine elasmobranch.

Carbohydrate Metabolism

Carbohydrate metabolism of elasmobranchs is not as well developed as in more derived fishes. Elasmobranchs lack insulin-dependent glucose transporters and thus have a slow insulin response with no antagonism by glucagon. The activities of lactate dehydrogenase are lower than those of comparable teleost fish. During exhaustive exercise, glycogen is broken down and lactate is accumulated anaerobically in part because pyruvate dehydrogenase activity is low in white muscle and is not activated during exhaustive exercise or recovery, unlike the situation in teleost fish. The extent to which carbohydrate is used aerobically during nonexhaustive exercise is not known, although it is likely used in conjunction with amino acids and ketone bodies.

Nitrogen Metabolism

A major factor in the organization of nitrogen metabolism is the overriding impact of urea synthesis (**see also Nitrogenous-Waste Balance**: Ureotelism). The urea lost at the gills (although minimized) must be replaced. Unlike the situation in mammals and many other vertebrates, urea synthesis via the urea cycle requires glutamine instead of ammonia as the nitrogen donor via carbamoyl phosphate synthetase III (CPS III) (**Figure 4**). The heavy reliance on glutamine results in low circulating levels of glutamine, especially in food-deprived individuals. Dietary glutamine is insufficient to supply the needed glutamine, and a considerable recycling of ammonia from amino acid degradation is needed for glutamine synthesis. The need of nitrogen for urea synthesis means that very little ammonia is excreted compared to bony fishes. The main enzyme involved in ammonia assimilation is glutamine synthetase, and this is found in high activities in many elasmobranch tissues including muscle. The K_m for ammonia for this enzyme is very low (15 μM), allowing it to scavenge ammonia at very low concentrations. The subcellular compartmentation of urea synthesis in the urea cycle is different from that of other vertebrates (**Figure 4**), with arginase (the enzyme producing urea from arginine) being found in the mitochondrion. The importance of this has not been established, but a special transporter has been found to facilitate movement of urea out of the mitochondrion.

Urea is a disruptor of hydrophobic interactions and could disrupt protein and membrane structure if it were not for the counteracting effect of methylamines such as TMAO. A 2:1 ratio of urea to methylamines is optimal for counteraction in many cases. However, not all elasmobranch proteins are disrupted by urea, and some may be intrinsically insensitive to these solutes. Urea has a fluidizing effect on membranes, and some elasmobranch membranes may contain a higher proportion of saturated phospholipid fatty acids to compensate for this.

The counteracting methylamines, especially TMAO, are largely taken in from the diet and only members of the Carcharhiniformes and Orectolobiformes are known to have the capacity to synthesize these molecules *de novo*.

The high levels of the glutaminase in heart and red muscle of elasmobranchs have led to the suggestion that

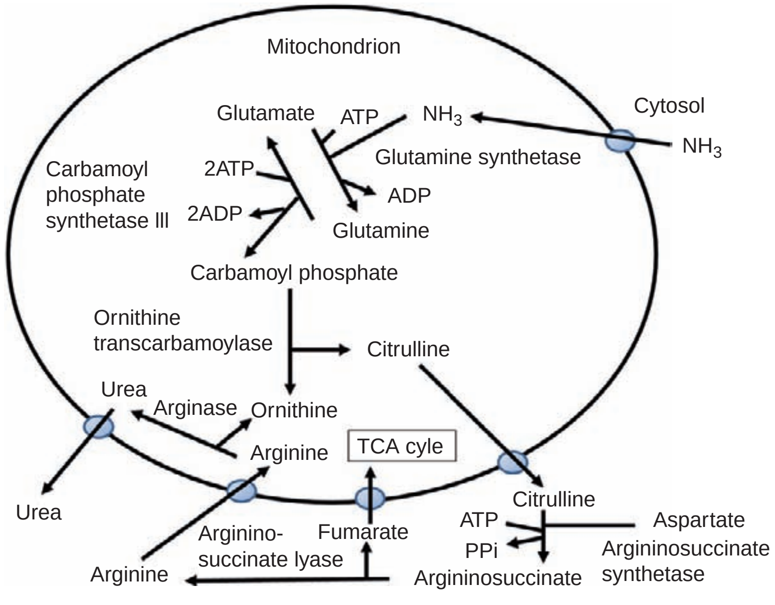

Figure 4 Compartmentation of key enzymes and metabolites in the hepatic urea cycle of a marine elasmobranch. Not all intermediates are displayed.

amino acids are important fuels for exercise. This has not yet been demonstrated.

Lipid Metabolism

The elasmobranchs do not rely on lipids as an energy source for locomotion, and the levels of circulating non-esterified fatty acids (NEFAs) in the plasma are the lowest of any vertebrate. In most vertebrates, the plasma NEFAs are used for rapid delivery of lipids to tissues such as muscle and heart. Fatty acids are not very soluble in water and must be carried on specialized proteins such as albumin. Albumin is apparently absent in the plasma of marine elasmobranchs, based on fatty acid binding studies, but the existence of the protein in elasmobranchs has not been ruled out by genome analysis. The enzymes of fat catabolism (e.g., carnitine palmitoyltransferase) are absent in the heart and muscle of elasmobranchs. The elasmobranch kidney and rectal gland have some capacity for lipid oxidation.

The transfer of lipids from reserves and dietary intake takes place via plasma lipoproteins as in other vertebrates. All the plasma lipoproteins found in other vertebrates, very low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs), have been found although the HDL levels are lower than those of other vertebrates. Hydrocarbons and DAGEs are also transported on these lipoproteins especially via LDL.

Ketone Body Metabolism

Unlike the situation in most vertebrates, where ketone bodies are only used extensively during periods of starvation to replace fuels such as glucose needed by the brain, elasmobranchs use ketone bodies routinely as aerobic fuels in tissues such as heart and, perhaps, red muscle during nonexhaustive exercise. Elasmobranchs have high levels of the enzymes of ketone body metabolism in these tissues and high circulating levels of ketone bodies. This strategy allows carbon from fatty acids partially oxidized in the liver to be transported as ketone bodies without the need to transport NEFAs via albumin in the plasma. Ketone bodies are highly soluble compounds.

Excretion

Because marine elasmobranchs are slightly hypertonic, there is a net influx of water unlike the situation in hypotonic marine teleost fish. One of the roles of kidney, therefore, is to produce a hyposmotic urine (~80% of seawater osmolality) to offset the water influx. Another major role of the kidney is urea retention. As the major osmolyte, urea conservation is essential. While the gills have mechanisms to help retain urea, the kidneys must also recover urea from the filtrate before excretion takes place. The kidneys of marine elasmobranchs are complex. The kidney tubules are very long with four loops and a countercurrent arrangement of capillaries that allow them to produce urine without urea in it. Urea transporters, which are sodium-linked with very low K_m's (~0.7 mM), allow urea to be recovered to very low levels, have been identified in the kidney. The main constituents of the urine are sodium and chloride, with magnesium, phosphate, and sulfate making up most of the remainder.

Elasmobranchs lose both ammonia and urea, primarily at the gills, but at rates much lower than in marine teleost fish. This is because both the molecules are in high demand and need to be conserved. Any losses are usually due to inefficiencies in the retention and recovery systems. Only a small percent of an injected load of urea is lost per day, orders of magnitude less than that lost by other fish. This efficient retention system is due to both structural and transport-mediated phenomena. The gills of marine elasmobranchs have transporters for recovery of any urea that might escape at the gills and a high cholesterol content in the basolateral membrane of the gill that further reduces gill permeability to urea.

Neurophysiology

The osmotic and ionic environment of the nerve cells of the brain is isolated from that of the blood by a blood–brain barrier as in other vertebrates, but it is leakier than that of higher vertebrates. This is because there are no tight junctions between endothelial cells – only between glial cells in the perivascular region. The brain is enveloped in a fluid (cranial fluid, extradural fluid, and perimeningeal fluid) different in composition from the cerebrospinal fluid and both are regulated independently of the blood. The elasmobranchs are the earliest known vertebrate group to use myelin around their nerves to improve conduction velocity.

Immune System and Disease Resistance

In the absence of bone and bone marrow, much of the generation of red and white blood cells occurs in two organs unique to elasmobranchs: the Leydig's organ and the epigonal organ. The epigonal organ is found in various locations in the body cavity, often near the gonads. It contains sinuses containing developing leukocytes (white blood cells) analogous to mammalian bone marrow. The extent of erythropoiesis in the epigonal organ can be judged by the color. The more red the greater the extent of red blood cell production. The Leydig's organ is usually found in close association with the esophagus and is histologically similar to the epigonal organ. Both the organs

Table 1 Hormones and their functions in elasmobranch fishes

Hormone	*Occurrence and function in elasmobranchs*
Adrenaline	Present. Glomerular diuresis, mobilization of energy reserves, regulation of blood pressure, regulation of blood flow to gut, regulation of perfusion and ventilation of gills
Adrenocorticotropic hormone (ACTH)	Present. Regulation of production of 1-alpha-hydroxycorticosterone, hyperglycemia
Amylin	Not reported for elasmobranchs
Angiotensin I	Present. Precursor to angiotensin II
Angiotensin II	Present. Modulation of HPI axis, vasoconstriction, stimulation of drinking, stimulation of 1-alpha-hydroxycorticosterone; regulation of kidney secretion, glomerular filtration rate, and urine flow rate, inhibition of salt secretion by rectal gland (due to reduced blood flow)
Arginine vasotocin	Present. Regulation of urine flow and GFR; vasoconstriction, influence on urea reabsorption and osmoregulation in high salinities
Atrial natriuretic peptide	Not reported for elasmobranchs
Bombesin	Present. Increased blood flow to gut, inhibits rectal gland secretion
Calcitonin	Present. Regulation of calcium homeostasis during uterolactation, fetal nutrition
Cholecystokinin	Present. Stimulation of bile and pancreatic enzymes
Corticotrophin-releasing factor (CRF)	Not reported for elasmobranchs.
C-type natriuretic peptide CNP	CNP3 only reported. Increase in urine flow rate, GFR, increased clearance of urea, Na and Cl, stimulation of salt secretion in rectal gland, inhibition of drinking
Endothelin I	Present. Stimulation of salt secretion in rectal gland
Enkephalin	Met- and leu-enkephalinpresent. Function not established
17beta-estradiol	Present. Stimulation of vitellogenin synthesis in liver, stimulation of growth of oviducal gland, development of follicles, modulation of placental function, and regulation of gonad development
Follicle-stimulating hormone (FSH)	Not reported for elasmobranchs
Galanin	Present. Vasoconstriction
Gastric-inhibitory polypeptide	Not reported for elasmobranchs
Gastrin	Present. Stimulation of gastric acid secretion
Gastrin-releasing peptide	Presents. Increased blood flow to gut
Glucagon	Present. No effect on blood glucose
Glucagon-like peptides 1 and 2	Not reported for elasmobranchs
Gonadotropin-releasing hormone	Present.
Growth hormone	Present. Function not determined
1-alpha-Hydroxycorticosterone	Present. Control of rectal gland secretion, sodium and chloride retention
Insulin	Present. Decreases plasma glucose, increases muscle and liver glycogen, reduces plasma free amino acids, increases lipid uptake
Insulin-like growth factor I (IGF -I)	Present. Increased cartilage growth
Hypocalcin	Not reported for elasmobranchs
Leptin	Present. Function not determined
Luteinizing hormone	Not reported for elasmobranchs
Melanocyte-concentrating hormone	Present. Color change
Melanocyte-stimulating hormone (MSH)	Present. Color change
Melatonin	Present. Regulation of light production by photophores in deep-water elasmobranchs
Neuropeptide Y	Present. Increased blood flow to gut, inhibits rectal gland secretion
Neurotensin	Present. Function not determined
Noradrenaline	Present. Mobilization of energy reserves, increase blood pressure, reduced blood flow to gut, increased perfusion and ventilation of gills
Pancreatic polypeptide Y	Not reported for elasmobranchs
Parathyroid hormone	Parathyroid hormone-related peptide reported. Potential role in ionoregulation
Peptide YY	Present. Function not determined
Progesterone	Present. Inhibition of vitellogenin production, regulation of gonad development
Prolactin	Present. Increases GFR, stimulates melanosome dispersion
Propiomelanocortin	Not reported for elasmobranchs
Relaxin	Present. Increase in compliance of cervix, regulation of semen quality

(*Continued*)

Table 1 (Continued)

Hormone	*Occurrence and function in elasmobranchs*
Scyliorhinin I	Present. Increased blood flow to gut
Scyliorhinin II	Present. Increased blood flow to gut
Secretin	Present. Stimulation of pancreatic secretions
Somatostatin	Present. Inhibition of gastric acid production, inhibits rectal gland secretion
Stanniocalcin	Not reported for elasmobranchs
Testosterone	Present. Regulation of oviducal sperm storage, regulation of oviposition, regulation of gonad development, regulation of mating behavior
Thyroxine	Present. Regulation of urea synthesis
Triiodothyronine	Present. Regulation of urea synthesis, regulation of expression of amino acid enzymes in liver, development of embryos
Thyroid-stimulating hormone	Present.
Thyrotropin-releasing hormone	Present.
Urotensin I	Present. Blood pressure regulation
Urotensin II	Not reported for elasmobranchs
Urotensin III	Not reported for elasmobranchs
Vasoactive intestinal peptide (VIP)	Present. Increases GFR, reduces perfusion of gut and gut motility, stimulates salt secretion by rectal gland

have cells that secrete immunoglobulin. There are species-specific differences in the size of each organ with one or the other sometimes being reduced or absent. There is generally a reciprocal relationship between the sizes of these two organs such that in species lacking one, the other is larger. Elasmobranchs have lymphocytes, granulocytes, monocytes, and macrophages involved in the immune response (**see also Blood**: Cellular Composition of the Blood). Of these, lymphocytes account for almost half of the circulating leukocytes. Elasmobranchs are the first vertebrate group to develop a fully functional adaptive immune response involving antibodies, T-cell receptors, major histocompatibility proteins, and recombination-activating gene proteins. The antibody system involves a Y-shaped system with two light and two heavy chain proteins as in other higher vertebrates. To generate a large array of these, elasmobranchs have more than 100 copies each of the genes for the heavy and light chains. This contrasts with only a few copies of these genes in other vertebrates and a reliance on cutting and splicing these to generate antibody diversity.

Endocrinology

Elasmobranchs have many of the typical vertebrate hormones (**see also Hormonal Control of Reproduction and Growth**: Endocrine Regulation of Fish Reproduction; **Integrated Function and Control of the Gut**: Endocrine Systems of the Gut, **Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids, The Hormonal Control of Osmoregulation in Teleost Fish and **Hormonal Responses to Stress**: Catecholamines), although the number of isoforms of some hormones is less than those found in higher vertebrates. Elasmobranchs have a pancreas with both exocrine and endocrine functions unlike most teleosts where these functions are in separate structures. As in higher vertebrates, there is a functional hypothalamic–pituitary–interrenal axis with associated hormones. **Table 1** summarizes the main vertebrate hormones and their known function (if any) in elasmobranchs. Much more work is needed to establish roles for many of these hormones. Elasmobranchs have a unique stress hormone, 1-alpha-hydroxycorticosterone, which replaces cortisol in the stress response (**see also Hormonal Responses to Stress**: Hormone Response to Stress). Binding of this hormone to a receptor has been demonstrated in the gills of elasmobranchs and it may function in regulating salt and urea permeability.

Endothermy in Elasmobranchs

A few elasmobranchs have the capacity to maintain parts of their bodies above ambient temperature (**see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks). The extra speed made possible by warm muscles is an advantage when feeding on cold-bodied fishes or squids and on marine mammals. In endothermic sharks, the red muscle is localized in the interior of the body, close to the vertebral column unlike the peripheral location of that tissue in other sharks. Heat generated by this muscle is trapped in the muscle by a countercurrent arrangement of blood vessels called 'retia mirabilia' (**see also Design and Physiology of Arteries and Veins**: The Retia). Retia have been found above the liver (maintaining a warm stomach) in red muscle and in the head (carotid rete, keeping the eyes warm). The fast sharks of the family Lamnidae have documented higher body temperatures, and members of the Alopiidae and the some mobulids have the anatomical features needed for endothermy. The lamnids include the great white shark (*C. carcharias*), the longfin and shortfin mako sharks (*Isurus paucus* and *Isurus oxyrinchus*, respectively), the porbeagle (*Lamna nasus*), and the salmon shark (*Lamna ditropis*).

Acid–Base Physiology

The gills of elasmobranchs play an important role in acid–base regulation (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). Ion regulation and acid–base regulation are connected in that the uptake of Cl^- is coupled to the extrusion of HCO_3^- via the Cl^-/HCO_3^- exchanger, and Na^+ uptake is coupled to the extrusion of H^+ via the Na^+/H^+ exchanger. Carbonic anhydrase, which interconverts carbon dioxide and bicarbonate in maintaining acid–base balance, is found in gill cells. The kidney has a limited capacity for hydrogen-ion excretion.

Summary

Many aspects of the physiology of elasmobranchs reflect their early evolutionary position and offer insights into the pathways leading to the more sophisticated physiological systems of higher vertebrates. Their continued existence attests to the early optimization of their physiological systems. Many aspects of their physiology require more extensive investigation.

Glossary

Forward genetics The induction of random mutations in an organism followed by examining of the resulting phenotype.

Fusiform A body shape characterized by tapering at both the anterior and the posterior ends.

Gastrulation Migration and rearrangement of cells after embryo undergoes proliferation to increase cell number (cleavage stage) to create three primary germ layers during early development.

Insertional mutagenesis Insertion of one or more bases into the genome.

Retrovirus An RNA virus that is replicated in a host cell via the enzyme reverse transcriptase to produce DNA from its RNA genome, which is then incorporated into the host's genome.

Reverse genetics Identification of gene function through selective manipulation of that gene followed by analysis of the arising phenotype.

Introduction

The zebrafish, *Danio rerio*, is now one of the mostly widely used experimental animals in biological and biomedical research. This popularity is primarily due to their reasonably fast generation time and the vast array of genomic resources available, which allow for manipulations at the smallest scale. Furthermore, they are almost transparent during the majority of their embryonic development, making them amenable to direct visualization of developmental processes. Until recently, however, their use in physiological studies has been limited and, for the most part, the vast majority of the published literature on these fish does not work toward understanding their physiology, but rather understanding basic biological processes. They are also extremely small when it comes to tissue sampling.

With the incorporation of genomics tools into physiological research, fish physiologists are now flocking to this small cyprinid to ask new and exciting questions about physiology, adaptation (**see also Responses and Adaptations to the Environment**: General Principles of

Biochemical Adaptations), and how this animal responds to environmental challenge. This article, however, focuses primarily on the natural history, development, and genomic resources available in this important biological model. Aspects of their physiology are covered elsewhere in this encyclopedia.

Appearance

The zebrafish is aptly named for the five uniform, horizontal blue or black stripes that are located on the side of the body, all of which extend from the operculum through to the caudal fin (**Figure 1**). The fish shape is characterized by tapering at both the anterior and the posterior ends (commonly referred to as fusiform) and it is laterally compressed with an upward directed mouth. Zebrafish are sexually dimorphic, meaning males and females look different. Male zebrafish are thinner and more torpedo shaped, with yellow stripes between the blue/black stripes; female zebrafish are generally larger, with white bellies and silver stripes instead of yellow ones. Adult zebrafish have been recorded to grow up to ~6.5 cm, but for the most part captive zebrafish do not exceed 4 cm in length.

Taxonomy

Zebrafish are a tropical freshwater fish belonging to the family Cyprinidae from the taxonomic order Cypriniformes. The Cyprinidae is the largest family of freshwater fish with roughly 2500 species in just over 200 genera. Of particular note, this family includes the carps (e.g., the anoxia-tolerant Crucian carp (*Carassius carassius*; **see also Bony Fishes**: Crucian Carp) and the goldfish (*Carassius auratus*) as well as the true minnows.

The genus *Danio* was at one point comprised of somewhere between 35 and 50 species, but this traditional grouping of all species under the genus *Danio* was split and now the species are divided among two different genera, *Danio* and *Davario*. An example phylogeny showing the split in species is depicted in **Figure 2** and was originally constructed in order to examine coloration patterns among different species.

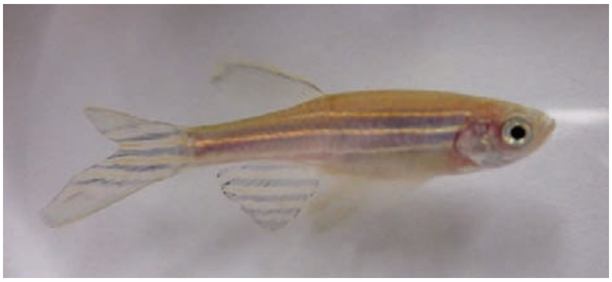

Figure 1 Photo of a male *Danio rerio.*

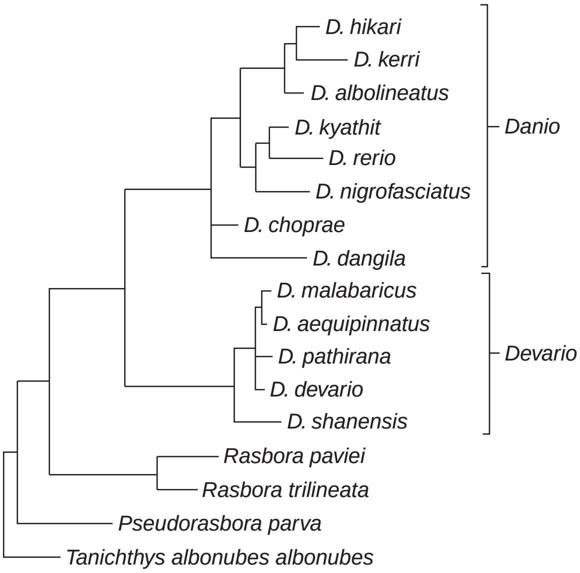

Figure 2 Phylogenetic relationship of 13 species of *Danio* and *Davario* based on maximum likelihood and Bayesian analysis of 12S and 16S ribosomal DNA sequence. Phylogeny has been modified from Parichy DM (2006) Evolution of *Danio* pigment pattern development. *Heredity* 97: 200–210.

Distribution and Natural History

Zebrafish originate from the waters from the southeastern Himalayan region, but there is some controversy over their precise natural range. Recent analysis of collection records suggest that the natural geographic range of zebrafish extends from Pakistan to the western edge of Myanmar and from Nepal in the north to the Indian state of Karnataka in the south. They are primarily found in streams, canals, ditches, rice fields, and other slow-moving bodies of water with clay, silt, or cobble substrates. The waters are typically still and clear, roughly ranging in temperature between 27 and 34 °C and a slightly alkaline pH (7.9–8.5). In these environments, they mostly feed on mosquito larvae and other small insects, but they are omnivorous and have also been observed feeding on phytoplankton. They are unlikely to experience large variations in temperature within a single body of water, although the temperatures are warm and there is likely temperature variation over their natural range. The highly vegetated nature of their water and the fact that it can be stagnant likely means zebrafish experience large variations in dissolved oxygen on a daily basis (**see also Hypoxia**: The Expanding Hypoxic Environment). Oddly, despite the fact that hypoxia is likely prevalent in their natural environment, only a small amount of work has been done on their hypoxia tolerance. For more information on hypoxia response of zebrafish, the reader is referred to **Hypoxia**: Respiratory Responses to Hypoxia in Fishes.

Lifecycle and Reproduction

The typical life span of zebrafish is roughly 2–3 years, but it can be up to 5 years under ideal conditions in captivity, but probably much shorter in the wild. The generation time from a fertilized egg to a reproductively active adult is between 3 and 4 months. Adult females are able to spawn every 2–3 days and each female can lay up to 200 eggs/week, but ovulation and spawning only occur in the presence of a male. Zebrafish mate in the morning and it is well known that light is the primary cue for mating. Within 30 min of the lights being turned on (if in the laboratory) or sunrise (if in the natural environment), a female will sometimes lay hundreds of eggs, which are subsequently fertilized by a male. At high densities in aquarium-bred zebrafish, it is typical to observe group-spawning behavior where egg fertilization is done in an indiscriminate fashion. Upon the release of eggs, embryonic development begins immediately, but if not fertilized, growth is halted after the first few cell divisions and the eggs die or are eaten.

Upon fertilization, the eggs almost immediately become transparent and development progresses quickly (see **Figure 3** for an outline of the lifecycle of a zebrafish (**see also Reproduction**: The Diversity of Fish Reproduction: An Introduction). Within 4 h, the fertilized egg has gone from a single cell to ∼1000 cells. Shortly after that, the embryo undergoes gastrulation, which is the developmental stage associated with the formation of a double-walled embryo resulting from the invagination of the blastula, which is associated with the differentiation of the ectoderm into the mesoderm and endoderm. The development of discreet organs, referred to as organogenesis, begins between 16 and 24 h postfertilization (hpf) and the precursors to all major organs appear within 36 hpf. For example, the zebrafish heart starts off as a 'heart tube' which is formed by 18 hpf and rhythmic, peristaltic contractions can be observed by 24 hpf (**see also Circulation**: The Circulatory System: An Introduction). Hatching Ultimately takes place 48–72 hpf, depending on the temperature, and feeding and swimming begin at roughly 72 hpf. Within 2–3 months, the zebrafish have matured into adults and can then begin breeding.

Although the reproductive behavior of captive zebrafish is well known, the reproductive behavior of wild zebrafish is largely unexplored. Wild-reared zebrafish

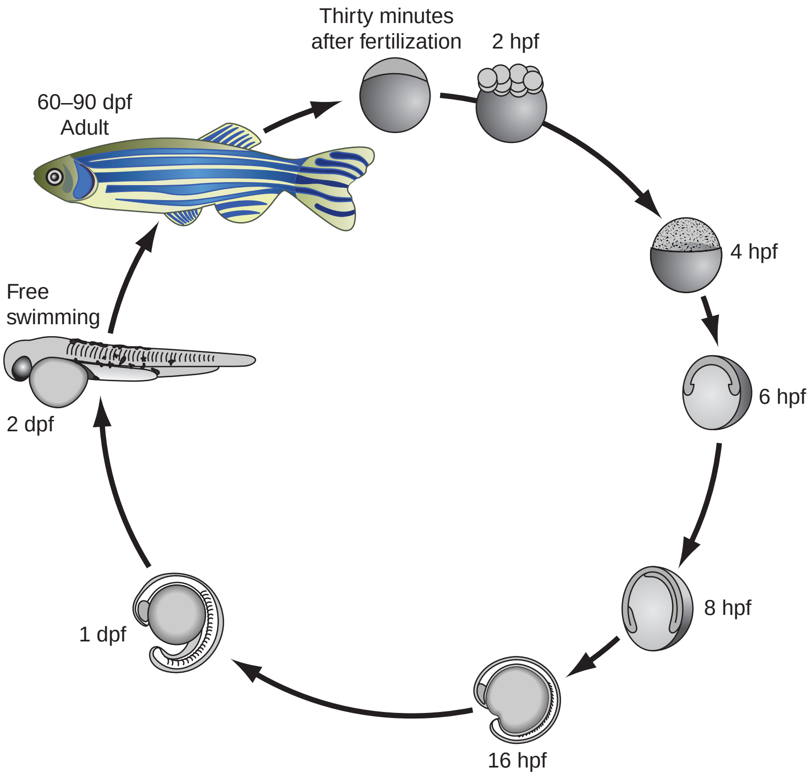

Figure 3 Lifecycle of the zebrafish. The development of zebrafish is rapid with the fertilized embryo transforming into a 1000-cell stage within 4 h postfertilization (hpf) and organs being visible at roughly 1 day postfertilization (dpf). Hatching occurs at 2 dpf and the zebrafish matures within 2–3 months. Image adapted from Wolpert L, Beddington R, Jessell T, *et al*. (2002) *Principles of Development*, 2nd edn. New York: Oxford University Press.

take up to 4–5 months to reach sexual maturity rather than the 2–3 months commonly observed in the laboratory. In one study, wild-caught zebrafish from India were observed to spawn in pairs rather than in groups as is common in aquaria. Furthermore, there was evidence for sexual selection and females taking an active role in choosing their mates. This discrimination may be primarily mediated by density in that, at low densities as seen in the wild, there may be elevated levels of sexual selection and pair formation; however, at high densities, characteristic of aquarium breeding, sexual selection and pair formation break down.

Zebrafish as a Model Organism for Scientific Research

Zebrafish have long been an important model in developmental biology, but their rise as an important experimental system in biology emerged from several major advances that have occurred since the early 1990s. First, the most important advance came in the 1990s, where several research groups induced large-scale genetic mutations in the zebrafish and subsequently screened the mutants for identifiable phenotypes. This approach of inducing random mutations and then searching for the genetic underpinnings is referred to as forward genetics. The second major advance was the start of a whole-genome sequencing project that was initiated in 2001 and is still underway. This large-scale sequencing project has facilitated the third major advance, reverse genetics, which involves modifying single genes and then examining the effects of these genetic changes on the whole-animal phenotype.

Forward Genetics in Zebrafish

The first step in the popularization of zebrafish as a model organism in biology was the mutagenesis projects initiated in the early 1990s. This work followed in the footsteps of earlier work performed on the fruit fly (*Drosophila melanogaster*) and the nematode (*Caenorhabditis elegans*). In 1996, two important works were published by Driever and Haffter and their respective co-workers that described two large-scale genetic mutation screenings, where a chemical mutagen, ethylnitrosourea, was used to induce random mutations in zebrafish sperm. Ethylnitrosourea induces point mutations in the sperm genome that could affect protein sequences or gene structure and ultimately cause, through random chance, a loss of some physiological or biochemical function. After breeding, the developing embryos were screened for visible abnormalities in muscle and other organs at several different time points and from these screens more than 6500 mutants were identified. It is important to note that the majority of the mutations were lethal if they appeared homozygous in the fish.

At the same time as the chemical mutagenesis was underway, in a separate research laboratory Gaiano and co-workers used a retrovirus to perform insertional mutagenesis, which refers to the insertion of one or more bases into the genome. The subsequent screening of these mutants resulted in the identification of roughly 500 mutations at the phenotypic level of which just over 300 have been explicitly linked to a specific genetic change. One important advantage of this technique over the chemical mutagenesis described above is that a portion of the retroviral gene sequence is inserted into the host zebrafish genome, thereby providing a genetic tag aiding in the identification of which gene is affected in the genome.

The systemic issue with forward genetics is that it is resource intensive and the direct links between phenotype and specific mutations are difficult to establish (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Fish as Model Organisms for Medical Research). Establishing these links is easier with insertional mutagenesis compared with chemical mutagenesis, but many of the direct links from these early studies have not yet been established. The genome sequencing project, started in 2001, has greatly enhanced the ability of researchers to identify where mutations have occurred and it plays an important role in advancing this field.

The Zebrafish Genome

Sequencing of the zebrafish genome was started in 2001 by the Sanger Institute and is due to be completed sometime in 2011. The zebrafish genome consists of 25 linkage groups, which are equivalent to chromosomes and the entire genome size is $\sim$1.4 gigabases. The genome is currently being annotated, which refers to the identification of genes and, once complete, this resource will be invaluable to researchers trying to understand the genetic basis of physiological and biochemical phenotypes. In addition, the genome sequencing has greatly facilitated the development of reverse genetic approaches in zebrafish.

Reverse Genetics in Zebrafish

Reverse genetics refers to the identification of gene function through selective manipulation of the gene followed by analysis of the arising phenotype. This approach attempts to identify what phenotype arises as a result of a particular gene and, for the most part, this approach involves knocking down the expression of genes of interest with subsequent examination of phenotype. These types of studies are broadly referred to as loss-of-function studies.

The most common approach for performing loss-of-function studies in zebrafish is using antisense technology.

The basic premise of this technique is that if the genetic sequence of a particular gene of interest is known, then researchers can synthesize a strand of RNA that will bind to the messenger RNA (mRNA) transcript produced by that gene. The synthetic RNA is called antisense because its nucleic acid sequence is complementary to the gene's normal mRNA sequence, which is referred to as the 'sense' sequence. The binding of the synthetic antisense RNA to the sense mRNA results in a doubled-stranded RNA molecule, which cannot be translated into protein. As a result, the incorporation of antisense RNA strands either limits or eliminates the protein coded for by the mRNA transcript.

The most common antisense approach using zebrafish reverse genetics is morpholinos. Morpholinos are synthetic oligonucleotides, in which the normal ribose or deoxyribose sugars are replaced with a morpholine ring, which are constructed to be antisense to the mRNA of interest. Normally, morpholinos are ~25 nucleotides long and are designed to bind to the native mRNA, usually near the protein translation start site. The advantage of incorporating a morpholine ring into the antisense sequence is that it makes the morpholino resistant to the normal nucleases that are present in cells and would break down unwanted RNA. The binding of the morpholino to the native mRNA causes translation blockade, where the gene of interest is silenced and very little protein is translated. It is a typical practice in the zebrafish to inject the morpholinos into the freshly fertilized egg while it is still in the one-to-eight cell stage, after which the morpholino becomes more or less uniformly distributed through the cells of the developing embryo. After this point, the efficacy of the knockdown is assessed and the resultant effects of the knockdown on phenotype are typically assessed over the first 5 or so days postfertilization.

Other commonly used methods of reverse genetics for loss-of-function studies in zebrafish are targeting-induced local lesions in genomes (TILLING) and zinc finger nucleases. TILLING combines forward genetic approaches with reverse genetics to identify specific mutations in genes of interest from a random mutagenesis screening. Specifically, this approach begins with the generation of a large number of mutated zebrafish, normally from a chemical mutagenesis screen as described earlier (**see** Section Forward Genetics in Zebrafish). DNA is then sampled from these fish and TILLING is performed. In the most basic sense, the purpose of TILLING is to look for specific mutations in specific genes in a collection of DNA samples prepared from chemically mutagenized individuals. Identification of these mutations is done using standard polymerase chain reaction (PCR) and sequencing of PCR products. Additional methods for identifying whether mutations have occurred in select areas can also be carried out to reduce the excessive sequencing costs associated with the TILLING approach.

Zinc finger nucleases represent another method for reverse genetics. Zinc finger nucleases consist of several zinc-finger DNA-binding domains plus restriction enzymes that, when combined, can be engineered to target specific DNA sequences and cut the double-stranded DNA in intact cells. The normal cellular DNA repair mechanisms then repair the broken DNA strands, but often insert nucleotides during the repair process, thus altering the genetic sequence disrupting codon arrangement.

Far less frequent are gain-of-function studies, which attempt to insert specific genes or alter genes in a way that could result in a new or enhanced phenotype. There are various techniques for inserting genes to examine gain of function, the simplest of which is microinjection of synthesized mRNA into the fertilized zebrafish eggs. These eggs then express, or, in some cases, overexpress the gene of interest and investigators can then examine the resulting phenotype. Other techniques are available for the expression or overexpression of genes in zebrafish and some of these techniques even allow researchers to target specific tissues or cells at precise developmental stages.

Overall, there is an ever-expanding collection of cell biology and genomic techniques for the zebrafish that allow manipulation of proteins and development at the most basic level. Slowly, fish physiologists are adopting this model organism and its impressive array of tools to explicitly establish links between genes and physiological attributes. Consideration of the natural habitat and use of the wide array of species available will facilitate adoption of this model system to investigate environmental adaptation and evolutionary physiology.

Glossary

Adenosine An inhibitory neuromodulator and vasodilator formed from the breakdown of phosphorylated adenosines such as ATP.

Anoxia Complete absence of dissolved oxygen in water.

Brain slices A preparation of thin slices of isolated brain tissue used for metabolic and electrophysiological studies.

Eurythermy The ability to live in a wide temperature range.

Gamma-amino butyric acid (GABA) Synapse that uses GABA as its neurotransmitter, the major inhibitory neurotransmitter across the central nervous system.

Hypoxia Low partial pressures of oxygen in external or internal environments.

***N*-methyl-D-aspartate (NMDA) receptor** An abundant receptor for the excitatory neurotransmitter glutamate in the brain of vertebrates, named after the artificial agonist *N*-methyl-D-aspartate.

P_{50} The oxygen partial pressure at half-maximal oxygen saturation of blood or hemoglobin.

Pyruvate dehydrogenase (PDH) complex A three-enzyme complex responsible for producing acetyl coenzyme A from pyruvate, thereby linking glycolysis with the citric acid cycle.

Introduction

Like virtually all vertebrates, most fishes need a constant supply of oxygen to survive. Nevertheless, there are two cyprinid fishes, the crucian carp (*Carassius carassius* L.) (**Figure 1**) and the closely related goldfish (*Carassius auratus* L.), which can survive for extended periods of time without any oxygen (anoxia). Consequently, the anoxia tolerance of these species has been the focus of intensive study. Anoxic survival is not indeterminant, however, as certain activities are suspended, including reproduction, or greatly limited, such as locomotion, and the fuel needed to survive anoxia becomes progressively depleted. The key phrase, therefore, is prolonged anoxia survival. By comparison, mammals survive interruption of the constant oxygen supply for just minutes rather than months.

Studies on goldfish have mainly used fish obtained from the aquarium trade, where this species has been cultured for more than a thousand years. Unfortunately, goldfish in the aquarium trade have been intensely selected for their ability to breed in captivity as well as for their pretty colors and odd morphology. Thus, they are likely to have lost some of their original anoxia tolerance. This article therefore focuses primarily on the crucian carp and the mechanisms that allow it to survive days to months of anoxia, depending on temperature.

The only other adult vertebrates that show a similar degree of anoxia tolerance are some North American freshwater turtles (particularly of the genera *Trachemys* and *Chrysemys*), which can survive anoxia from a few days at room temperature to several months at near-freezing temperatures. Like the crucian carp, these turtles also rely on their anoxia tolerance for overwintering at the bottom of ice-covered lakes and ponds.

Occurrence and Habitat

The crucian carp occurs in central Asia and Europe, reaching the Arctic Circle in Scandinavia. It is found both in large lakes and small ponds. They have distinct morphological types in these two environments. In large lakes, where it occurs together with numerous other fish species, including predatory ones such as pike and perch, the crucian carp is deep bodied. In small ponds, prone to seasonal anoxia and where it is the only fish species, it has a much more slender body shape. It has been suggested that the deep body form found in large lakes is the result of phenotypic plasticity induced by the smell of predators or injured crucian carp, and the function of the deep body

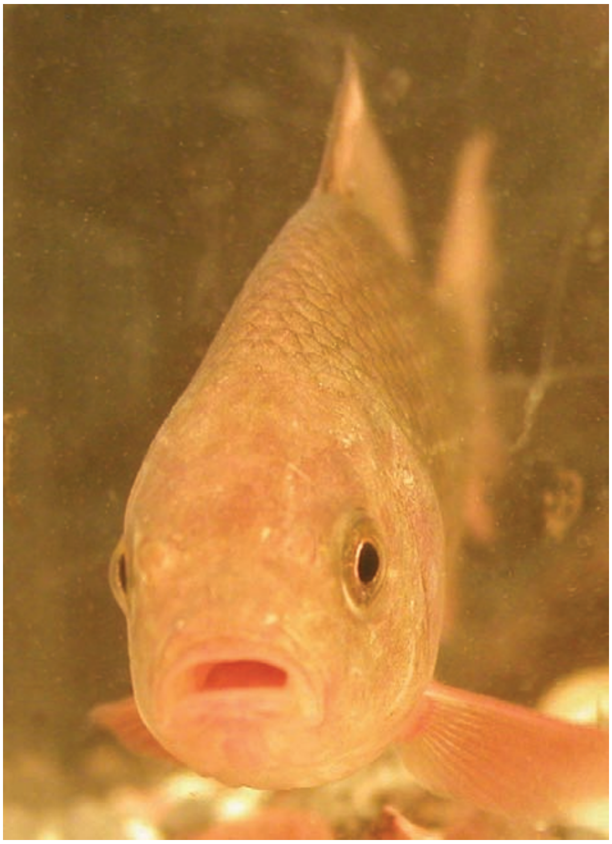

Figure 1 The crucian carp. Photo GE Nilsson.

is to make the crucian carp less likely to fit into the mouth of a predatory fish.

Extreme as this phenotypic plasticity is, equally extreme is the anoxia tolerance of the crucian carp. Anoxia tolerance can also be regarded as a predator-avoidance strategy as it allows the crucian carp to inhabit small ponds where wintertime anoxia excludes other fish species. Anoxia develops in these small ponds during wintertime because ice cover blocks oxygen diffusion from the atmosphere. In addition, limited light penetration through the ice blocks plant photosynthesis. The result is progressive hypoxia following ice formation and finally anoxia when organisms have removed all oxygen from the water. In the spring when ice melts, oxygen from the atmosphere and from photosynthesis reoxygenate the ponds, but until then, anoxia may persist for several months. The same shallow ponds also show extreme seasonal changes in water temperature. Thus, the crucian carp is exceptionally eurythermal, being able to tolerate an unusually large temperature range of 0–38 °C, with a thermal optimum of 27 °C. However, with rising temperature its anoxia tolerance falls sharply, from several months at close to 0 °C to just a day or two at 25 °C. A prime reason for this must be the temperature-dependent rise in metabolic rate.

Avoiding Anoxic Energy Deficiency

Anoxia halts oxidative phosphorylation leaving glycolysis as the only option for adenosine triphosphate (ATP) production in vertebrates. However, due to the poor ATP yield per mole of glucose by glycolysis, which is about 6–10% of the complete oxidation of glucose to H_2O and CO_2, anoxia leads to a rapid decrease in ATP levels in most vertebrates. The brain and heart are particularly sensitive to anoxia due to their very high intrinsic rates of ATP consumption and limited stores of glucose. If the ATP production in the brain and heart is not matched to ATP demand, the ATP pools of these organs will be depleted within minutes and the cells will die.

Clearly, the crucian carp has the means to avoid the anoxic catastrophe seen in tissues of other vertebrates. These mechanisms allow the crucian carp to maintain stable cellular ATP levels during anoxia, thereby avoiding energy deficiency and death. Its adaptations to anoxic survival involve: (1) producing ethanol as the major glycolytic end product, which prevents a buildup of more toxic wastes; (2) supporting glycolysis with exceptionally large glycogen stores; and (3) depressing the cellular use of ATP through increased levels of inhibitory neurotransmitters and neuromodulators in the brain and curtailing other activities. During the fall, the crucian carp will be exposed to progressive hypoxia and finally anoxia. During this initial hypoxic period, oxygen uptake is aided by an extremely high blood oxygen-binding affinity and gill remodeling to acquire a larger respiratory surface area (**see also Ventilation and Animal Respiration**: Plasticity in Gill Morphology).

Ethanol Production

Possibly the most spectacular mechanism underlying the crucian carp's impressive repertoire of adaptations for anoxia tolerance is the ability to produce ethanol as the major end product of anaerobic glycolysis. This ability is shared by the goldfish and according to one report, by another cyprinid fish, the bitterling (*Rhodeus amarus*). The main advantage of producing ethanol during anoxia is that it allows the fish to avoid a buildup of lactate and hydrogen ions, which would otherwise accumulate to very high concentrations leading to unmanageable osmotic and acid–base disturbances. The ethanol production allows the crucian carp to remain relatively active during anoxia exposure. Ethanol production, however, does present a clear energetic drawback because its release to the environment means that an energy-rich hydrocarbon is forever lost to the fish. Therefore, keeping metabolic rate low during anoxia is advantageous.

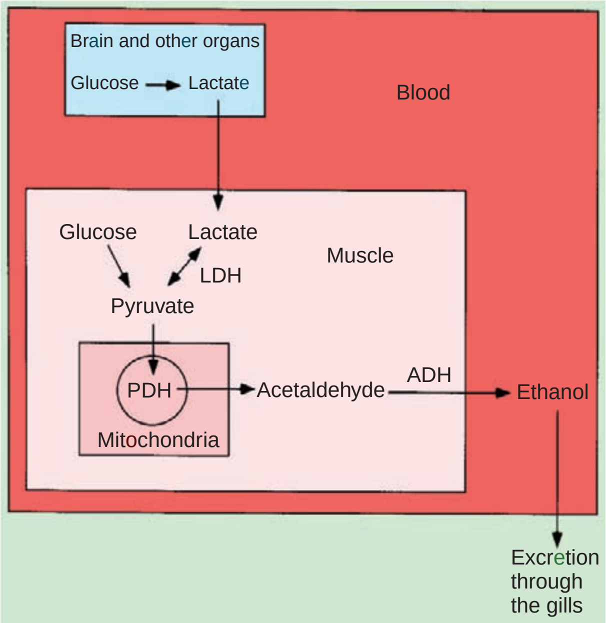

Figure 2 The ethanol-producing pathway in anoxic crucian carp that allows it to avoid lactic acidosis in anoxia. Ethanol production is confined to muscle tissue. Other organs produce lactate during anoxia. In muscle, lactate is turned into pyruvate by lactate dehydrogenase (LDH). The pyruvate is further converted to acetaldehyde by pyruvate dehydrogenase (PDH). Unlike other vertebrates, crucian carp muscle PDH appears to leak out acetaldehyde during anoxia. The acetaldehyde is turned into ethanol by alcohol dehydrogenase (ADH). Subsequently, ethanol diffuses out into the blood and finally leaves the fish over the gills.

The ethanol-producing pathway of the genus *Carassius* (**Figure 2**) is confined to the red and white skeletal muscle. Lactate produced by other tissues reaches the muscle through the blood circulation. Here, it is turned into pyruvate by the enzyme lactate dehydrogenase (LDH). Subsequently, the pyruvate is turned into acetaldehyde by one of the enzyme subunits of the pyruvate dehydrogenase (PDH) complex. The enzymes of the PDH complex normally channel substrates and intermediates from enzyme subunit to enzyme subunit, meaning that acetaldehyde is typically never released from the enzyme and is directly converted into acetyl-CoA. In *Carassius*, however, this complex must be modified to allow acetaldehyde to leak out of the PDH complex. Ethanol is finally formed from acetaldehyde by an enzyme called alcohol dehydrogenase (ADH). In crucian carp and goldfish, ADH is detected only in skeletal muscle, so all other tissues, including the brain and heart cannot make ethanol. Therefore, all tissues other than skeletal muscle produce lactate during anoxia, which they transfer into the blood. Ethanol is highly lipophilic, meaning it can readily pass through cellular membranes. Thus, ethanol produced in the muscle can easily diffuse into the blood stream and finally pass over the gills into the water. As a result, ethanol levels in anoxic crucian carp are normally below 10 mM.

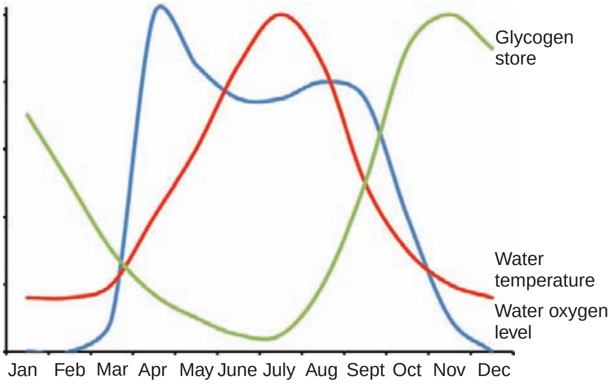

Figure 3 A normal year in the life of a crucian carp illustrated by the annual changes in the crucian carp glycogen store, shown together with changes in water temperature and oxygen level that are typical for many crucian carp habitats in Scandinavia and Finland. In this case, the crucian carp is exposed to about 2 months of anoxia from mid-December to mid-February, at which time water temperature is likely to be below 4 °C. This is also the time when most of the glycogen store is being used up. Also, note the build up of glycogen during the autumn.

To sustain long-term survival in anoxia, the crucian carp has the largest glycogen stores of any vertebrates studied and these stores peak just prior to the winter. The liver contains the largest glycogen store, and the maximal anoxic survival time depends primarily on how large the liver glycogen store is before winter. During winter anoxia, these glycogen stores are progressively depleted. In **Figure 3**, the annual changes in the crucian carp glycogen store are shown together with typical changes in water temperature and oxygen level.

Neural Depression

Although ethanol production allows the crucian carp to sustain activity during anoxia, the fish will need to suppress energy use as much as possible to avoid running out of glycogen. Under laboratory conditions, anoxic crucian carp maintain some, but limited swimming activity. They do not enter a comatose-like state as seen in anoxia-tolerant freshwater turtles which have an electrically silent brain. In goldfish, a 70% reduction in whole-body heat production occurs after 3 h in anoxia at 20 °C, indicating whole-animal metabolic depression. This is likely due to the suppression of certain metabolically demanding activities such as protein synthesis, which can be switched off or greatly turned down (**see also Hypoxia**: Anaerobic Metabolism in Fish).

In brain slices from crucian carp, anoxia results in a 30% drop in metabolic rate. Moreover, a profound suppression of the activity of the auditory nerve has been observed in anoxic goldfish. The response of the crucian carp retina (and optic tectum of the brain) to light virtually disappears in anoxic crucian carp. Thus, the crucian carp is probably temporarily deaf and blind during anoxia. Apparently, these senses are not essential for life in the cold dark anoxic water under the ice, where there are no aquatic predators, so energy is saved by shutting them down.

Heart Activity in Anoxia

In contrast to the brain, heart activity, including cardiac output, is maintained at normoxic levels during anoxia in crucian carp (**Figure 4**). Indeed, the crucian carp is the only animal known to have a heart that can function under anoxic conditions as if it was fully oxygenated. Maintenance of heart activity during anoxia is probably important for the shuttling of lactate and ethanol to and from the muscles, thereby avoiding the accumulation of ethanol and possible intoxication. It is certainly no longer needed to move oxygen! The continued function of the heart is aided by low temperature and low intrinsic energy demands.

Mechanisms of Metabolic Depression

The degree of metabolic depression in the brain of crucian carp appears to be less drastic than in turtles. At a

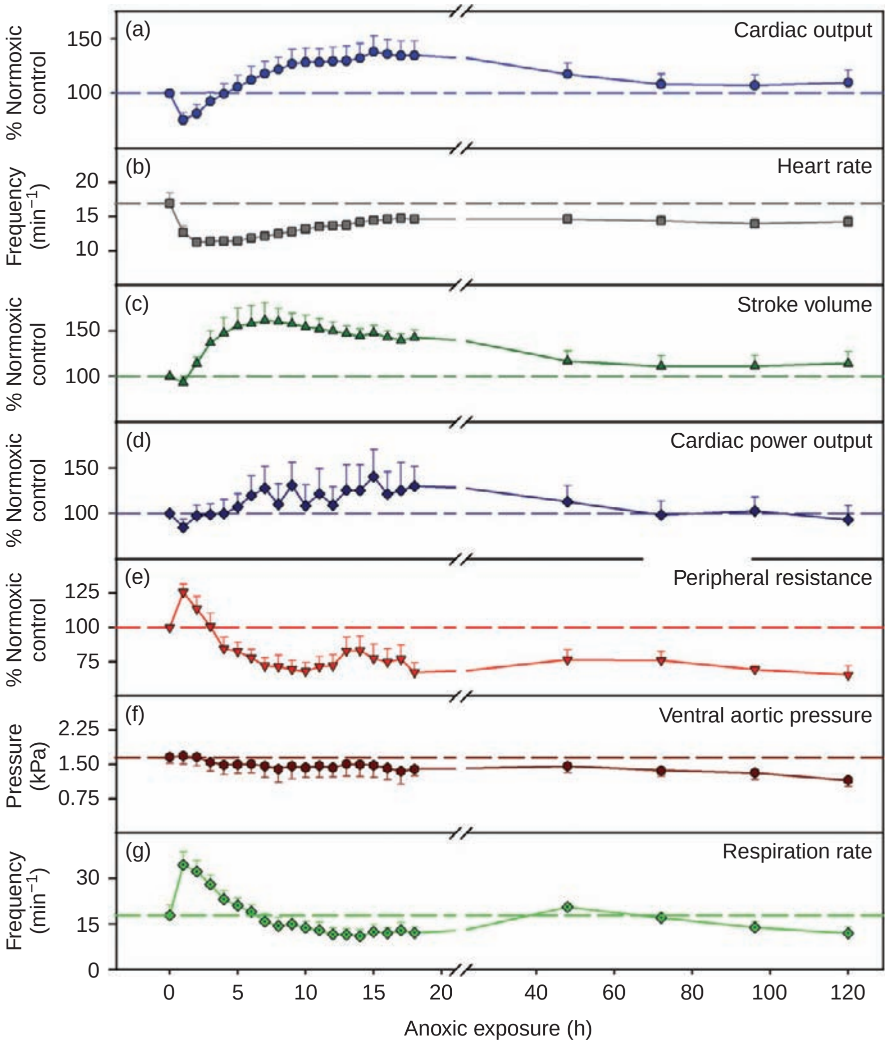

Figure 4 Changes of cardiorespiratory variables in crucian carp during 5 days of anoxia exposure at 8 °C. (a) Cardiac output, (b) heart rate, (c) stroke volume, (d) cardiac power output, (e) peripheral resistance, (f) ventral aortic pressure, and (g) respiration rate. Dashed lines indicate the control normoxic level for each measured parameter. For cardiac variables, significant differences (asterisks) are only indicated between normoxic control (time zero) and hours (48, 72, 96, and 120). For respiration (ventilation) rate, all significant differences from the normoxic control are indicated. Values are means ± SEM from 6 to 18 fish. From Stecyk JAW *et al.* (2004) Maintained cardiac pumping in anoxic crucian carp. *Science* 306: 77.

mechanistic level, the activity of Na^+/K^+-ATPase, the most energy-consuming enzyme in brain, is maintained in crucian carp brain, while it is suppressed in the brain of turtles. The sustained metabolic activity of the crucian carp brain during anoxia at 10 °C is supported by a sustained doubling in brain blood flow, which is probably needed to support the high glucose requirements of the brain when glycolysis is the only available route for ATP production.

A major difference between the crucian carp and turtles appears to be their utilization of reduced ion-channel conductivity (channel arrest) during anoxia. While reduced channel conductivity is thought to play a major role in depressing neural activity in turtles during anoxia, there is little evidence for such mechanisms in the anoxic crucian carp. Here, brain K^+ permeability appears to be unaffected by anoxia, and in crucian carp brain slices there is a lack of change in Ca^{2+} permeability, at least during the initial hours of anoxia. One exception is probably the *N*-methyl-D-aspartate (NMDA) receptor – a major excitatory glutamate receptor. While the expressions of most excitatory neurotransmitter receptors and ion channels are quite stable in the anoxic crucian carp brain, mRNA levels of some NMDA receptor subunits, including the ubiquitous NR1 subunit, fall by about 50% after 7 days of anoxia at 10 °C. Similarly, experiments using patch-clamp techniques in telencephalic brain slices from goldfish show that 40 min of anoxia causes a 40–50% fall in the NMDA receptor activity.

Protein synthesis rates are often depressed in response to hypoxia/anoxia exposure in many fish species and tissues. In the crucian carp brain, however, protein synthesis is maintained unlike the strong reduction in protein synthesis in the turtle brain. All the same, there is a 95% suppression of protein synthesis in the liver and a 50% fall in muscle and heart tissue of anoxic crucian carp, suggesting that reduced protein synthesis contributes significantly to their whole-body metabolic depression (**Figure 5**).

The most important mechanisms for reducing brain energy use in crucian carp involve neurotransmitters and neuromodulators. Gamma aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the vertebrate brain and it is the target of many neurosuppressive drugs such as anesthetics and tranquilizers. Microdialysis measurements of fluids in the brain show that the extracellular GABA concentration doubles in the crucian carp telencephalon after 6 h of anoxia. This is a relatively modest change compared to the 80-fold increase in extracellular (GABA) that has been measured in the anoxic turtle brain, suggesting that GABA acts more like a tranquilizer than an anesthetic in the anoxic crucian carp. Moreover, there is a relatively large individual variation in how the brain GABA concentration changes during anoxia in crucian carp, ranging from a sixfold increase to no change after 6 h of anoxia exposure. However, these measurements had to be done on anesthetized fish so the GABA upregulation in awake animals could be different, possibly higher. Nevertheless, the neurosuppression brought about by the elevated GABA levels in the crucian carp brain could mediate significant energy savings especially for a tissue that has limited glycogen storage capacity. Treatment of crucian carp with either inhibitors (isoniazid or 3-mercaptopropionic acid) of the GABA-synthesizing enzyme glutamate decarboxylase or a blocker of $GABA_A$ receptors (securinine) causes the fish to release up to 3 times more ethanol to the water during anoxia (**Figure 6**), suggesting that GABA mediates a considerable inhibition of energy use also on the whole-body level.

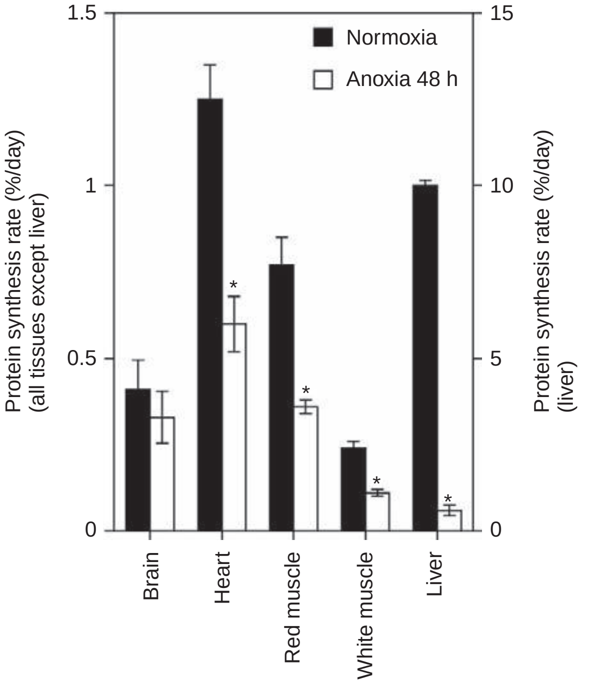

Figure 5 Rates of protein synthesis *in vivo* in tissues of crucian carp exposed to anoxia for 48 h at 9 °C. Values are means ± SEM from 12 to 16 fish. From Smith RW *et al.* (1996) Tissue specific changes in protein synthesis rates *in vivo* during anoxia in crucian carp. *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 271: R897–R904.

Also, the neuromodulator adenosine is probably involved in metabolic depression in crucian carp. Similar to the effect of inhibiting the GABAergic system, blocking adenosine receptors pharmacologically with a drug called aminophylline causes anoxic crucian carp to release 3 times more ethanol to the water. Moreover, the anoxia-induced increase in cerebral blood flow in crucian carp can be blocked by aminophylline treatment, suggesting that adenosine not only suppresses ATP use but simultaneously promotes ATP production also by stimulating glucose delivery to the brain, thereby helping to balance the ATP budget during anoxia. Microdialysis experiments have so far failed to detect an increase in

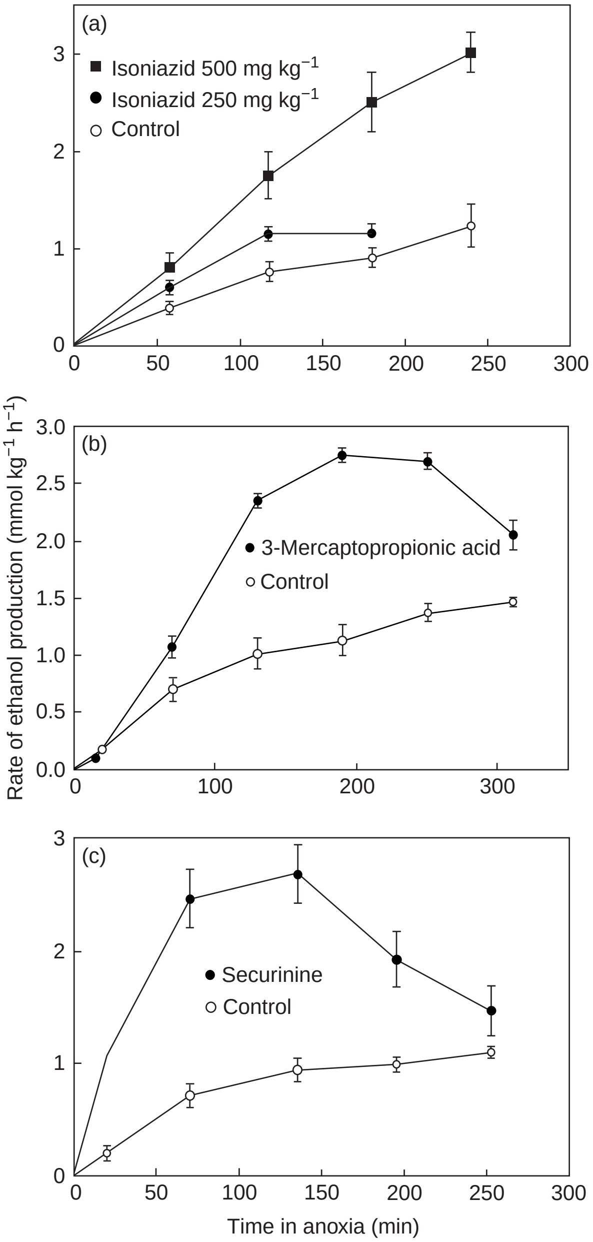

Figure 6 Evidence for a role of GABA in metabolic depression, as suggested by the increased ethanol release to the ambient water casued by three different anti-GABAergic agents. Isoniazid (250–500 mg kg^{-1} i.p.) and 3-mercaptopropionic acid (200 mg kg^{-1} i.p.) both blocks the GABA-synthesizing enzyme glutamate decarboxylase. 3-mercaptopropionic acid also inhibits neuronal GABA release. Securinine (20 mg kg^{-1} i.p.) blocks GABA$_A$ receptors. Experiments were done at 18 °C. Values are means ± SEM from 4 to 6 fish. From Nilsson GE (1992) Evidence for a role of GABA in metabolic depression during anoxia in crucian carp (*Carassius carassius* L.). *Journal of Experimental Biology* 164: 243–259.

extracellular adenosine in the brain of anoxic crucian carp. However, in freshwater turtles a rapid but temporary 10-fold rise in the extracellular adenosine level, linked to the simultaneous fall in ATP, has been measured during the early part of anoxia exposure.

Strategies to Avoid Tissue Anoxia

As mentioned, surviving anoxia by producing ATP glycolytically is energetically very expensive for the crucian carp as an energy-rich hydrocarbon, ethanol, is lost to the environment and wasted. If the entry into anoxia can be delayed, thereby reducing the time spent surviving on glycolysis alone, then the chance of the glycogen stores lasting all through the winter will be improved.

In its natural habitat, anoxia does not appear suddenly, but rather it is preceded by a long period of falling oxygen levels. The crucian carp has evolved some striking physiological adaptations that maximize oxygen uptake during severe hypoxia. First, crucian carp hemoglobins have the highest oxygen-binding affinity measured in any vertebrate ($P_{50} = 0.8$ mmHg at 10 °C). This will obviously aid in oxygen uptake during hypoxia. The high blood oxygen affinity is most likely a prerequisite for another striking adaptation to hypoxia: the ability to change the gross morphology of the gills to match its oxygen need (**see also Ventilation and Animal Respiration**: Plasticity in Gill Morphology). In cold normoxic water, the high blood oxygen affinity allows the crucian carp to have gills that lack protruding secondary lamellae (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy and **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics), possibly allowing it to reduce the energy spent on osmoregulation (**see also Role of the Gills**: The Osmorespiratory Compromise). When exposed to hypoxia, it remodels its gills by reducing the intralamellar tissue mass, which results in a sevenfold increase in the respiratory surface area. This should greatly aid its ability to take up oxygen during hypoxic periods. Interestingly, normoxic crucian carp that are directly transferred to anoxic water do not remodel their gills. This makes sense as there is no oxygen to take up and it remains to be shown if the crucian carp actually go from having gills with protruding lamellae to gills without protruding lamellae when it goes from severe hypoxia to true anoxia.

Conclusions

When the crucian carp is exposed to severe hypoxia, and even anoxia, it has a better chance of survival than probably any other fish, the reason being a set of striking physiological and biochemical adaptations. In the small ponds it inhabits, wintertime anoxia will be preceded by hypoxia. During hypoxia, it is extremely good at taking up the little oxygen there in the water by having an unusually high blood oxygen affinity and by remodeling its gills to boost the respiratory surface area. When the water becomes so depleted of oxygen that it needs to produce ATP through anaerobic glycolysis. The lactate it produces is turned into ethanol, allowing it to avoid a lactic acidosis, which is the fate of nearly all other vertebrates in anoxia. To do this, lactate produced by organs such as the brain and heart is transported to muscle, where the ethanol-producing pathway is confined. The ethanol is subsequently released to the water over the gill epithelium. Its anaerobic ATP production is supported by the largest glycogen stores found in vertebrates, which, when combined with cellular metabolic depression, is sufficient to allow anoxic survival for months at low temperatures. Even so, the anoxic crucian carp maintains some physical and neural activity in anoxia, unlike anoxia-tolerant freshwater turtles. Brain Na^+/K^+-ATPase activity and neural ion permeability remain unchanged, but there is probably a downregulation of glutamatergic NMDA receptors. The major contributors to its metabolic depression are probably inhibitory neurotransmitters and neuromodulators such as GABA and adenosine. The crucian carp is the only vertebrate known to maintain a high cardiac activity during anoxia. A maintained cardiac output is probably needed to ensure sufficient glucose delivery to tissues and ethanol release to the water, thereby avoiding self-intoxication. Thus, while this animal can survive months of anoxia, it can probably not tolerate being drunk the whole time.

Glossary

Clade A group consisting of a single common ancestor and all its descendants.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Phenotypic plasticity Variability in the form or function of an organism within its genetic makeup.

Primary production The total amount of carbon fixed into biomass by photosynthetic organisms.

Salinity Number of grams of salt per kilogram of water.

Introduction

New World pupfish in the genus *Cyprinodon* are classified into five distinct species groups or clades that are believed to have diverged from a common ancestor 6–7 million years ago (Mya). Periods of heavy rainfall and tectonic shifts in the landscape of southwestern North America produced a network of large lakes and interconnecting streams that allowed dispersal of pupfish, and by 3.6–3.8 Mya one of these clades appeared in the Death Valley system that includes the present-day Owens Valley, Amargosa River, Death Valley, and Ash Meadows (**Figure 1**). Climate change over the past 10 000–20 000 years has caused the lakes to dry up, the streams to become intermittent, and has resulted in isolated populations in the remaining springs and pools (**Figure 2**).

Habitats

Few fish are known to live at such high-temperature extremes as the pupfish. Water temperatures in the individual springs and pools can be relatively constant and range from approximately 28 to 34 °C, while spring outflows and associated marshes are subject to extreme environmental temperatures that range from near freezing in the winter to over 40 °C in the summer. Below is a summary of desert pupfish species and their habitats.

Cyprinodon radiosus, the Owens Valley pupfish, was historically widespread in the region and used as a food source by Native Americans as recently as the nineteenth century. They are found in 33 °C springs and have been seen under the ice during the winter.

The desert pupfish, *Cyprinodon macularius*, was historically found along the Colorado River and is closely related to *C. radiosus*, indicating a historical connection between the Owens River and Colorado River drainages. Current populations are confined to isolated springs, including those that drain into the Salton Sea in southern California where they encounter temperatures in excess of 40 °C and salinities in excess of seawater.

The Salt Creek pupfish, *Cyprinodon salinus*, is only found in Salt Creek, in the floor of Death Valley. Salt Creek originates from McClain springs with a temperature that varies seasonally between 15 and 30 °C and has a salinity of 15–20 parts per thousand (ppt; seawater is 33–34 ppt) (**Figure 3**). Downstream flows are variable and water temperatures in excess of 40 °C have been reported in the summer with salinities in excess of seawater (**Figures 4** and **5**). Winter temperatures, in contrast, have been reported to be near freezing. A subspecies, *C. salinus milleri*, is found in nearby Cottonball Marsh, so named because of white crusts of salt surrounding the water, which has a salinity of 45 ppt (**Figures 6** and **7**). Air temperatures near Cottonball Marsh have been reported in excess of 55 °C, the hottest in North America, but water temperatures are cooler, ranging from 23 to 36 °C during the course of one day in August when measurements were made. The other habitats are essentially freshwater and with the exception of *Cyprinodon diabolis* are inhabited by subspecies of *Cyprinodon nevadensis*.

The Saratoga Springs pupfish, *Cyprinodon nevadensis nevadensis*, are found in Saratoga Springs at the southern

edge of Death Valley, which provides a relatively constant headwater with cooler temperatures that average 27 °C (**Figures 8** and **9**). However, the springs flow into a downstream marsh that may have temperatures in excess of 40 °C.

The Amargosa River pupfish, *Cyprinodon nevadensis amargosae*, are found in the short sections where there is flow in the Amargosa River and in hot springs near Tecopa, California. One spring, Tecopa Bore, was formed by humans drilling into the water table and has water temperatures as high as 47 °C at the headwaters. Water temperature cools as the outflow reaches downstream marshes and most fish live in water between 28 and 34 °C. Brief sections of river that flow continuously have annual variation in temperature that may be over 40 °C in the summer and near freezing in the winter.

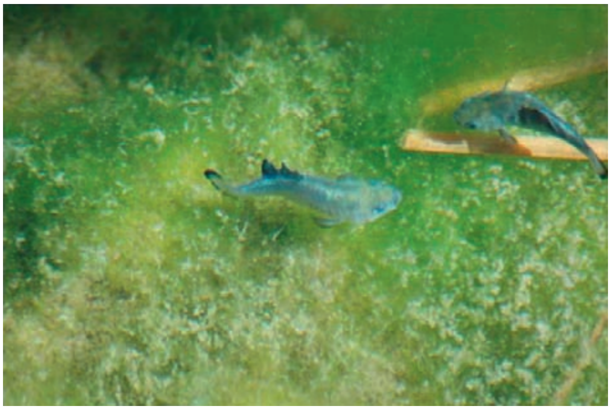

Figure 11 *Cyprinodon nevadensis mionectes* in King's Pool. Note the rich algal growth. Photo courtesy of Frank van Breukelen.

Two species of pupfish, the Ash Meadows pupfish, *C. nevadensis mionectes*, and the Warm Springs pupfish, *C. nevadensis pectoralis*, are found in Ash Meadows, which is a system of springs and pools that are fed by a large carbonate aquifer (**Figures 10** and **11**). Temperatures in the springs are relatively constant and vary among the springs from about 26 to over 33 °C.

The most unique habitat in Ash Meadows is Devils Hole, an opening into the aquifer that is believed to have resulted when the roof over a subterranean pool collapsed about 60 000 years ago (**Figure 12**). At some point after the collapse, the Devils Hole pupfish, *C. diabolis*, colonized the pool whose water level currently lies 15 m below the surrounding desert such that direct sunlight does not reach the water during the winter months, late November to early February, when air temperatures may be near freezing. Sunlight reaches the water for the remainder of the year, the most intense being in the summer when air temperatures routinely exceed 45 °C. Despite these variations, the main pool has a remarkably stable temperature of 33–34 °C. However, reproduction occurs on a shallow ledge where daily and seasonal variation in temperature and solar energy input result in water temperatures that range from <30 °C in the winter to >35 °C in the summer (**Figures 13** and **14**). The seasonal fluctuation in sunlight also limits primary production in Devils Hole and a large fraction of the total carbon input is from external sources, such as blown organic matter and matter washed in by rainfall.

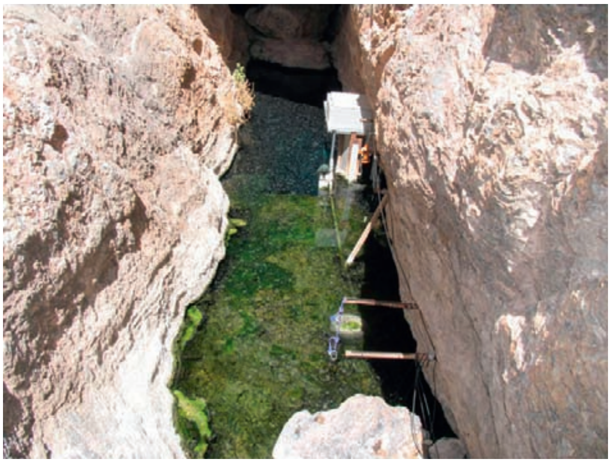

Figure 13 Closer view of Devils Hole shows algal growth on the shallow breeding ledge during times when sunlight reaches the water. Photo courtesy of the US National Park Service.

The population is greatest in the fall following breeding and recruitment that occurs in the spring and summer, while it is minimal in the spring following the dark winter months (**Figure 15**). Between 1969 and 1973, agricultural pumping drew the water level down, exposing the breeding ledge and causing a decline in the population. After a prolonged legal battle and favorable judgment by the Unites States Supreme Court, pumping was halted, the water level rose, and the population recovered to maximal levels of over 500 fish in the mid-1990s. The population then mysteriously declined until by the spring of 2006 only 38 fish were counted. In the spring of 2008, the minimum had stabilized to 45 and increased to 126 fish in the fall. A variety of hypotheses have been proposed to account for the decline, including energy limitation, thermal stress, and hypoxia. The degree that these factors, alone or in concert, contributed to the decline remains unknown. However, physiological measurements on pupfish species provide insight into the capacity of *C. diabolis* and other pupfish species to cope with stressful habitats.

Physiological Studies of Desert Pupfish

Critical Thermal Maxima and Minima

A common method for making species comparisons of thermal tolerance is the critical thermal maximum (CTMax), which is determined by placing fish in a cooler aquarium and heating the water, approximately 2 °C per minute until some marker of stress is observed, such as the inability to swim normally. The CTMax values in the literature are variable according to the rate of temperature rise and the chosen end point. When comparisons are made using the same criteria, CTMax values from species taken directly from warmer thermally stable habitats have been shown to be greater than those from cooler springs (**Figure 16**). Species that inhabit seasonally variable habitats show considerable variability in CTMax: the mean value for CTMax of *C. nevadensis amargosae* from the Amargosa River averages less than 39 °C during the winter but is near 42 °C in the spring. Laboratory experiments have similarly shown that species, regardless of native habitat, acclimated to warmer temperatures have a higher CTMax (**Figure 17**). The overall conclusion is that desert pupfish as a group display considerable plasticity in their ability to acclimate to a wide range of temperatures.

Winter temperatures in the deserts are often near or below freezing and cool temperatures may also impair physiological function. Critical thermal minima (CTMin) can be determined by cooling aquaria until coordinated swimming activity is impaired. CTMin are generally raised when pupfish are acclimated to warmer temperatures, that is, raising CTMax produces a corresponding rise in CTMin. However, when fish are acclimated to cycling temperatures that reflect minimal and maximal levels in the habitat, CTMin is lowered to give a broader scope for thermal tolerance (**Figure 18**).

Evidence has been obtained for genetic differences that may contribute to the broader scope for thermal tolerances in subspecies inhabiting thermally fluctuating habitats. *Cyprinodon nevadensis mionectes* collected from a stable 27 °C spring in Ash Meadows, and *C. nevadensis amargosae* from the more variable Amargosa River, were bred in the laboratory and first- and second-generation offspring for

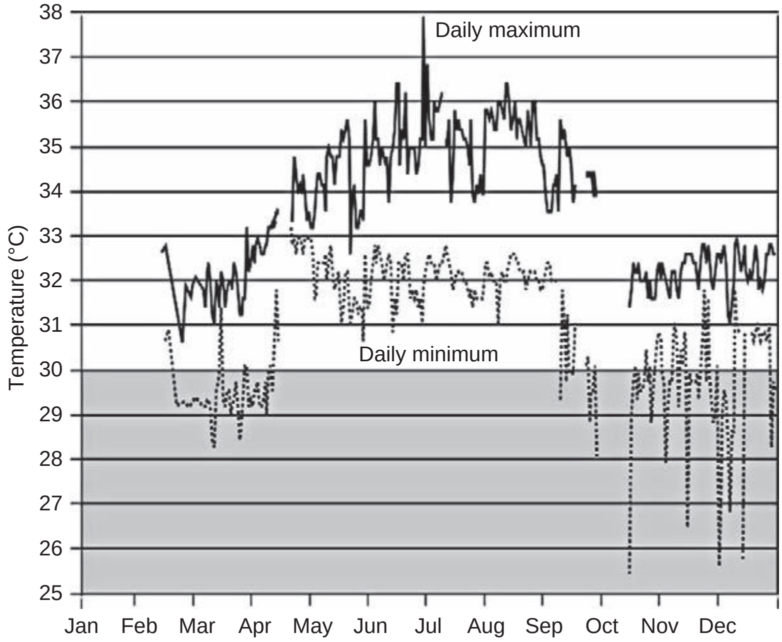

Figure 14 Temperature fluctuations on the breeding ledge recorded over a 1-year cycle in 2001. Spring-Fed Wetlands: Important Scientific and Cultural Resources of the Intermountain Region*, pp. 1–38. Las Vegas, NV, 7–9 May, 2002.

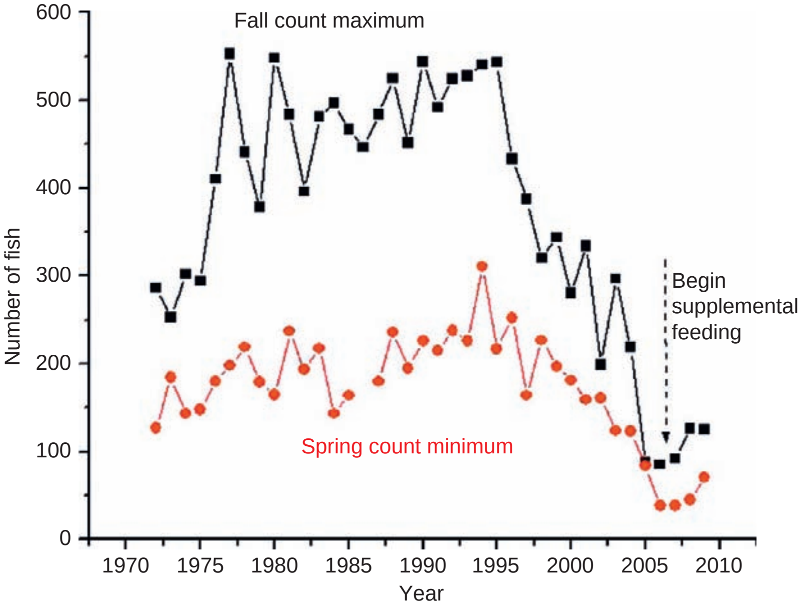

Figure 15 Maximal and minimal population estimates for *C. diabolis* based on surface counts from the breeding ledge and underwater SCUBA counts in the deeper water. Plotted from data provided by the US National Park Service.

both subspecies were maintained in the laboratory under constant (25–27 °C) temperatures. When subject to higher and lower temperatures, CTMax was greater (~41.9 °C vs. 41.6 °C) and CTMin was lower (~2.4 °C vs. 2.7 °C) in *C. nevadensis amargosae*. These small differences were statistically different suggesting selective advantage for fish in the more variable habitat.

Thermal Limits to Reproduction

CTMax and CTMin studies are generally done with adults to reflect the capacity to survive extreme temperatures. This may be advantageous for individual survival, for example, *C. nevadensis amargosae* in Tecopa Bore have been observed to move rapidly to feed on algae at

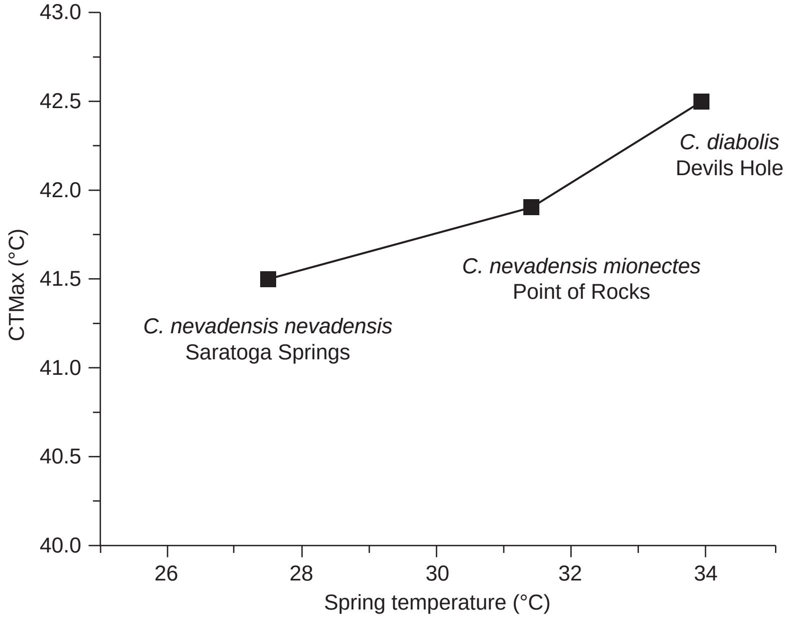

Figure 16 CTMax values are greater for species taken directly from springs having progressively warmer temperatures. Data from Brown JH and Feldmeth CR (1971) Evolution in constant and fluctuating environments: Thermal tolerances of desert pupfish (*Cyprinodon*). *Evolution* 25: 390–398.

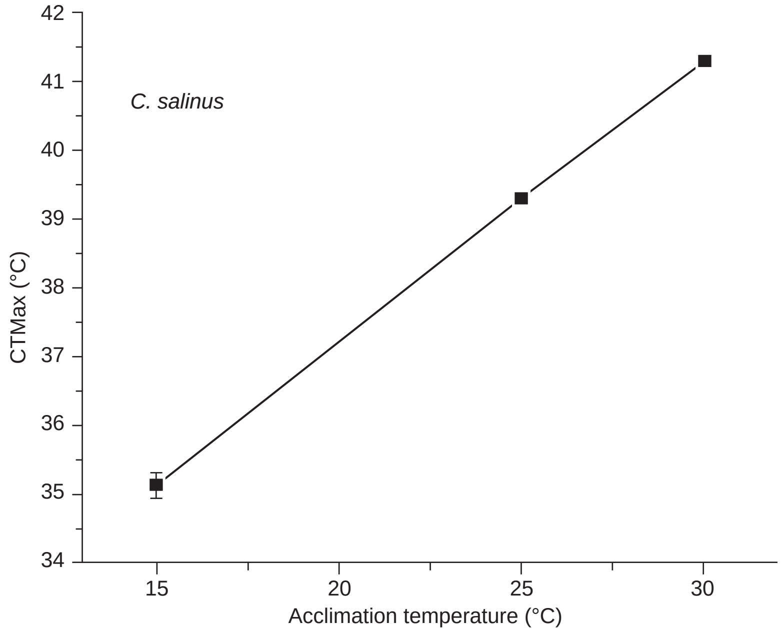

Figure 17 CTMax, shown here for *C. salinus*, increases when fish are acclimated to warmer temperatures. Data from Stuenkel EL and Hillyard SD (1981) The effects of temperature and salinity acclimation on metabolic rate and osmoregulation in the pupfish *Cyprinodon salinus*. *Copeia* 1981: 411–417.

temperatures above their CTMax before returning to cooler water. However, reproductive capacity and recruitment of young into the population are more sensitive to temperature extremes than the adults. In this regard, oogenesis appears to be the most thermally sensitive stage in pupfish reproduction. The number of eggs per spawning by *C. nevadensis nevadensis* bred in the laboratory is maximal when the fish are maintained at constant temperatures between 24 and 32 °C or fluctuating temperature regimes of 28–32 °C or 28–36 °C. Spawning activity was greatest over a slightly wider range (~24–34 °C). Hatching of fertilized eggs exceeded 50% at temperatures between 20 and

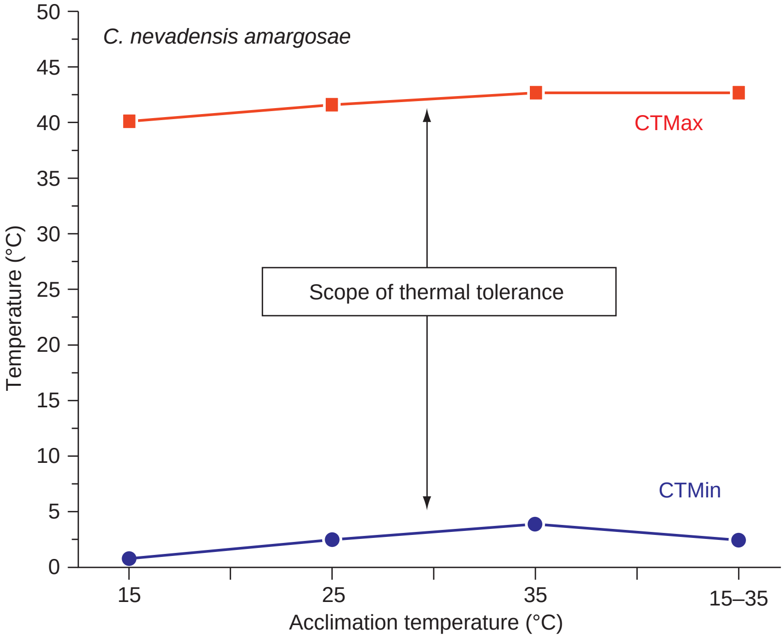

Figure 18 Increasing critical thermal maxima by warm acclimation also increases the critical thermal minima. Acclimation to fluctuating temperatures increases critical thermal maxima without raising CTMin. Data from Feldmeth CR, Stone EA, and Brown JH (1974) An increased scope for thermal tolerance upon acclimating pupfish (*Cyprinodon*) to cycling temperatures. *Journal of Comparative Physiology* 89: 39–44.

36 °C, while the CTMax for newly hatched fish acclimated to 36 °C was about 44 °C, similar to that of adults.

The temperature of the main pool at Devils Hole (33–34 °C) is above the upper limit for maximal oogenesis in Saratoga Springs' pupfish. The number of eggs released per spawning is similar to that for *C. nevadensis nevadensis* at 34 °C. The greatest number of mature oocytes in female *C. diabolis* and the greatest number of larval fish (≤5 mm length) occur between early February and late May when lower ambient temperatures, cool shallow water on the breeding ledge, and sunlight begins to reach the water to increase primary production and photosynthetic oxygen production.

Metabolism

Metabolic rates, like other chemical reactions, increase with increasing temperature. This is typically evaluated as

$$Q_{10} = (R_2/R_1)^{(10/T_2 - T_1)}$$

where R_2 and R_1 are rates at increasing temperatures $T_2 > T_1$. For a 10 °C rise in temperatures, Q_{10} values for biological rates are typically about 2–3 indicating a doubling or tripling of rate (**see also Temperature**: Effects of Temperature: An Introduction). Thus, even a 1°C rise in temperature will produce a 20–30% rise in metabolic rate. An important question for desert pupfish conservation is how close to the edge are they living and how might even small increases in temperature associated with climate change approach or exceed this limit. Increasing rates for maintenance metabolism will clearly limit the energy available for growth and reproduction illustrating why reproduction is sensitive to even small increases in temperature.

The temperature sensitivity of metabolic rate, measured as oxygen consumption, can be seen for the Salt Creek pupfish, *C. salinus*. Lower rates are observed at higher acclimation temperatures to compensate for the thermal effect on metabolic reactions (**Figure 19**). Increasing temperature also reduces oxygen solubility. Thus, fish will need to pump more water over the respiratory surfaces and require additional energy expenditure for maintenance levels of metabolic function (**Figure 20**).

Desert pupfish living in stable flowing springs generally have well-aerated water and a rich supply of photosynthetic algae. Fish in more variable habitats may encounter a wider range of oxygen levels in addition to thermal fluctuation. Offspring of Ash Meadows pupfish, *C. nevadensis mionectes*, collected from a stable spring are less tolerant of hypoxic conditions (1.00–1.45 ppm) than the offspring of *C. nevadensis amargosae* collected from areas of the Amargosa River that become hypoxic during periods of low flow and elevated temperature during the summer. These results were obtained by placing fish in a hypoxic aquarium and measuring the time before all the fish in the experimental groups became disoriented, at a temperature

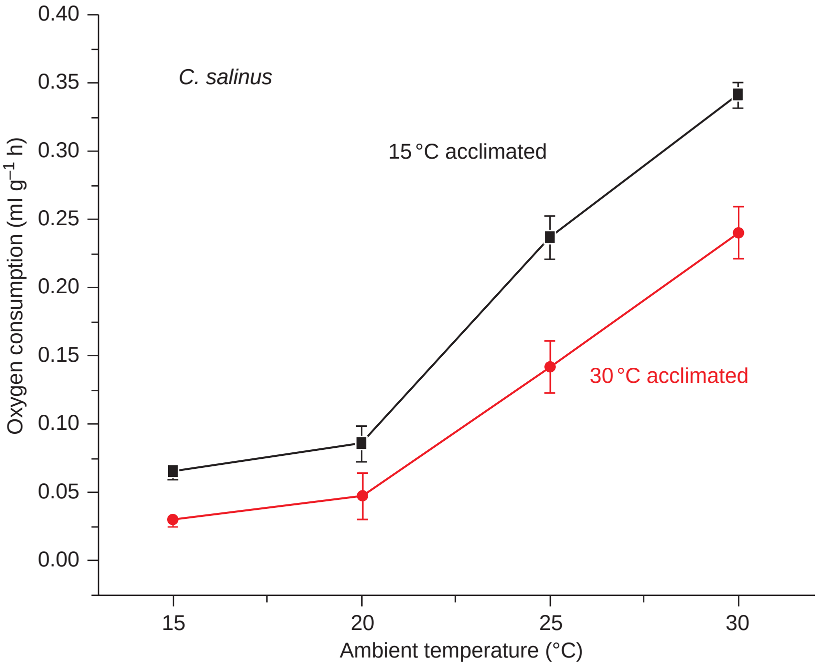

Figure 19 Metabolic rate, measured as oxygen consumption, increases with increasing temperature but is lower in fish acclimated to warmer temperatures to compensate for the thermal effect on biochemical rates. Redrawn from tabular data in Stuenkel EL and Hillyard SD (1981) The effects of temperature and salinity acclimation on metabolic rate and osmoregulation in the pupfish *Cyprinodon salinus. Copeia* 1981: 411–417.

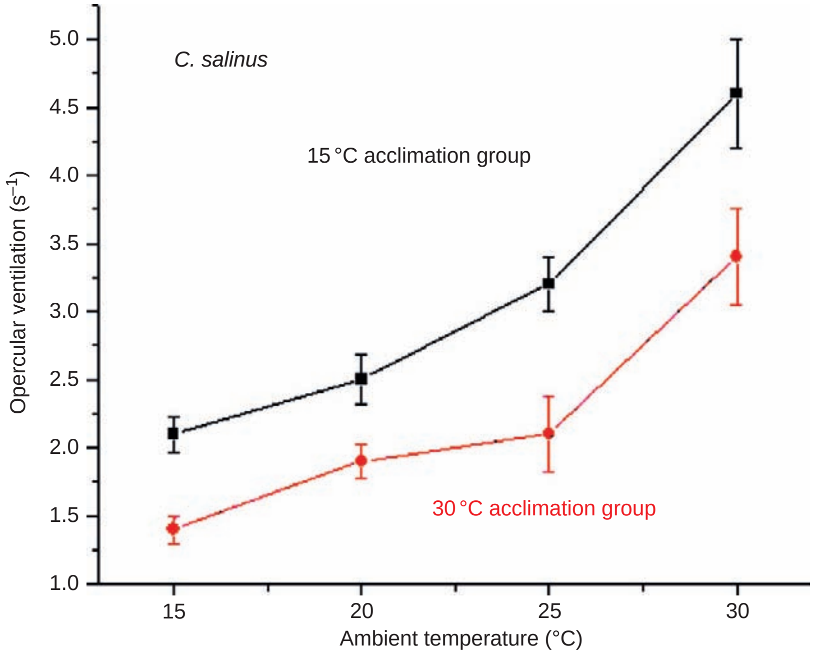

Figure 20 The rate of opercular ventilation, opercular beats per second, increases with increasing temperature to support increased metabolic rate. As with metabolic rate, opercular ventilation is lower in fish acclimated to a higher temperature. Redrawn from tabular data in Stuenkel EL and Hillyard SD (1981) The effects of temperature and salinity acclimation on metabolic rate and osmoregulation in the pupfish *Cyprinodon salinus. Copeia* 1981: 411–417.

well below the CTMax. The time course for the loss of orientation was in the order of minutes. It is obvious that a level of aerobic metabolism sufficient to maintain reproductive activity and stable population size will require greater oxygen levels, especially when the temperature approaches the upper limit for normal oogenesis.

Devils Hole presents an especially challenging combination of high temperature and low oxygen levels. Except for a west-facing wall outside of the breeding ledge, direct sunlight seldom hits the deeper levels and oxygen levels are approximately 2.3–2.4 ppm. The oxygen content of air-saturated water at the ambient altitude (~800 m) and temperature (33 °C) of Devils Hole is approximately 7 ppm and near saturation levels occur on and around the breeding ledge during the day in months when photosynthetic algae receive direct sunlight (**Figure 21**). At night and during the winter months, the saturation level declines to values similar to that of the main pool (**Figure 22**).

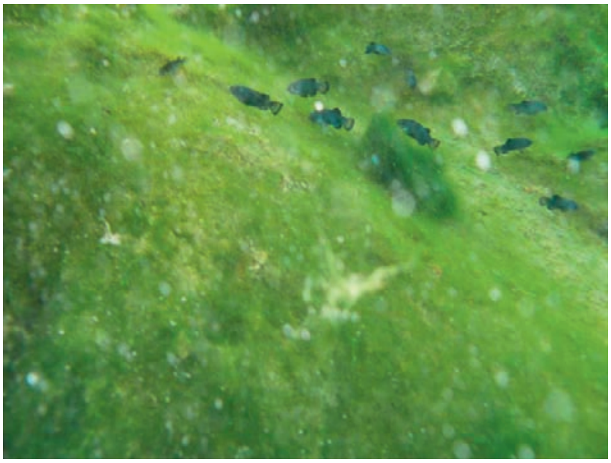

Figure 21 *Cyprinodon diabolis* on the edge of the breeding ledge during the summer where algal growth provides oxygen levels at saturated or near saturated levels. Photo courtesy of the US National Park Service.

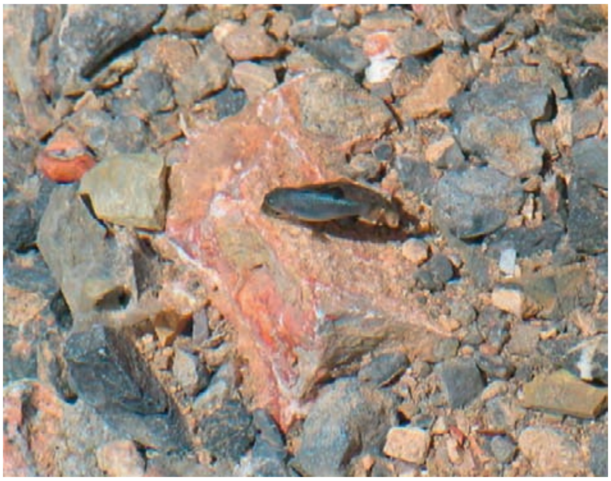

Figure 22 *Cyprinodon diabolis* on the breeding ledge with no algal growth encounter oxygen levels reported to be one-third that of saturated levels. Photo courtesy of the US National Park Service.

Below the shallow breeding ledge, there are three accumulations of rock and gravel that form deeper ledges at approximately 5, 15, and 25 m. Below 25 m, the cavern expands and has been explored to depths near 150 m but fish are not seen below the 25-m ledge. Notably, there is a 10-cm lunar tide fluctuation in the water level and earthquakes even as far away as Alaska and Mexico routinely produce water-level fluctuations in excess of 1 m that can disrupt the algal mats on the breeding ledge.

Historically, an appreciable fraction of the total population has been counted by self-contained underwater breathing apparatus (SCUBA) divers at the lower levels with the greatest number on the 5-m ledge. The fraction on the breeding ledge is consistently lower during the hot summer months even though photosynthesis may increase the oxygen content to near saturation values. In recent years, a smaller fraction of the total population has been observed on the breeding ledge at all times of the year (**Figure 23**) and the population has declined drastically. The reason for this change is not known but may be due to a warming trend in southwestern North America and a reduction in algal mats that previously covered the breeding ledge during the summer months.

Energetics

Depending on the habitat, pupfish may feed on aquatic insects, crustaceans, copepods, snails, or their own eggs and young. Three main factors determine energy available for maintaining a stable population: (1) primary production; (2) the fraction of primary production that is ingested by the fish; and (3) The efficiency with which the ingested food can be assimilated for growth and reproduction. One measure of food utilization is the conversion efficiency for fish fed in the laboratory, measured as the percentage increase in dry mass relative to the dry mass of food ingested over the same period. Conversion efficiency for *C. macularius* raised in 35 ppt salinity and fed invertebrates varied with temperature and age with the greatest efficiency at 20 °C. Efficiency declined progressively in fish reared at 25, 30, and 35 °C with a value of 7.3% for adult fish at 30 °C (**Figure 24**). Amargosa pupfish living in Tecopa Bore have been found to ingest 17.5% of the primary production, while 6.1% of the ingested food was assimilated into biomass. Thus, pupfish production corresponded to only 1.1% of the total primary production. Most of the ingested food was poorly digestible plant matter and the values obtained for *C. nevadensis amargosae* are comparable to herbivorous fishes raised in pond culture. Tecopa Bore is a productive habitat (46 296 kJ m^2 over a 1-year sampling period) that was found to support a population that varied between 13 and 196 fish m^2.

Devils Hole presents quite a different picture. Primary production between the years 1999 and 2001 was

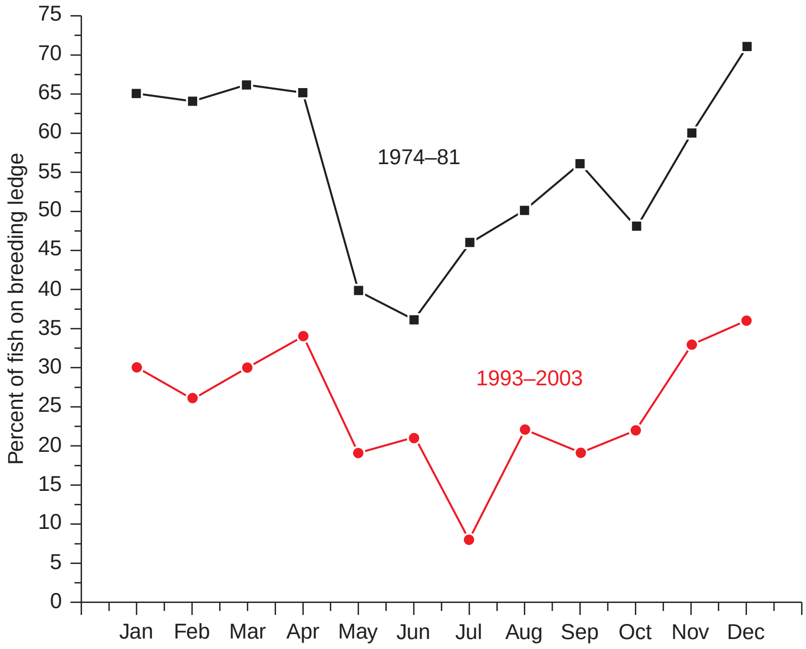

Figure 23 A smaller percentage of *C. diabolis* are counted on the breeding ledge in the hot summer months relative to the cooler winter and spring. In recent years, a smaller percentage has been counted on the ledge at all times of the year. Redrawn from Riggs AC and Deacon JE (2002) Connectivity in desert aquatic ecosystems: The Devils Hole story. In: Sada DW and Sharpe SE (eds.) *Conference Proceedings. Spring-Fed Wetlands: Important Scientific and Cultural Resources of the Intermountain Region*, pp. 1–38. Las Vegas, NV, 7–9 May, 2002.

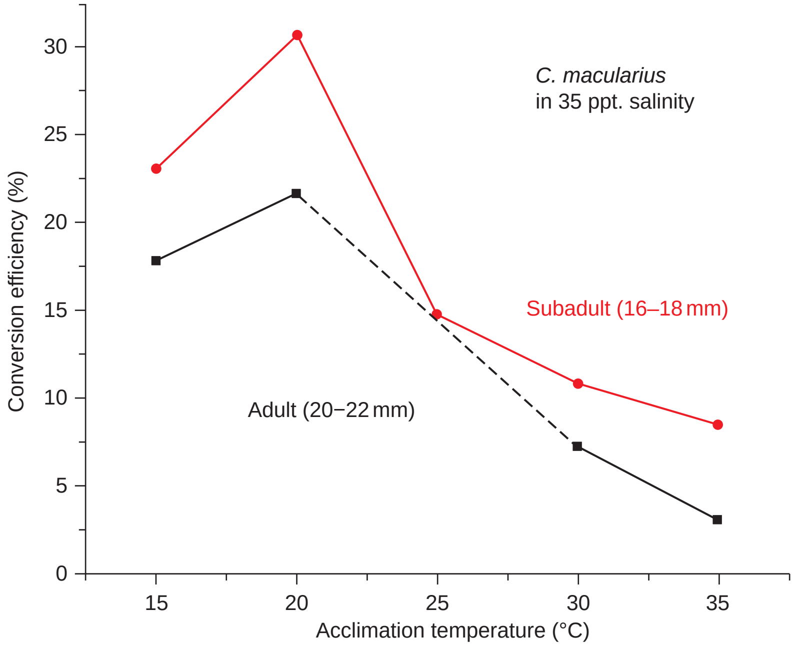

Figure 24 Conversion efficiency of young adult and adult *C. macularius* was found to decrease with increasing temperature. Redrawn from tabular data in Kinne O (1960) Growth, food intake and food conversion in a euryplastic fish exposed to different temperatures and salinities. *Physiological Zoology* 33: 288–317.

estimated to be approximately 5000 kJ yr^{-1} for the whole system at a time when the population was in rapid decline. If the ingestion and assimilation values for *C. diabolis* are comparable to those of *C. nevadensis amargosae*, even 2% of the primary production will provide only 100 kJ yr^{-1} for the fish. Beginning in winter 2007, a supplemental feeding program was initiated and resulted in the stabilization and modest recovery of the population. This suggests that the *C. diabolis* population is energy limited and raises the question of why the productivity has declined from the levels in the mid-1990s when the population exceeded 500 fish.

Conservation

Because of the precarious nature of pupfish habitats, refuge populations have been established for several of the species, including *C. radiosus*, *C. macularius*, and *C. diabolis*. Captive breeding experiments with *C. nevadensis amargosae* have shown that increased acclimation temperature and reduced food supply can produce changes in morphology that produce offspring which resemble *C. diabolis* in having lower body mass, proportionately large head and eyes, and reduction in pelvic fin development. Fish reared in this manner had lower levels of thyroid hormone, and rearing young fish in the presence of goitrogenic drugs (that inhibit endogenous thyroid hormone production) produced a similar phenotype. Thus, pupfish display plasticity in both morphological and physiological characteristics.

Refuge populations of *C. diabolis* have not fared well and, unlike other pupfish species, captive breeding has not been successful. In one refuge, near Point of Rocks Spring, *C. nevadensis mionectes* were somehow introduced and hybridized with *C. diabolis*. The hybrids reproduce well in captivity at temperatures comparable to springs in Ash Meadows (~28 °C) and Devils Hole (~33 °C). Captive populations provide the opportunity to carefully evaluate the physiological responses to environmental variables at each life stage and factors that might allow captive populations of native *C. diabolis* to be established. In conjunction with physiological and reproductive studies on the hybrids, detailed analyses of the temperature and oxygen-level profiles on the breeding ledge are being conducted, as are studies on the community structure and productivity that will be required for recovery to more sustainable levels.

Albinism Absence of melanin pigment.

Apoptosis The process of programmed cell death.

Candidate gene Gene likely to be involved in a process as determined by its expression pattern and/or function.

Constructive trait Trait increased or gained during evolution.

Convergence Independent evolution of the same traits in taxa lacking a recent common ancestor.

Morpholinos Modified oligonucleotides antisense to a part of an mRNA or its nuclear precursor that are used to prevent its translation into protein.

Phenocopy Mimic of a phenotype caused by genetic manipulation.

Pleiotropy Process in which a single gene controls two or more seemingly unrelated traits.

Quantitative trait locus Chromosomal region defined by genetic linkage that contains a gene(s) responsible for a phenotypic trait.

Regressive trait Trait reduced or lost during evolution.

Sonic hedgehog Ligand initiating a key signaling pathway in vertebrate development.

Stream capture Geologic process in which surface streams and their organisms are diverted into caves in limestone areas.

Troglomorphism Suite of convergent constructive and regressive traits in cave-adapted animals.

Introduction

Blind cavefish is the common name for teleost fishes that have adapted to life in limestone caves. As a consequence of evolution in the absence of light, cavefish lost their eyesight and pigmentation and gained other traits. Cavefish exhibit troglomorphism, a convergent suite of regressive and constructive characters shared by cave-adapted animals in many different phyla. Troglomorphism has evolved many times in teleosts. At least 136 species of troglomorphic cavefish have been described belonging to 19 different families. Of the large number of known cavefish species, very few have been subjected to comprehensive study. The best studied are the poecliid *Poecilia mexicana*, the amblyopsid *Amblyopsis* (and related forms), and the characid *Astyanax mexicanus*.

A limiting factor in studying cavefish is their ability to survive in the laboratory. Accordingly, most cavefish research has been done with *A. mexicanus*, which is domesticated for laboratory study and has other attributes that make it the preferred model for investigating troglomorphism. Because of the wealth of knowledge about *A. mexicanus* cavefish, they are the subjects of this review.

Astyanax Cavefish

A. mexicanus (sometimes called *A. fasciatus*) is a single species consisting of a surface-dwelling form with normal eyes and pigmentation and a cave-dwelling form with troglomorphic features (**Figure 1**). There are 30 known *Astyanax* cavefish populations showing various degrees of troglomorphism. The evolutionary relationships and degree of isolation between these cavefish populations are complex and are not completely understood. However, it is generally agreed that some populations evolved independently from the same or similar surface fish ancestors. The surface- and cave-dwelling *Astyanax* are capable of hybridization in the laboratory, and thus considered the same species. It is also possible to hybridize different cavefish populations. The hybrids can recover ancestral traits that were lost during cavefish evolution, supporting multiple indpendent origins of troglomorphism in *Astyanax* cavefish.

The genus *Astyanax* initially spread to Central America from South America after the Isthmus of Panama was formed, and then extended its range northward into Mexico and the southwestern United States. Beginning about a million

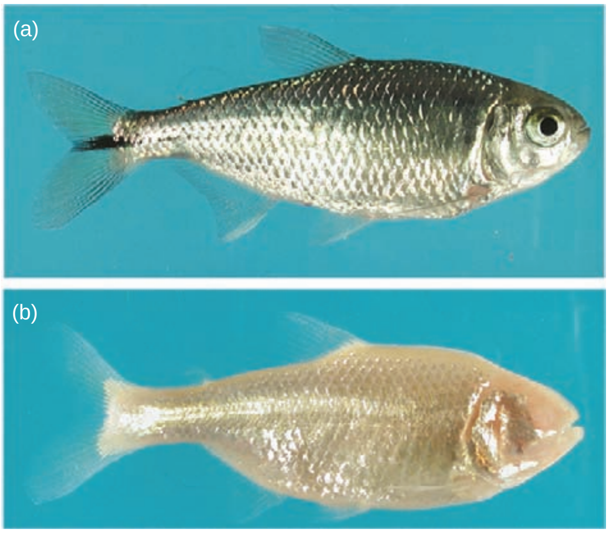

Figure 1 *A. mexicanus* surface fish (a) and Pachón cavefish (b). Note the absence of eyes and pigmentation in the latter.

years ago, *Astyanax* surface fish entered limestone caves resulting from stream capture and gradually evolved troglomorphism. The major site of *Astyanax* cavefish evolution is the Sierra de El Abra region in the states of Tamaulipas and San Luis Potosí in northeastern Mexico, which contains 29 known caves with troglomorphic populations (**Figure 2**). There is a single cavefish population in the southwestern state of Guerrero. Despite the extensive range of *Astyanax* surface fish in the vast limestone terrains of Texas, Mexico, and Central America, the cave-adapted forms are restricted to these two relatively small areas in which the conditions for cave adaptation may be ideal. *Astyanax* cavefish are named according to their cave of origin (**Figure 2**). For example, Pachón and Molino cavefish inhabit Cueva de El Pachón and Sotáno de El Molino, respectively.

The surface and cave forms of *A. mexicanus* are excellent laboratory organisms. They can be maintained on a simple diet, spawn frequently, have robust and rapidly developing embryos, and exhibit generation times of less than a year. Interbreeding can be done between the surface and cave forms, as well as among the various cavefish populations, allowing genetic analysis of troglomorphic traits. Embryological manipulations are possible and molecular technologies have been successfully developed. Finally, *Astyanax* is closely related to *Danio rerio* (zebrafish), allowing the extensive resources developed for zebrafish to be used in *Astyanax* research. For example, there is sufficient genomic synteny to allow traits mapped genetically in *Astyanax* to be identified as candidate genes on the zebrafish genome map.

Troglomorphism

Astyanax cavefish exhibit a suite of regressive and constructive traits that constitute troglomorphism in this species.

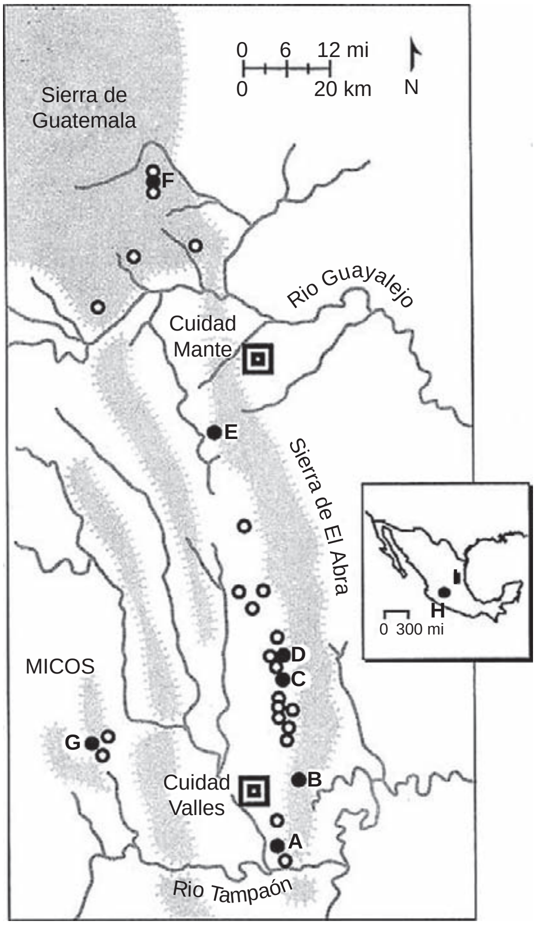

Figure 2 *A. mexicanus* cavefish distribution in northeastern Mexico. The spheres indicate the approximate positions of caves containing the following cavefish populations: A, Chica; B, Curva; C, Tinaja; D, Los Sabinos; E, Pachón; F, Molino; and G, Subterráneo. (Inset) Mexico showing the location of northeastern region shown in the larger map (shaded rectangle) and the outlying Granadas cavefish population in Guerrero (shaded sphere).

Regressive Traits

The most famous regressive traits are loss of eyes and pigmentation (**see also The Skin**: Coloration and Chromatophores in Fishes). These troglomorphic characters can be considered developmental defects because the primordia of eyes and body pigment cells (e.g., the pigmentogenic neural crest) are present in embryos, but their growth and differentiation is arrested during development. Accordingly, adult cavefish have small vestigial eyes buried beneath the skin of their orbits and melanophore precursors that remain undifferentiated throughout the body. Various parts of the cavefish eye appear to be more affected than others, suggesting a degree of independence in their troglomorphic evolution. For example, the lens shrinks to a tiny vestige, and the cornea and ciliary body are absent. By contrast, a layered retina is formed, although its growth is retarded and its layers disorganized. Neurites intially extend from the retinal ganglion cells to the optic tectum, but these connections probably decay in adults. In concert with visual decay, cavefish have a smaller optic tectum (**see also Vision**: Optic Tectum).

Craniofacial morphology also changes in cave dwelling *Astyanax*. The orbital bones surrounding the eye sockets are larger and more numerous due to their fragmentation and overgrowth into the space normally occupied by the eyes. These differences are due to the absence of a normal eye, which negatively influences orbit bone growth and fragementation. Surface fish-like craniofacial structure can be restored when the cavefish eye is rescued by lens transplantation (see below).

There are three types of body pigment cells in *A. mexicanus*: silver iridophores, orange xanthophores, and black melanophores. The pigment cell types are also subject to differential regression. Melanophores are reduced in number and in some cases melanin pigment is completely lost, causing albinsm. Pachón and Molino cavefish include a high proportion of albino individuals. The effects on iridophores and xanthophores, if any, are less severe.

Other regressive traits in *Astyanax* cavefish are (1) reduced metabolism, which is presumably adapative for survival in the cave environment, (2) reductions in the size of scales and number of fin rays, and (3) loss of one or two rib-bearing vertebrae. The purpose of scale and skeletal reductions, if any, is obscure. Finally, behavioral traits displayed by surface fish can be absent in cavefish. These behaviors include schooling behavior, which is based on vision, aggressive behavior toward conspecifics (**see also Sensory Systems, Perception, and Learning**: Communication Behavior: Visual Signals and **Sensory Systems, Perception, and Learning**: Spatial Orientation: How do Fish Find their Way Around?), and the scattering (or alarm) reaction, which is triggered by a secretion that warns schooling fish of predator approach (**see also Hormones in Communication**: Hormonal Pheromones). Predator absence could be a facilitator of some of these behavioral changes.

Constructive Traits

Many constructive traits are presumably related to feeding requirements in the cave environment, including larger jaws, more taste buds, and additional maxillary teeth. There is also a dramatic change in feeding behavior itself. Adult surface fish feed primarily in the water column guided by visual imputs, but in complete darkness, they search for food on the bottom, approaching the substrate at a 90° angle and ackwardly swivelling on their body axis to pick up food. In contrast, adult cavefish feed on the bottom in both light or darkness, smoothly gliding across the substrate at a 45° angle and apparently using their larger jaws to scoop up and sample detritus. An experiment was done to compare the ability of surface fish and cavefish to compete for limited food in lighted or darkened tanks. The results showed that surface fish outcompete cavefish in the light, but cavefish obtain food more successfully in the dark.

Because primary producers are lacking, food can only enter caves from the outside, and its availability may be restricted to certain seasons of the year. In northeastern Mexico, there is a wet season, when food supply may be abundant, and a dry season, when food may be minimal. Probably to facilitate survival during periods of low food availability, cavefish exhibit a higher lipid content and have more extensive fat deposits than surface fish. Clearly, a large part of adapting to life in caves may involve enhancing the ability to detect food and store energy.

Cavefish must also navigate without vision in the dark cave environment. This appears to be accomplished by increasing the size and number of motion-detecting neuromasts. As in most other teleosts, *A. mexicanus* has canal neuromasts located in the lateral lines and superficial neuromasts distributed individually in the head (**see also Hearing and Lateral Line**: Lateral Line Structure and **Hearing and Lateral Line**: Lateral Line Neuroethology). The number and size of superficial neuromasts is increased in cavefish, particularly above the empty eye sockets. In addition to assisting with navigation in the dark, the neuromast system may allow cavefish to memorize their complex physical environment. *Astyanax* perform exploratory swimming behaviors when challenged with new environments that later allow them to avoid obstacles, and this behavior seems to be enhanced in cavefish (**see also Sensory Systems, Perception, and Learning**: Spatial Orientation: How do Fish Find their Way Around?).

Remarkable changes have also occurred in the cavefish brain: the ventral forebrain and hypothalamus are significantly enlarged compared to surface fish (**see also Brain and Nervous System**: Functional Morphology of the Nervous System: An Introduction). A benefit of these increases may be to enhance information processing from additional taste buds in the secondary and tertiary gustatory centers. Ventral forebrain enhancement also involves the formation of more olfactory interneurons, suggesting that increases in olfaction could be an important troglomorphic trait. This possibility is supported by the greater size, and presumably receptor capacity, of cavefish nasal areas.

Eye Degeneration

Four steps involving combinations of various transcription factors (e.g., Pax6 and Pax2) and signaling systems (e.g., Sonic hedgehog (Shh)) are important for vertebrate eye development: (1) specification, (2) commitment, (3) differentiation, and (4) growth and maintenance. Each of these steps has been modified to some extent during cavefish evolution.

Specification

From the earliest stages of eye specification, cavefish exhibit smaller pre-optic (and pre-forebrain) Pax6 expression domains are reduced in the anterior neural plate relative to surface fish. Reduction of Pax6 expression is caused by inhibitory effects of Shh, which is overexpressed along the cavefish anterior midline (**Figure 3**). The Pax6 expression domains in the lens placodes, which form in the ectoderm adjacent to the neural plate, are also reduced. Together, these changes account for specification of smaller eye primordia in cavefish.

Commitment

The commitment stage involves the formation of several different parts of the optic vesicle: the future retina, retinal pigment epithelium (RPE), and optic stalk. The optic vesicle is much smaller in cavefish than in surface fish, and the relative proportions of its parts have been changed. Continued Shh overexpression along the midline and ventral forebrain upregulates Pax2 and Vax1 in the anterior part of the optic vesicle, the optic stalk precursor, and these factors downregulate Pax6 expression in the posterior optic vesicle, which becomes the retina and RPE (**Figure 3**). Thus, the cavefish optic stalk is increased at the expense of the optic cup (retina and RPE). This is one of several developmental trade-offs revealed by studies of cavefish eye development.

Differentiation

By the beginning of the differentiation stage, lens vesicles have been induced from surface ectoderm on each side of the optic cups. In accordance with smaller optic cups, smaller lens vesicles are induced in cavefish relative to surface fish. The two parts of the lens vesicle, the lens epithelium and the zone of primary fiber cells, are formed in cavefish but further lens development is gradually arrested and apoptosis begins, eventually resulting in the virtual disappearnce of the cavefish lens. The *aA-crystallin* gene, which encodes an anti-apoptotic factor that is

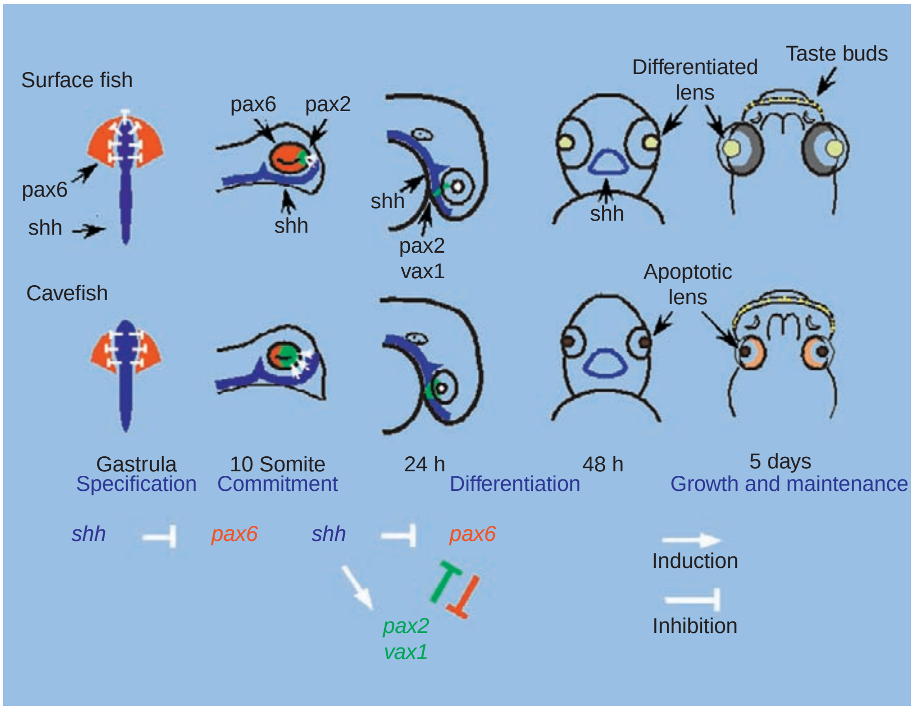

Figure 3 Summary of events during the pleiotropic trade-off between eyes and jaws/taste buds in cavefish. Shh is enhanced at anterior midline, reducing Pax6 expression in the anterior neural plate of cavefish gastrula. Later, *shh* expression is also enhanced in the ventral head region, inducing expanded *pax2* expression in the anterior optic cup. The *pax2* expression domain becomes optic stalk. Cavefish have enhanced the optic stalk at the expense of the ventral optic cup. Cavefish have a small optic cup with a tiny lens. In surface fish, the lens differentiates and accumulates crystallin proteins, but in cavefish the lens undergoes apoptosis. At the same stage, Shh is expressed at the edge of the mouth, which is larger in cavefish, and later in the taste buds. During the larval stage, cavefish have small eyes and wider jaws with increased numbers of taste buds.

downregulated in the cavefish lens, and *heat shock protein 90α* gene (*HSP90α*), which encodes a putative pro-apoptotic factor that is upregulated in the cavefish lens, are two of the factors likely to be responisble for lens apoptosis.

Meanwhile, the parts of the retina begin to differentiate. Although total cell numbers are less, ganglion, amacrine, horizontal, bipolar, and Muller glial cells are produced in the cavefish retina. Rod photreceptor cells appear transiently, but subsequently undergo apoptosis and are lost. The transient photoreceptor cells appear to be abnormal, having shortened outer segments. Eventually, apoptotic bodies also appear within the layered retina, and the layers become disorganized. Pigmentation appears in the RPE of some cavefish populations, although not in albinitic Pachón and Molino cavefish. Later, the RPE also may undergo cell death.

Growth and Maintanence

In teleosts, growth of the eye continues through adulthood, with new cells added at the margin of the lens and the outer edges of the retina/RPE, a region called the ciliary marginal zone (CMZ). The proliferation rate of cavefish lens cells is apparently not sufficient to replace the cells removed by apoptosis, and thus the lens gradually becomes smaller. In contrast, there is a healthy rate of cell division in the cavefish CMZ, the same or even perhaps greater than its surface fish counterpart. After the early stages of development, however, the cavefish retina does not increase in size at the same rate as in surface fish. This is attributed to complete turnover of newly born retinal cells by apoptosis after they leave the CMZ, a process unique to the cavefish retina. Surprisingly, cavefish relentlessly form new cells at the CMZ, only to destroy them before they can contribute to the retina. Thus, net growth is arrested in the cavefish eye, which is eventually overgrown by adjacent head tissues and sinks into the orbit. The final size of the vestigial eye is variable both between and within *Astyanax* cavefish populations.

Rescue and Phenocopy

There are three ways in which the cavefish eye has been rescued during development: (1) genetic rescue, (2) pharmacological rescue, and (3) rescue by lens replacement. Furthermore, cavefish phenocopies with degenerating eyes can be produced in surface fish. It is important to consider both rescue and phenocopy because they provide important clues about the mechanisms of eye degeneration.

Genetic rescue

In some cases, eyes and vision have been rescued in hybrids produced by crossing two different cavefish populations. Genetic rescue shows that different genes are responsible for eye degeneration in various cavefish populations.

Pharmcologial rescue

Pharmacological rescue depends on the inhibition of HSP90 function with the drug radicicol. When cavefish embryos are treated with radisicol prior to lens apoptosis, cell death does not occur and a larger lens is formed. However, HSP90 is also important for other events in embryogenesis, such as muscle development, and thus cavefish with rescued lenses do not survive. However, pharmacological rescue shows that the program leading to lens death is reversible.

Rescue by lens replacement

Early defects in the cavefish lens suggest a role in eye degeneration. To test this possibility a cavefish lens was removed from the optic cup during early development and replaced with a surface fish lens. Remarkably, the transplanted lens survived and was able to recuse other eye parts, including the cornea, ciliary body, and retinal photoreceptor cells. Moreover, the retina did not undergo apoptosis after lens replacement, and a large eye was eventually formed in cavefish. Whether the rescued eye is functional in vision remains to be shown, but the lens replacement experiments indicate that eye degeneration is controlled largely by the lens and that rescued eye parts contain the intrinsic information required to build a complete eye.

Phenocopy of Eye Degeneration

In vertebrates, the midline signaling molecule Shh has an important role in bilateral separation of the eyes. When Shh was overexpressed in surface fish, either by injecting into eggs an excess of *shh* mRNA or a DNA expression construct containing Shh driven by a heat shock promoter, the resulting larvae showed eye degeneration. Just as in cavefish, Pax2 is expanded and Pax6 depressed in the optic vesicles, resulting in large optic stalks and small optic cups. Importantly, Shh overexpression also induced apoptosis in the cavefish lens. The phenocopy studies show that Shh overexpression causes eye degeneration through inducing lens apoptosis in *Astyanax* cavefish.

Feeding Apparatus Amplification

Cavefish larvae have a feeding apparatus consisting of larger and wider jaws with more taste buds on their lips relative to surface fish larvae. Taste buds are a chemosensory organ important for finding food (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction). Thus, these modifications could be associated with changes in feeding behavior. Surface fish larvae find a food item using visual information and bite off pieces of the food. In contrast, cavefish larvae stop swimming when food is near, open their mouths widely, and appear to suck in the food. As described above, the wider jaw with enhanced taste buds may help cavefish feed in a dark cave.

Shh is also involved in feeding apparatus development. When the mouth develops, *shh* is expressed along its edges, and later in taste buds. To test whether Shh activity is required for producing the feeding apparatus, morpholinos were used to downregulate *shh* mRNA translation. The injected embryos developed small jaws with reduced taste bud numbers. In contrast, Shh overexpression results in larger jaws with increased taste buds. Importantly, conditional expression of the Shh DNA construct revealed a period during gastrulation in which Shh is required both for eye loss and feeding apparatus enlargement, defining a linkage between these regressive and constructive traits via the Shh signaling pathway.

Inheritance of Troglomorphic Traits

In *Astyanax* cavefish, eye degeneration is controlled by mutations in as many as 12 different genes, each playing a small role in the loss of vision. Quantitative trait locus (QTL) analysis with microsatellite markers has been used to map traits involved in eye regression and identify candidates for the mutated genes based on synteny with zebrafish. One of the eye candidate genes is *aA-crystallin*, whose downregulation may affect the survival of the cavefish lens.

The reduction in melanophore number is also controlled by multiple genes with additive effects. Similar to the case of eyes, the genes responsible for melanophore reduction can be different in various cavefish populations. Accordingly, pigmentation can be rescued in F1 hybrids. Eighteen different QTLs affect melanophore pigmentation. Among the many QTLs and predicted pigmentation genes, there are some traits with simple inheritance. Considerable progress has been made in identifying the genes governing two of these simple traits: albinism and the brown eye phenotype.

Cavefish albinism is inherited as a simple Mendelian trait controlled by a single recessive gene. The responsible gene is *oculocutaneous albinism2* (*oca2*), which also has a major role in mouse and human albinisms. Loss of *oca2* function has occurred in both Pachón and Molino cavefish, but the mutations are distinct: they are large deletions encompassing different regions of the protein-coding sequence. Thus, the *oca2* gene has been a repeated target for mutation, resulting in independent origins of albinism during cavefish evolution.

Mutations in the *brown* gene decrease the number of melanophores and change eye pigmentation from black to brown. Hybridization of different cavefish populations indicates that this gene is responsible for brown pigmentation in the (degenerate) eyes of many different cavefish populations. Genetic analysis predicted a single gene responsible for the *brown* phenotype, and as expected only one QTL was identified. The *brown* gene encodes melanocortin 1 receptor (Mc1r). The Mc1r ligand is melanosome stimulating hormone-*a* (MSH-*a*), which is involved in pigmentation changes in many different vertebrates. Similar to albinism, different mutations in the same *Mc1r* gene are known to cause the brown eye phenotype in various cavefish populations. In some cavefish populations, loss of function mutations are found in the *Mc1r*-coding region, whereas in others, the mutation is likely to be in gene regulatory regions. Thus, *Mc1r* is another example of a gene that has been repeatedly mutated to generate the same troglomorphic phenotype.

In contrast to the large number of genes involved in eye and pigment degeneration, only three gene loci, one major gene and two modifiers, are required to change feeding behavior. This is surprising because of the complexity assumed to underlie behavioral traits. Candidate genes for feeding behavior have yet to be identified.

Evolution of Troglomorphism

It is generally agreed that constructive troglomorphic traits have evolved by natural selection, but the evolutionary forces controlling regressive traits are less clear. Two major hypotheses have been proposed: (1) accumulation of neutral mutations under conditions of relaxed selection and (2) selection against the lost trait based on either energy conservation and/or pleiotropy.

In the case of eye loss, selection seems to be supported over neutral mutation by the following arguments. All of the eye QTLs decrease eye size, which is unexpected if random neutral mutations are occurring. The restoration of eyes by lens transplantation suggests that downstream eye genes are functional. The genes involved in eye development identified thus far have not mutated to loss of function. Most genes with modified expression patterns, such as those in the Shh signaling pathway and *HSP90α*, increase rather than decrease their activity during eye degeneration. Eye loss may be a result of indirect selection involving a developmental trade-off: reduction of eyes allows for enhancement of adaptive feeding traits (wider jaws and more taste buds) controlled by the pleiotropic *shh* gene. In contrast, loss of pigmentation seems to be caused by neutral mutation. Genetic analysis shows that individual QTL can increase or decrease melanophore abundance, supporting a random process. Loss-of-function mutations in *oca2* may be permitted if this gene is not pleiotropic and its disruption does not affect other important developmental pathways. These results suggest that a combination of different evolutionary forces may have contributed to the evolution of troglomorphism in *Astyanax* cavefish.

Glossary

Air-breathing organ (ABO) A structure or body surface of a fish having the specialized structural capacity for aerial gas exchange; utilized by air-breathing fishes to supplement the normal respiratory mode which is aquatic respiration using gills.

Amphibious air breathing The mode of air breathing when a fish is out of water.

Aquatic surface respiration (ASR) A hypoxia-driven behavior in which a fish surfaces and places its the mouth as close to the water surface as possible in order to ventilate the gills with the upper few millimeters of water that remains well oxygenated because of atmospheric diffusion.

Autapomorphy A specialization unique to one group and thus not useful for establishing relationships.

Bimodal respiration The capacity to exchange respiratory gases in both air and water and to do so either simultaneously or sequentially.

Continuous air breathing The frequent and regular occurrence of air gulping, even when aquatic oxygen levels are sufficient to sustain aquatic respiration. This behavior often indicates the use of ABO gas for functions other than respiration such as buoyancy.

Facultative air breathing Emergency aquatic air breathing initiated in response to a diminished capacity for aquatic respiration usually associated with aquatic hypoxia or some other stress factor.

Hypoxia-inducible factor (HIF-1α) Integrated hypoxia response that activates genes whose protein products either increase O_2 transfer (i.e., erythropoiesis, Hb affinity increases, angiogenesis, etc.) or upregulate metabolic adaptation by regulating anaerobiosis and O_2 consumption rate. HIF-1α induction is an ancient adaptation that first appeared in eukaryotic cells and thus long preceded the origin of metazoans.

Lung The principal aerial respiratory organ of all vertebrates and some primitive air-breathing fishes. An outpocketing along the vertebrate digestive tube having a vascular epitheilial surface that functions for aerial gas exchange through its connection to the body surface by a duct through which air can be inhaled and exhaled.

Obligatory air breathing A high degree of physiological dependence on air breathing for the maintenance of basal oxidative processes or to prevent suffocation. This is usually associated with a reduction in gill surface area that occurs with progressive specialization for air breathing.

Physoclistous gas bladder A gas-filled structure within the body of the fish that has lost its connection to the body surface and thus cannot function for gas exchange but retains functions for buoyancy and either or both sound production and sound reception.

Physostomous gas bladder A gas-filled structure within the body of a fish that is connected to the body surface by the pneumatic duct that allowing inflation or deflation. In different fishes, functions of this organ may include aerial respiration as well as buoyancy and both sound reception and production.

Placoderm Armored Paleozoic fish that were the first vertebrates to have jaws.

Plesimorphy A primitive trait.

Pneumatic duct Tube linking the pharynx to either the lung or physostomous gas bladder which functions for the passage of air for either air breathing, volume control, or both.

Synapomorphy A specialized trait shared by two or more groups, which implies that an ancestral group also possessed this trait.

Tetrapodomorpha The group of vertebrates consisting of the tetrapods (four-limbed vertebrates) and their closest sarcopterygian (lobefin fish) relatives which invaded the land during the Devonian period.

Introduction

All of the over 28 000 living fish species use gills to exchange O_2 and CO_2 with water (**see also Gas Exchange**: Respiration: An Introduction). However, some fishes are also bimodal breathers, that is, they have the capacity to respire aerially as well as aquatically. This most usually happens when the water in which a fish lives becomes hypoxic (i.e., lower than atmospheric O_2 partial pressure). Because air has both a greater and less variable quantity of oxygen than water, some species have evolved the capacity to use aerial oxygen. Air breathing is an auxiliary respiratory mode that enables a fish to live in hypoxic waters or to become amphibious and to perhaps further utilize the mechanical processes integral to this adaptation in the augmentation of functions such as buoyancy, sound reception or production, and reproduction.

Air breathing is an ancient trait that first evolved in fishes and has played a significant role in vertebrate evolution. Not only were fishes the first vertebrates to breathe air, it was an air-breathing, lobe-finned fish that gave rise to the Tetrapodomorpha – a group that lived in shallow water, developed an amphibious capacity, invaded the land in the late Devonian period (360 million years ago, mya), and became the ancestors of all tetrapods. While air breathing is an ancient fish trait, it has also evolved in a number of derived fish groups, including the modern teleosts.

The objective of this article is to develop a biological synthesis of fish air breathing that examines the evolution and diversity of this adaptation and the ways it has contributed to the survival, radiation, and natural history of different species. This perspective sets the stage for subsequent articles on the structure and function of fish air-breathing organs (ABOs; **see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes) and on how the blood circulation of air-breathing fishes is modified for the transport of respiratory gases between the body tissues and both aerial and aquatic gas-exchange surfaces (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes, **Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns, Branchial Anatomy, **Circulation**: Circulatory System Design: Roles and Principles, and **Design and Physiology of the Heart**: The Coronary Circulation).

The Diversity of Fish Air Breathing

Phylogeny and Diversity

An understanding of the evolutionary relationships of fishes is required to comprehend the evolution and diversity of air breathing as well as the structure and function of fish ABOs. The phylogenetic relationship of the families of air-breathing fishes is shown in **Figures 1(a) and 1(b)**. Air breathing occurs only in the bony fishes (Osteichthyes) where it is found in nearly 400 species distributed among approximately 140 genera in 50 families and spanning 18 orders. The Osteichthyes have a 400-million-year-old history and air breathing was present in many, if not all, of the earliest bony fishes and predated the Silurian (438–408 mya) separation of this group's two subdivisions: the Sarcopterygii (lobefins) and Actinopterygii (rayfins).

The broad phyletic distribution of the air-breathing fishes suggests that this adaptation is autapomorphic, meaning that it evolved independently in many groups. Assuming that the lack of an air-breathing synapomorphy (the absence of this specialization in the common ancestors of many of the groups that have it) indicates the independent origin of air breathing; then this adaptation has evolved independently at least 38 times in the bony fishes. Or, if it is further assumed that air breathing evolved independently among many of the species that

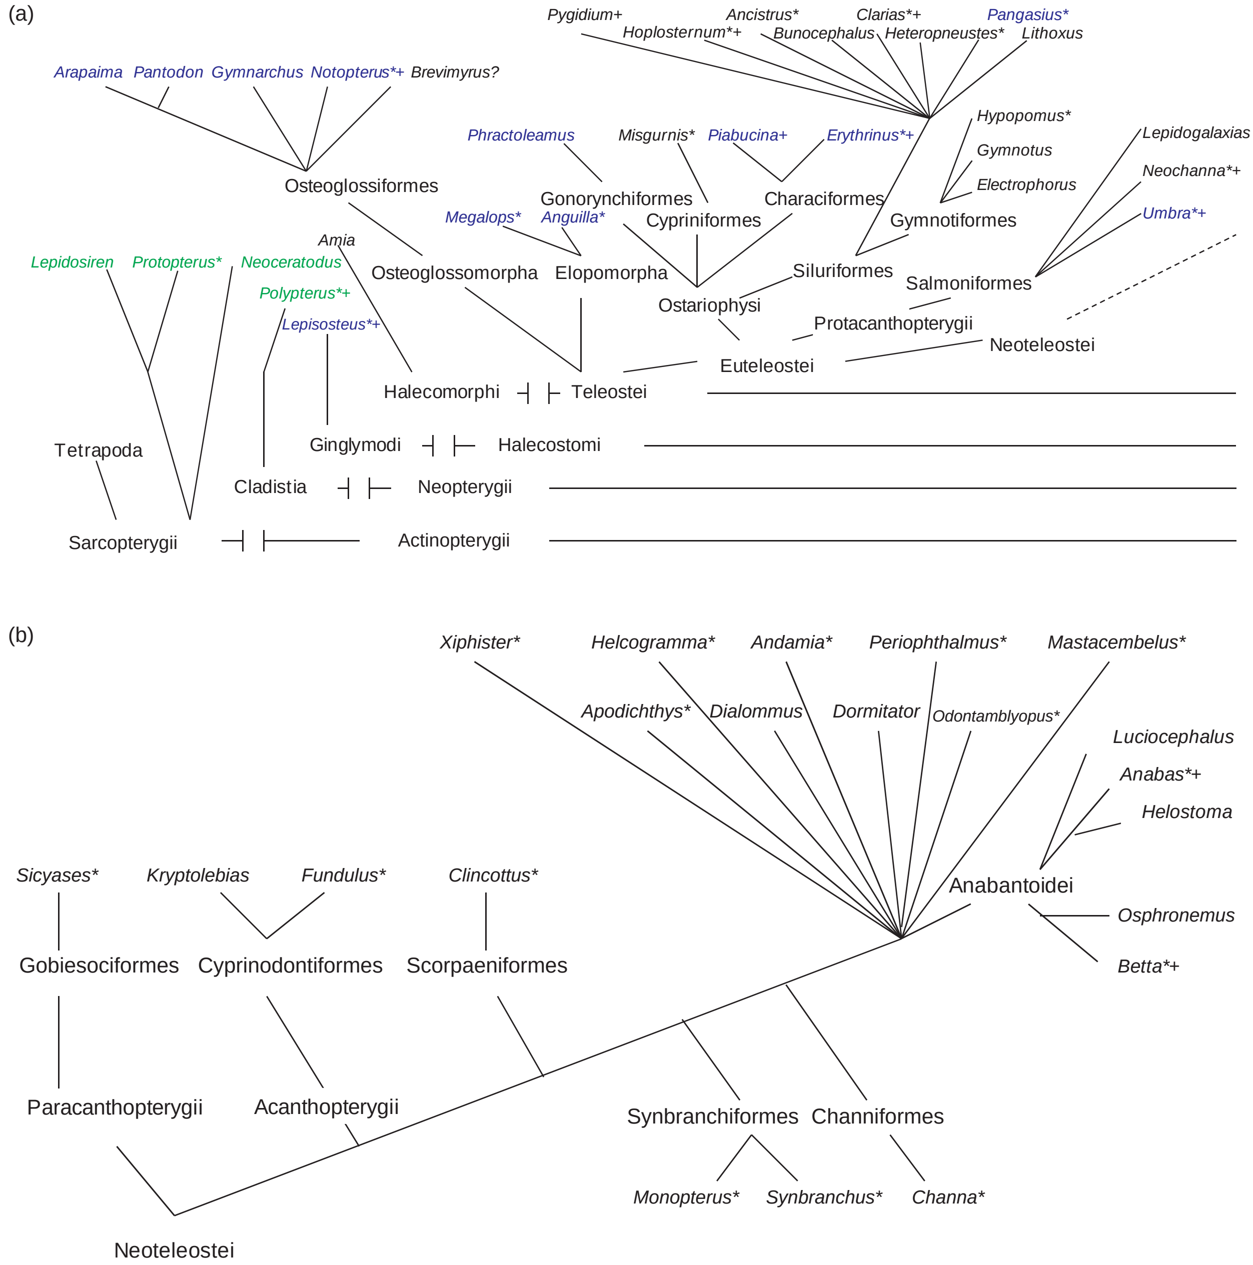

Figure 1 Phylogenetic arrangement of the 50 air-breathing fish families within the class Osteichthyes: (a) phylogeny from the subclass Sarcopterygii to the teleost infradivision Euteleostei, (b) infradivision Neoteleostei. (Note: Family names are replaced by the name of a genus representative of that family.) Asterisk indicates the presence of more than one air-breathing species in the specified genus. Cross indicates more than one genus of air breather in the family. Question mark indicates newer and incomplete data. Colors indicate ABO type: red, lung; blue, gas bladder; black, other structure. Modified from Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation.* San Diego, CA: Academic Press.

use either a lung or a gas bladder as an ABO (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes), then this adaptation could have independently evolved as many as 70 times.

Air breathing is not known to occur in any fish group other than bony fishes. It may occur in jawless fishes as several species of lampreys make occasional amphibious excursions during upstream migration and laboratory studies with one of these, New Zealand lamprey *Geotria australis* show it can respire in air and endure prolonged aerial exposure. There are no known chondrichthyan (sharks and rays) air breathers, although one species, the sand tiger shark, *Odontaspis taurus*, does swallow and discharge air in order to adjust its buoyancy. The only suggestion of air breathing at an earlier stage of vertebrate evolution than the Osteichthyes is the report of paired lung-like structures in fossils of the Devonian (408–360 mya) placoderm *Bothriolepis canadensis*.

The interpretation of these structures as lungs has remained controversial for nearly 70 years and should be resolved using high-resolution X-ray computed tomography on some of the many well-preserved *Bothriolepis* fossils (there are over 70 species) residing in many museum collections. Because placoderms are ancestral to the chondrichthyans, the report of lungs in *Bothriolepis* and knowledge that no air-breathing structures occur in living chondrichthyans prompted speculation that air breathing evolved in placoderms, was lost in chondricthyans, and reappeared in the osteichthyans. Support for this hypothesis has never been strong; however, in view of the extent to which the independent origin of air breathing occurs among osteichthyans, the presence of this specialization in a placoderm or an early jawless fish is not unexpected. *Orthacanthus* (at least three known species), a large, eel-like shark that lived in freshwater swamps during the mid- to late Paleozoic (400–225 mya), would seem a likely candidate for air breathing.

Phylogeny and the ABO

The vertebrate lung originated in fishes and is present in both the sarcopterygians (e.g., lungfish) and the actinopterygians (**Figures 1**(**a**) and **1**(**b**)). In nearly all instances tetrapod evolution is linked to increased lung efficacy; however, for actinopterygians the evolutionary history of the lung took a quite different course; it became gradually transformed, first into a physostomous (remotely linked to the air via a tube, the pneumatic duct, connection to the pharynx) respiratory gas bladder, then to a nonrespiratory physostomous gas bladder, and finally to a physoclistous (no duct connection) gas bladder primarily specialized for sound reception or production, buoyancy control, or several of these (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes and **Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes). The transition from lung to gas bladder closely paralleled the adaptive radiation of actinopterygians; paired lungs occur in the primitive Cladistia (bichirs, *Polypterus* (*P. senegalus* and about 13 other species) and the ropefish, *Erpetoichthys calabaricus*), while respiratory gas bladders occur exclusively in the other primitive groups (Ginglymodi, gars *Lepisosteus occulatus*, *Atractosteu* sp., and about seven total species; Halecostomi, *Amia calva*) and even in some teleosts (**Figure 1**(**a**)).

Among the Euteleostei, which includes the most highly derived bony fishes, the respiratory gas bladder is limited to the most primitive superorders Ostariophysi and Protacanthopterygii (**Figure 1** (**a**)). The ostariophysan order Siluriformes (catfishes) illustrates the manner in which the evolutionary canalization of the gas bladder structure and function (e.g., in some cases being embedded in bone to augment sound reception) had proceeded to the point where this organ could not be converted, through natural selection, into an ABO in cases where environmental or climate changes or a group's ecological radiation placed it in a habitat necessitating air breathing. Only one silurid, *Pangasius* (*P. sutchi* and at least three other species) has a respiratory gas bladder featuring a lung-like vascular or pulmonoid epithelium. *Pangasius* is in the family Pangasiidae which, as seen in the silurid cladogram (**Figure 2**), is not a basal group, is one of eight siluriform families with air-breathing species, but the only one of these having a respiratory gas bladder. This indicates the apomorphy of the pulmonoid gas bladder in *Pangasius* as well as the other siluriform ABOs, which occur in many genera and species in these other families and range in diversity from the buccal chamber (*Bunocephalus amaurus*) to the stomach (*Ancistrus* (= *Liposarcus*) *chagresi*, *Hypostomus plecostomus*, *Pygidium striatum*, and *Lithoxus lithoides*), the intestine (*Misgurnis anguillicaudatus*, *Hoplosternum thoracatum*, *Callichthys asper*, and *Corydoras aeneus*), and a suprabranchial chamber with gill-derived dendrites and fans (*Clarias batrachus* and several other species) having extended pharyngeal pouches (*Heteropneustes fossilis*) (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes).

Thus, and commencing with the Ostariophysi, adaptive specialization of the gas bladder for functions discordant with bimodal respiration led to natural selection for novel ABOs in all of the higher teleosts, especially the Neoteleostei (**Figure 1**(**b**)). Correlations between phylogeny and bimodal breathing morphology extend to the patterns of blood circulation, to the mechanisms for and the control of ABO ventilation, and to morphological specializations (body size and shape, gill structure, and fin position) favoring amphibious life (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes and Circulatory Adaptations for Air-Breathing Fishes).

The Types of Air-Breathing Fishes

Initial categorizations of air-breathing fishes were based on ABO structure (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes) but these had limited utility because they did not account for phylogeny, were not based on the fine-scale ABO structure, and were not inclusive of the many neoteleost air breathers lacking a well-developed ABO. A categorization based on the functionality of air breathing is an efficient way of incorporating these important features and circumscribing the range of physical and ecological factors likely affecting aerial and aquatic respiration.

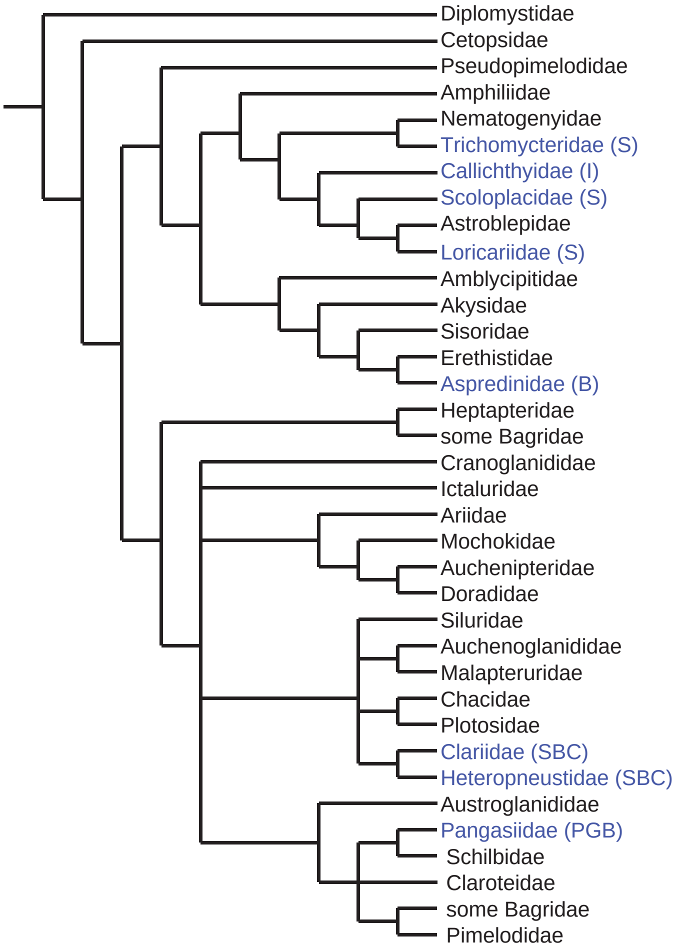

Figure 2 Phylogenetic relationships within the order Siluriformes showing the families in which air breathing occurs (blue) and their ABO type in parentheses: B, buccal chamber; I, intestine; PGB, pulmonoid gas bladder; S, stomach; SBC, suprabranchial chamber. Modified from Graham JB and Wegner NC (2010) Breathing air in water and in air: The air-breathing fishes. In: Nilsson GE (ed.) *Respiratory Physiology of Vertebrates: Life With and Without Oxygen*, pp. 174–220. Cambridge: Cambridge University Press.

Aquatic Air Breathers

From a functional standpoint, fish air breathing is readily classified as either aquatic or amphibious. Aquatic air breathers remain in water (although some species doing this can also be amphibious air breathers) and there are two types, facultative and continuous. Facultative air breathers normally respire aquatically and use air breathing only when it is required by environmental conditions, principally hypoxia. Functional hypoxia caused by intense exercise or other stress factors can also elicit facultative air breathing. Included among many facultative air breathers are the Australian lungfish *Neoceratodus forsteri*, nearly all of the genera of the South American suckermouthed armored catfishes (Loricariidae, e.g., *Liposarcus chagresi* and many other species) and other Amazon catfishes (*Gymnotus carapo*, *Hypopomus brevirostris*, and *H. occidentalis*), the swamp eel (*Synbranchus marmoratus*), the salmoniforms (*Umbra limi* and three other species and *Dallia pectoralis*), the estuarine goby (*Gillichthys mirabilis*), and the Asian eel goby (*Odontamblyopus lacepedi* and other species), which switches to air breathing only when its burrow water becomes hypoxic at low tide.

Some aquatic air breathers do this regularly even in normoxic water and are termed continuous air breathers. Continuous air breathing is common in species living in habitats where hypoxic water is either a chronic or frequent occurrence, and in many cases continuous air breathing is not solely for respiration but also functions to maintain the volume and wall tension of the ABO in order to serve additional and potentially multiple purposes such as buoyancy and either or both sound production and reception (e.g., featherbacks *Notopterus notopterus* and two other species, also *Papyrocranus afer* and *Xenomystus nigri*).

Obligate Air Breathers

Although most aquatic air breathers are continuous air breathers, some are also obligatory air breathers, meaning they completely depend on and require access to aerial oxygen and, even if they are in water that is well oxygenated, they will have a reduced aerobic scope or possibly even drown if prevented from air breathing. Examples of obligatory air breathers include the four African lungfish (*Protopterus atheiopicus*, *P. amphibius*, *P. annectens*, and *P. dolloi*), the South American lungfish (*Lepidosiren paradoxa*), the Amazon osteoglossid (*Arapaima gigas*), the African butterfly fish (*Pantodon bucholzi*), the Atlantic tarpon (*Megalops atlanticus*), the silurid (*Pangasius sutchi*), some species of clariid catfishes (but results vary, *C. batrachus, C. lazera, C. gariepinus, C. macrocephalus*), the armored catfish *H. thoracatum*, the monotypic Amazon electric knifefish (*Electrophorus electricus*), several anabantoids including *Anabas testudinus*, *Osphronemus goramy*, *Trichogaster trichopterus* and *T. pectoralis*, and *Colisa fasciatus*), the swamp eel (*Monopterus cuchia*), and probably the seven other species in this genus), and probably some of the 12–14 species of snakehead (*Channa*), but this has not been studied.

Obligatory air breathing appears to be the consequence of developing such a proficient level of air-breathing specialization that the capacity for aquatic respiration using the gills is compromised (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes, **Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns, Branchial Anatomy, **Circulation**: Circulatory System Design: Roles and Principles, **Design and Physiology of the Heart**: The Coronary Circulation, and **Ventilation and Animal Respiration**: Plasticity in Gill Morphology). An ABO that develops within the branchial chamber can, for example, occlude the gills or restrict their size. Reductions in gill area can also be caused by the functional conflict between the in-series circulation typical of fishes and the positioning of the ABO. In most aquatic air breathers, oxygenated blood exits the ABO via the venous circulation and passes through both the heart and gills before entering the systemic circulation. The exposure of oxygenated blood to hypoxic water in the gills increases the potential for the trans-branchial loss of O_2 and this is often countered by reduction in gill surface area or the permanent shunting of blood through nonexchange surfaces within the gill.

Amphibious Air Breathing

There are three grades of amphibious air breathers: species that endure seasonal exposure in drying mud, those that endure brief stranding by a receding tide, and those that volitionally emerge from the water. Fishes subject to long-term exposure in drying mud include the African and South American lungfish (*Protopterus* and *Lepidosiren*), swamp eels (Synbranchidae), armored catfish (*Liposarcus*, *Hypostomus*, and *Callichthys*), anabantoids (*Anabas* and *Ctenopoma*), snakeheads (*Channa*), clariid catfishes (*Clarias*), and many other species, including non-air-breathers inhabiting lowland tropical streams that stagnate and disappear during the dry season. Many intertidal fish species including *Fundulus majalis* (and other species in this genus) can become trapped on land during low tide and fishes residing in congested littoral tidepools that become progressively hypoxic during low tide may, under extreme conditions, emerge from the water (e.g., the sculpins *Clinocottus globiceps* and *Oligocottus snyderi*). The estuarine mudsucker goby *G. mirabilis* also does this. The mangrove killifish (*Kryptolebias* (=*Rivulus*) *marmoratus* and other species in this genus) occupies unique, above-the-water-line habitats such as in leaf litter and termite burrows in floating logs. While amphibious air breathing is often associated with hypoxic stress and disappearance of water from a habitat, the natural behavior of a number of tropical and subtropical intertidal fishes such as the rockskipper *Dialommus* (=*Mnierpes*) *macrocephalus*, numerous blennies (*Blennius pholis*, *Entomacrodus nigricans*, *Alticus kirki*, and *Andamia tetradactyla*, there several species in each of these genera), and the mudskippers (*Scartelaos histophorus*, *Boleophthalmus pectinirostris*, *Periophthalmus modestus*, and *Periophthalmodon schlosseri*, there are numerous species in each genus) make frequent terrestrial sojourns for the purpose of exploiting resources above the water line.

The Evolution of Air Breathing

For the majority of air-breathing fishes a close link exists between this specialization and environmental hypoxia, suggesting that natural selection for air breathing has been driven largely by the cyclic occurrence, over geologic time, of severe environmental hypoxia (about 30–40% air saturation of water). For each group in which air breathing has evolved, selection has operated on a specific combination of factors that included genetic variation and the potential advantages in terms of inter-specific competition and ecological radiation through niche expansion afforded by increased hypoxia tolerance and air breathing. The potential interaction of these factors over time is illustrated in **Figure 3**.

The important consequence of selection for air breathing has been to preserve or open ecological access to habitats that would otherwise be inaccessible to non-air-breathing fishes. In terms of the mechanism for selection, the initial steps toward air breathing probably emerged from hypoxia adaptations common to non-air-breathing fishes. A key behavioral response to hypoxia is searching for nearby water having a higher O_2 concentration, such as more shallow areas or at the water surface. Many non-air-breathing fishes use aquatic surface respiration (ASR), a behavior in which the mouth is positioned as close to the water surface as possible in

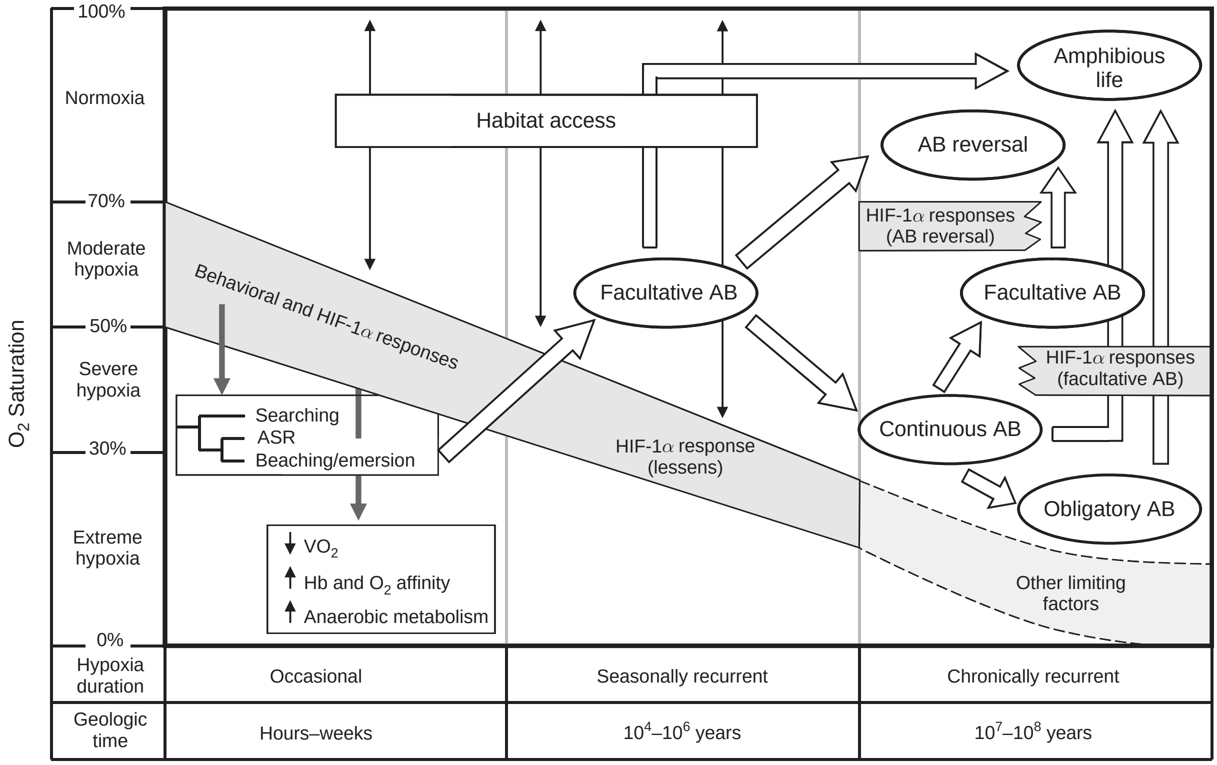

Figure 3 Integrated aspects of environmental hypoxia adaptation and the selective mechanisms operating over different periods of time leading to the evolution of air breathing and terrestriality in different fish groups and its effect of opening limited habitats for occupation and promoting radiation and diversification. Behavioral responses such as ASR that takes a fish close to the surface increased the potential for inadvertent air gulping may have been a major selective factor in the origin of air breathing. Specialization for hypoxia and air breathing would lead to down regulation of HIF-1α response mechanisms. Modified from Graham JB and Wegner NC (2010) Breathing air in water and in air: The air-breathing fishes. In: Nilsson GE (ed.) *Respiratory Physiology of Vertebrates: Life With and Without Oxygen*, pp. 174–220. Cambridge: Cambridge University Press.

order to ventilate the gills with the upper few millimeters of water that remains O_2 rich because of atmospheric diffusion. A further refinement in ASR, one that directly relates to the origin of air breathing, is gulping air which is done to increase buoyancy and place the mouth in a better position for surface ventilation. Whether air is gulped intentionally or inadvertently, the O_2 it contains has the potential to enrich the O_2 supply and could contribute to aerobic metabolism if the bubble contacts an absorptive epithelial surface in the mouth or other area, or if it is held in and oxygenates the ASR ventilatory stream. In this way, initial selection for gulping to aid ASR could, in recurrent conditions of environmental hypoxia extending over at time frame of perhaps 10^4–10^6 years or longer, select for adaptations leading to the use of aerial O_2.

Activation of the hypoxia-inducible factor (HIF-1α), an ancient eukaryote adaptation predating the origin of vertebrates, is another key hypoxia response. HIF-1α induction activates genes promoting O_2 transfer (i.e., erythropoiesis, Hb affinity increases, and angiogenesis) and upregulates metabolic adaptation through expression of genes controlling anaerobiosis and O_2 consumption rate (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function). The efficacy of HIF-1α has been demonstrated for both water-ventilating and air-breathing fishes and, as illustrated in **Figure 3**, it would play a key adaptive role during irregular and brief (i.e., hours–weeks) periods of aquatic hypoxia experienced by a non-air-breathing fish. Under such conditions, HIF-1α expression would be continually reinforced by natural selection (i.e., individuals having an effective HIF-1α response would survive and propagate the next generation), and, among populations of species experiencing chronic recurrences of severe hypoxia (i.e., 30–40% air saturation) over an extended time, both the suite of adaptive responses encompassed by HIF-1α and the threshold of its onset would likely change (**Figure 3**).

Both the increase in blood hemoglobin (Hb) concentration and the reduction of the quantity of intraerythrocytic nucleoside triphosphates (e.g., adenosine and glutamine triphosphate) resulting in a left-shift (increased) Hb-O_2 affinity in facultatively air-breathing loricariid catfish (*L. chagresi*, *Pterogoplicthys multiradiatus*, and other species) are signature features of HIF-1α induction. This affinity increase enables a fish to bind more O_2 in hypoxic water, lessens the potential for trans-branchial loss, and reduces critical oxygen partial pressure (P_{O_2}) and thus increases its proficiency for aquatic respiration in hypoxia. Moreover, the annual dry-season increase in loricariid Hb concentration that occurs in advance of either drying or hypoxia suggests that there has been selection for a preadaptive change that will mitigate these conditions if they occur.

Strong selection for more proficient air breathing, occurring over geologic time and driven by both the environmental change and the diversification and radiation of groups into different, and more variably oxygenated habitats, would have also contributed to the origin of continuous air breathing and ushered in morphological and physiological changes, such as a reduction in gill area to lessen the potential for O_2 loss, leading to obligatory air breathing (**Figure 3**). The respiratory specializations of different groups, brought on by regular exposure to environmental hypoxia over periods of probably 10^7–10^8 years, concomitantly reduce the importance of an aquatic-hypoxia-induced HIF-1α response; *Lepidosiren* and *Protopterus*, for example, are obligatory air breathers that are so proficient at air breathing that they are largely insensitive to the effect of aquatic conditions such as low P_{O_2} that control respiration and trigger air breathing in most other aquatic air breathers. The high degree of respiratory independence from water conditions afforded by well-developed air breathing expands potential habitat access to the point where it becomes limited by factors such as the absence of prey and adverse conditions such as temperature, drying, and lack of cover and H_2S.

Air Breathing and Natural History

Adaptive Radiations

Air breathing appears to have been an important factor in the radiation and diversification of certain groups. Many of the species in the families Callicthyidae and Clariidae, and all of the species in the five families comprising the anabantoid suborder (Anabantidae, Belontiidae, Helostomatidae, Osphronemidae, and Luciocephalidae), breathe air. Taken together, these groups comprise a large fraction of the total air-breathing fish diversity (about 14% of the families, 16% of the genera, and 39% of the species). Air breathing permits populations to expand into habitats where, because of adverse conditions, ecological success is assured through limited competition from non-air-breathers. In this way, formerly contiguous populations may become reproductively isolated and undergo genetic divergence into separate species. The degree of diversification present among the anabantoids illustrates that, despite the requirement to sustain air breathing, extensive adaptive radiation can result in dramatic modifications in dentition, jaw structure, and diet, as well as body shape and size. These functional changes have not altered ABO respiratory function; however, dependence on air breathing seems to have become more relaxed in some of the anabantoids that are not obligatory air breathers (*Sandelia capensis*, *S. bainsi*, *Trichogaster* sp., and *Colisa lalia*).

Another pattern of adaptive radiation is seen in the African clariid catfishes, many of which have evolved into habitats in which air breathing is not required. The ABO has regressed in species of *Dinotopterus* occurring in open waters and depths of Lakes Malawi and Tanganyika. Several other regressed genera (*Xenoclarias*, one species; *Clariallabes*, 16 species; *Gymnallabes*, three species; and *Taganikallabes*, one species) are small and anguilliform with reduced fins. Most of these fishes have taken up life in swift streams where they burrow in rubble and even make amphibious excursions and feed out of water (*Channallabes apus*), while others live in lakes at considerable depth. With their independence from habitat conditions, the fully bimodal clariids achieved a broad distribution across both Africa and Asia, whereas the regressive clariids are largely confined to a narrow central African distribution where they have diversified into unfilled niches. A parallel occurs in the two species of the anabantoid genus *Sandelia* which, having radiated into more oxygenated habitats of southern Africa, have a highly reduced ABO.

An additional aspect of aquatic air breathing now demonstrated for numerous species is synchronous air breathing, a behavior characterized by the closely timed and nearly simultaneous air gulping by a group. This behavior is a form of temporal schooling that reduces the danger of predation during surfacing for air.

The transition to land is another dimension of fish air breathing. Amphibious air breathers must respire without water contact and thus risk desiccation as well as the interruption of the normal functions of the gills in water such as CO_2 release, ion regulation, acid–base balance, and nitrogen excretion (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange, **Circulation**: Circulatory System Design: Roles and Principles, and **Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System). Amphibious air-breathing fishes are seldom far from water; however, air breathing does permit littoral-zone exploitation and is reflected in attendant biochemical, physiological, morphological, and behavioral adaptations for terrestriality. In the case of mudskippers, which are the most terrestrial teleosts, other facultative air breathing but mainly nonamphibious species (*Pseudapocryptes lanceolatus*, *Apocryptes bata*, and others) are members of the same clade (the goby subfamily Oxudercinae); however, for mudskippers the vacant niches of the mudflat proved to be the catalyst for amphibious life. Mudskipper amphibious adaptations include fin and body modifications for terrestrial crawling (crutching), skipping, jumping, and climbing. They also have prominent eyes and a good visual acuity in air. Although their lateral line is reduced, mudskippers can hear airborne sound (250–600 Hz). Also, their physiology is specialized to limit desiccation, to allow osmoregulation in different salinities, and to modify nitrogen excretion for water conservation. Some species can also sense the O_2 content of the air in their burrow. While most mudskippers retain the capacity for aquatic respiration, at least one species in the genus *Periophthalmodon* (*Pn. schlosseri*) is an obligatory air breather. Amphibious life poses a problem for vision because of the refractive differences of air and water. Solutions include, for some mudskippers, reduction of lens curvature to compensate for the added corneal refraction in air or, in *Dialommus macrocephalus* and some blennies (*E. nigricans*), flat corneas reduce aerial astigmatism and allow emmetropia in air without compromising aquatic accommodation. Amphibious fishes have the capacity to orient to water by using known reference points or possibly sun compass. Pit traps set at night near tropical streams demonstrate that some aquatic air breathers also leave the water. *Clarias lazera* was discovered to leave water at night to feed on stored grain while the amphibious, regressive air breather *Channallabes apus* is able to capture prey on land using a snapping (not suction) jaw action.

Ancillary Air-Breathing Functions

Aspects of air breathing have become integrated into functions unrelated to respiration. In *N. forsteri*, *Piabucina festae*, *H. thoracatum*, *Umbra limi*, *H. plecostomus*, and others, the ABO contributes to static lift (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). The loricariids have a stomach ABO and in some species thick, air-filled diverticulae that branch off from the esophageal–stomach junction and encircle the stomach contribute to near-neutral buoyancy which is important for foraging on vertical surfaces, submerged roots, or tree branches. Buoyancy control may also take precedence over

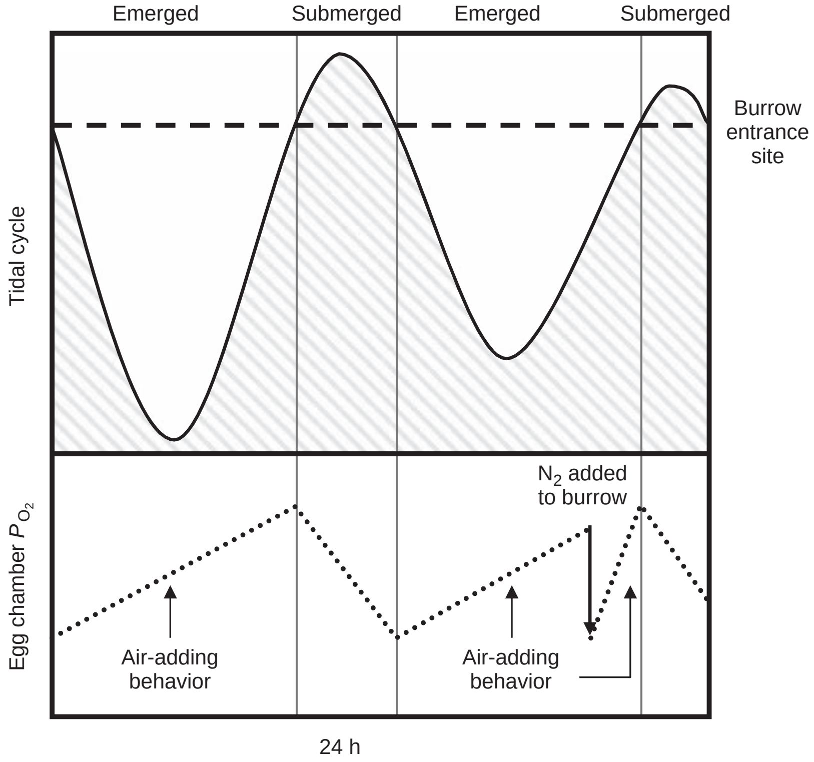

Figure 4 Tidal-cycle effects on the P_{O_2} of the egg chamber in the mudflat burrow of the mudskipper, *P. modestus*. The male mudskipper guards the intertidal mudflat nest and attends to the eggs, which hatch about 7 days postfertilization. During high tide, the burrow entrance is submerged and egg respiration combined with the reducing environment of the anoxic mud and possibly the respiration of the guarding fish reduce the egg chamber O_2 content. When the tide level recedes below the burrow opening, the male uses air-gulp transportation to raise egg-chamber O_2 content in preparation for the next high tide. The experimental injection of N_2 gas into the egg chamber causes the male fish to increase its frequency of air-deposition behavior in order to raise burrow P_{O_2} before the next incoming tide covers the burrow entrance. Modified from Ishimatsu A, Yoshida Y, Itoki N, *et al.* (2007) Mudskippers brood their eggs in air but submerge them for hatching. *Journal of Experimental Biology* 210: 3946–3954; and Graham JB and Wegner NC (2010) Breathing air in water and in air: The air-breathing fishes. In: Nilsson GE (ed.) *Respiratory Physiology of Vertebrates: Life With and Without Oxygen*, pp. 174–220. Cambridge: Cambridge University Press.

respiratory needs in some fishes; species of *Lepisosteus* and *A. calva* are known to regulate ABO volume for buoyancy purposes, and when in water mudskippers inflate their branchial chambers with enough air to allow them to float with their eyes in air. In anabantoids, bubbles derived from air breathing have a role in territoriality, courtship displays, and bubble-nest construction (*Betta splendens* and other species), and the ABO of these fishes is used to make sounds important in courtship behavior. *H. thoracatum* and other callichthyids also build bubble nests; the diffusive properties of these structures remain uninvestigated. Some anabantoid species (*Macropodus, Betta*) are mouth brooders, as is *A. gigas* and some species of *Chann*a; how this is coordinated with air breathing is unknown.

Air breathing plays a role in nest oxygenation. In male *Lepidosiren*, aerially obtained O_2 is exuded into the nests via gill-like filaments that form on their paired fins. (These were early studies that were controversial and more data are needed. Also, accounts differ as to whether the gill filaments form only on the pelvic fins or on both paired fins.) A comparable function has been suggested for the skin of *Synbranchus* and for cirri on the heads of male loricariids. Mudskippers incubate eggs in air-filled chambers within their littoral-zone mud burrows. An egg-tending male *P. modestus* can sense the P_{O_2} in its air chamber. During high tide when the burrow is submerged, chamber P_{O_2} decreases and during low tide the fish restores chamber P_{O_2} by bringing in gulps of fresh air. If air-chamber P_{O_2} is lowered by pumping in N_2, the fish responds with a greater rate of air transport (**Figure 4**).

Summary

Air breathing is an ancient fish adaptation that has independently evolved in many groups over 400 million years. The diversity of these fishes and their different types of ABOs and air-breathing behaviors all signify the efficacy of natural selection in achieving a nearly perfect solution to the common occurrence of environmental hypoxia in shallow water habitats throughout the long history of fish evolution. Diverse air-breathing groups demonstrate the central role of aquatic hypoxia in driving the independent origin of air breathing and for, over the expanse of geologic time, either intensifying or relaxing selection for air breathing and related adaptations, all in concert with changes in environmental factors, with shifts in the patterns of expansion and ecological radiation and morphological changes in a particular group. Specifically, the capacity of fishes to breathe air was an important precondition for the evolution of amphibious life, both in the tetrapodomorphs and in many extant air-breathing fishes such as the mudskippers. Although air breathing seemingly presents the perfect answer to shallow-water environmental hypoxia, not all fishes exposed to this environmental challenge answer it with air breathing. However, for the majority of air breathers this capacity enables them to remain in and better exploit an aquatic habitat in which they could not otherwise survive and associated with this are the examples of how air breathing has secondarily influenced other aspects of natural history. Because the independent evolution of air breathing is viewed as an ongoing process, it is likely that some fishes, because of environmental change or their potential for ecological radiation into less favorable habitats, may now be undergoing the initial selective processes leading to the acquisition of this capacity.

Glossary

Air-breathing organ (ABO) A structure or body surface of a fish having the specialized structural capacity for aerial gas exchange; utilized by air-breathing fishes to supplement the normal respiratory mode which is aquatic respiration using gills.

Bimodal respiration The capacity to exchange respiratory gases with either air or water and to do so either simultaneously or sequentially.

Ediculae A terminal gas-exchange unit in the honeycombed aerial respiratory structure offish lungs and respiratory gas bladders characterized by being wider than they are deep.

Faveolae A terminal gas-exchange unit in honeycombed aerial respiratory structure of fish lungs and respiratory gas bladders characterized by being deeper than they are wide.

Lung The principal aerial respiratory organ of all vertebrates and some primitive air-breathing fishes. An outpocketing along the vertebrate digestive tube having a vascular epitheilial surface that functions for aerial gas exchange through its connection to the body surface by a duct through which air can be inhaled and exhaled.

Parenchyma The essential and distinctive tissues of an organ.

Respiratory epithelium A specialized respiratory surface consisting of a single or few layers of epithelial cells ranging from <1 to 15 μm thickness and covering a network of capillaries (also referred to as a vascular epithelium).

Surfactant A chemical that stabilizes mixtures of oil and water by reducing the surface tension at their interface. As in their mammalian counterpart, the surfactant in fish lungs and respiratory gas bladders, and other gut derived ABOs serves to reduce the surface tension of fluids on these surfaces and promotes tissue-elastic properties.

Type I cells Squamous epithelial cells associated with a respiratory exchange surface.

Type II cells Cuboidal epithelial cells usually associated with a respiratory surface and characterized by the presence of lamellate (double membrane) layers.

Introduction

Another article has detailed the phylogenetic relationships among the air-breathing fishes and provided a functional classification for air breathing, emphasizing both the mode (aquatic or amphibious air breathing) and the level of dependence (facultative, obligate) of a species for aerial O_2 (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction). The objective of this article is to survey the structure and function of all air-breathing organs (ABOs), including the organs and tissues having functions other than aerial respiration. This article also presents a classification system for ABOs that incorporates position, structure, and function within a phylogenetic framework and describes the different mechanisms used for ABO ventilation.

Types

Most early accounts of air breathing classified fish ABOs on the basis of body position but this approach provided little comparative morphological data, did not account for phylogenetic influences, and was not in most cases inclusive of species that breathe air without a specialized ABO. A comprehensive classification of the ABO based on structure, position, and degree of development results in three groups:

I. Derivatives of the digestive tube including
   a. the lung and a physostomous gas bladder having a respiratory function and b. other sections of the digestive tube including the esophagus, pneumatic duct, stomach, and intestine.

II. Areas in and near the head, such as the buccal, pharyngeal, and opercular chambers having a dense covering of respiratory epithelium and, in most cases, an enhanced surface area, due to either or both an added chamber volume and the projection into it of branchial-arch extensions having a covering of respiratory epithelium.

III. Other organs such as the gills and skin, having structural modifications promoting aerial gas exchange.

Evolution

The three ABO categories reflect the sequence of changes in air breathing that occurred with the progressive evolution of the bony fishes (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction; **Figure 1**). Basal to group Ia is the lung, the plesiomorphic vertebrate ABO, which occurs in the three lungfish genera (*Neoceratodus forsteri*, *Lepidosiren paradoxa*, *Protopterus* (four spp., **see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) and in the polypterids (*Erpetoichthys calabaricus* and *Polypterus* about 14 species). Also in this group are 18 actinopterygian genera, including several teleosts, having a physostomous respiratory gas bladder which also often functions for buoyancy (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes) and for either or both sound reception and sound production (**see also Hearing and Lateral Line**: Psychoacoustics: What Fish Hear and Sound Source Localization and Directional Hearing in Fishes). As emphasized in **Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction, many of these gas bladder respiratory functions evolved independently.

Natural History

With few exceptions, groups I and II include most of the freshwater aquatic air-breathing fishes. Groups Ib, II, and III encompass the phase of novel ABOs in which, due its evolutionary specialization, the gas bladder was no longer suited for recruitment, through natural selection, for ABO function. The course of teleost radiation into many diverse ecological niches provides examples of groups in which the gas bladder was lost, became physoclistous (i.e., no pneumatic duct), or was embedded in bone to increase sound sensitivity. Group III consists mainly of

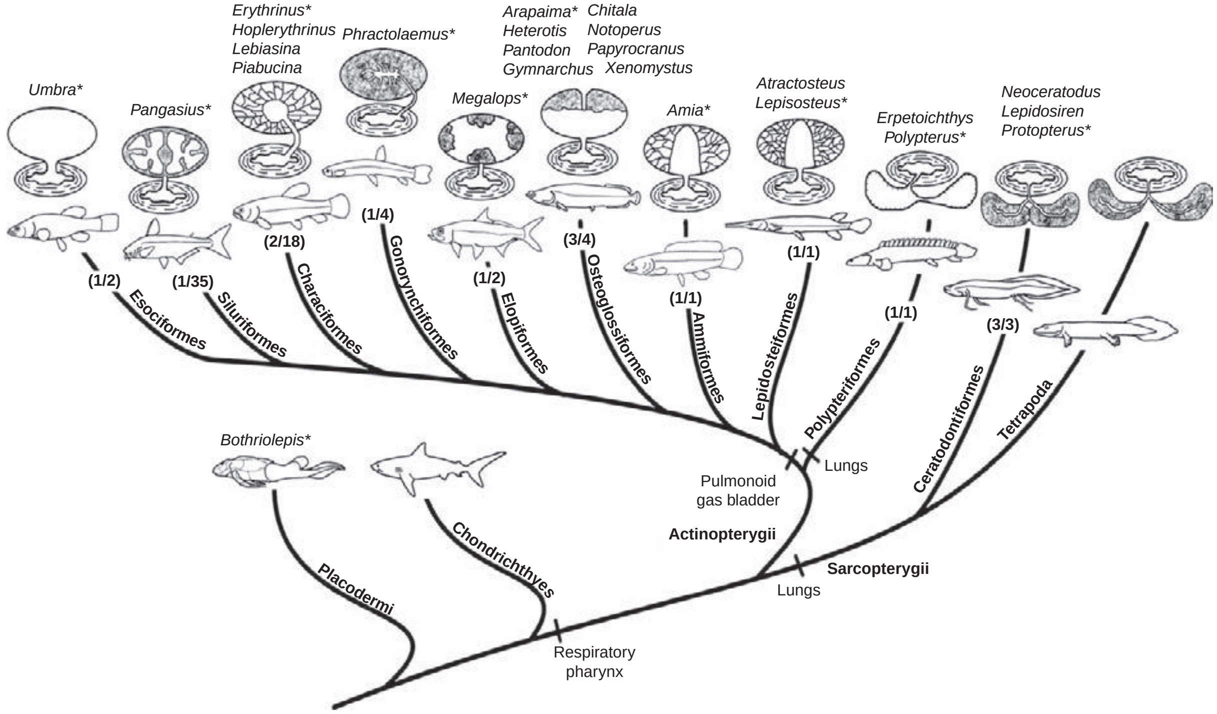

Figure 1 Occurrence and structural diversity of the lungs and respiratory gas bladders in 10 orders of extant fishes and the tetrapods. Shown for each fish order is the relative number of families having this type of ABO and a list of genera with the organ. Head-end views of transverse sections show the gut (thick with dashed lines) and the relative complexity of the ABO parenchyma. Pneumatic duct details for *Neoceratodus* are not illustrated (see **Figure 2**). Reproduced from Fig. 6.2 in Graham JB and Wegner NC (2010) Breathing air in water and in air: The air-breathing fishes. In: Nilsson GE (ed.) *Respiratory Physiology of Vertebrates: Life With and Without Oxygen*, pp. 174–220. Cambridge: Cambridge Press.

amphibious fishes, which take up O_2 and remove CO_2 via their skin or gills, and, in some cases, also have a well-developed respiratory epithelium in their buccal, pharyngeal, branchial, or opercular chambers.

Function

For most species in groups I and II, the ABO is an enclosed space into which air is inspired; aerial O_2 is absorbed across a respiratory epithelium (a thin layer of cells under which is a network of capillaries) and becomes bound to hemoglobin (Hb) in erythrocytes for circulation to the tissues (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). When most of the O_2 in the inspired breath has been absorbed, this air is expelled and a new breath is taken.

Although a range of ABO structures is represented by categories I and II, these share two common features: (1) being located in close proximity to the digestive tract which provides fairly direct contact with air taken in by the mouth and (2) close proximity to circulatory network surrounding the digestive tract, an essential feature for O_2 removal from the ABO. Another common feature of ABOs of the aquatic air breathers is that these organs function mainly for the uptake of O_2 and not for the release of CO_2, which remains the province of gills and other surfaces contacting water. This is in contrast to amphibious air breathers which are capable of a high aerial carbon dioxide release rate during aerobic respiration ($\dot{V}_{CO_2}$).

The Lung and Respiratory Gas Bladder

Figure 1 shows the phyletic distribution of lungs and respiratory gas bladders among the vertebrates. Lungfishes not only breathe air with a lung but also use their gills and skin for aquatic respiration, especially *Neoceratodus*. While not an air breather, the coelacanth, *Latimeria chalumnae*, a primitive lobefin related to lungfish and the Tetrapodomorpha, has a vestigial, fat-invested lung-like organ supplied by a pulmonary circulation (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes). Among actinopterygians only the polypterids (the many species *Polypterus* and *E. calabaricus*) utilize lung respiration. The actinopterygians using a respiratory gas bladder are dispersed among eight orders, 11 families, and 18 genera. Furthermore, they include both primitive nonteleosts such as the gars (*Lepisosteus* and *Atractosteus*, about seven species in total), the bowfin (*Amia calva*), and six teleost orders (**Figure 1**). Among these only *Amia*, a primitive species considered the common ancestor of the group that gave rise to the teleosts, has a respiratory gas bladder; however, this species also has a pulmonary circulation (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

Morphology

The four morphological features distinguishing the fish lung are:

1. formed as a ventral outpocketing or budding of the posterior embryonic pharynx;
2. paired or bilobed tube extending into the posterior, mainly ventral part of the peritoneal cavity;
3. tubular connection (pneumatic duct) with the pharynx, guarded by the glottal valve; and
4. perfusion by a pulmonary circulation – the arteries of this originate from the efferent arteries of either or both branchial arches 3 and 4, while a pulmonary vein returns O_2-rich blood to or near the heart (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

The four contrasting features of the physostomous respiratory gas bladder are:

1. formed as a budding of the dorsal or lateral wall of the posterior embryonic pharynx;
2. single or bilobed tube occurring within the dorsal mesentery and occupying the upper region of the peritoneum;
3. long or short pneumatic-duct connection with the top or side of the pharynx that is generally without a glottis; and
4. blood circulation that in most cases is nonpulmonary – the arterial supply is by a branch from the dorsal aorta and return to the heart is via the hepatic portal system (or the postcardinal vein; **see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

Evolutionary Relationship

In the *Origin of Species*, Darwin pointed to what he assumed had been a gradual transformation of a fully functional organ for fish buoyancy regulation into a fully functional lung as an example of descent with change. This would have entailed a vertical shift in organ position and a 180° rotation in the site of attachment of the pneumatic duct. Over a century ago, Bashford Dean illustrated this progression by arranging a sequence of species (unfortunately, without regard to precise anatomical detail or phylogeny) having different degrees of pneumatic duct migration (**Figure 2**). Later, as phylogenetic evidence showed that the lung and not the gas bladder was the primitive organ, Dean's illustration still served to illustrate the evolutionary progression, however, in the opposite direction!

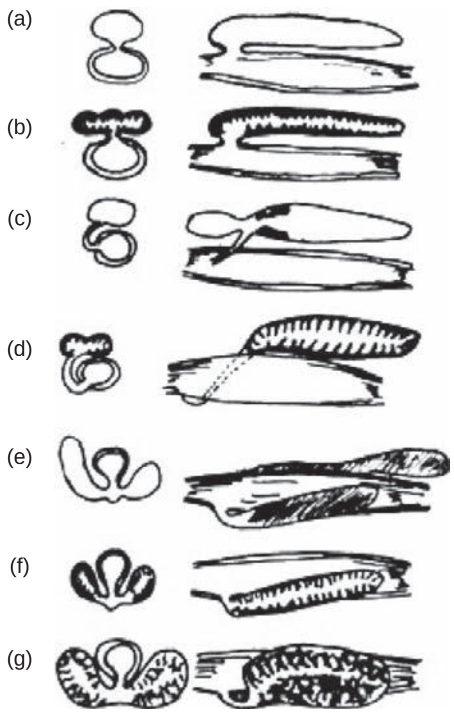

Figure 2 Modified version of Bashford Dean's illustration of the evolutionary progression of gut and lung or gas bladder position in fishes and tetrapods. Double-layered structure is gut. Dark or striated areas are respiratory epithelium. (a) Sturgeon (no aerial respiration). (b) *Lepisosteus* and *Amia.* (c) *Erythrinus;* pneumatic duct (note its left side origin). (d) *Neoceratodus;* ventrally originating pneumatic duct ascends right side. (e) *Polypterus*; note smaller left lung. (f) *Lepidosiren* and *Protopterus.* (g) Tetrapods. Reproduced from Fig. 3.4 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation.* San Diego, CA: Academic Press, with permission from Elsevier.

The relationship between the lung and gas bladder of fishes remains controversial. **Figure 1** demonstrates the lung's basal function in respiration and shows the evolutionary trend for the gas bladder's transition from (1) respiratory to nonrespiratory (although a number of groups such as the pangasiids have secondarily returned to a respiratory gas bladder (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) and (2) physostomous (pneumatic duct present) to physoclistous (no duct). The classical view is that aerial respiration is a basal osteichthyan character and that there was a single origin of the osteichthyan lung, which is homologous with the tetrapod lung and the lung of early actinopterygians. However, **Figure 1** suggests that, while the lungs of sarcopterygians and tetrapods are homologous, polypterid lungs may have evolved independently. While similarities in ultrastructure, cell type, and surfactant properties of the two organs are expected based on their common site of embryonic differentiation (posterior respiratory pharynx immediately behind the gill arches), the many structural differences between the two organs argue against the idea of single origin of the lung or for a sequential (by means of vertical movement and rotation) transformation of a functional lung to a functional gas bladder. The suggestion that the site of the embryonic pouch formation also determines the organ's pattern of blood flow (i.e., a pulmonary circulation formed with lungs and an in-series circulation formed with a respiratory gas bladder) is not supported by *A. calva*, which has a respiratory gas bladder supported by a pulmonary circulation (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

Epithelial and Structural Complexity

The respiratory surfaces of lungs and gas bladders have type I (squamous) and II (cuboidal) epithelial cells and chemically similar surfactant proteins. Surfactant, which is important for ABO inflation, is formed by membrane-bound lamellar bodies contained within type II cells and contains a mixture of surface-active lipids and proteins that lower the surface tension of the fluid lining the respiratory surface. Surfactant occurs in the epithelial lining of the pharynx and alimentary canal as well as in fish lungs, both respiratory and nonrespiratory gas bladders, and in ABO stomachs and intestines.

Despite underlying similarities, the gross morphology of lungs and respiratory gas bladders differs markedly among species (**Figures 1–5**). Lungfish lungs have a highly complex respiratory surface comprised of parenchymal septa containing smooth muscle and subdividing the lumen into a honeycomb of small alveolar-like respiratory chambers or units termed 'ediculae' (wider than deep) and faveolae (deeper than wide) into which is invested a dense capillary bed lying within a few micrometers of the air surface. Structural differences among the three lungfish genera correlate with differences in air-breathing capacity. The lung in the facultative air-breathing *N. forsteri* is unpaired, occurs entirely in the dorsal part of the body cavity, and has both a smaller respiratory surface area and a much longer pneumatic duct, which arises on the ventral pharynx and extends dorsally to the lung (**Figure 2**(**d**)). In contrast, the paired lungs of *Protopterus* and *Lepidosiren*, which are similar to one another, have greater septation. Also, these lungs are fused at the front where they form a common chamber below the pharynx to which they are connected by a short, vertical, and valved pneumatic duct (**Figures 1** and **2**(**f**)). Posterior to this fusion, the lungs separate as they project dorsally and extend nearly to the end of the coelom.

Polypterid lungs (**Figures 1–3**(**a**)) are paired but the left lobe, which has a ductal connection to the right lobe and not the pneumatic duct, is also truncated by the stomach. These lungs lack the structural complexity of lungfishes; the respiratory epithelium lines the walls but

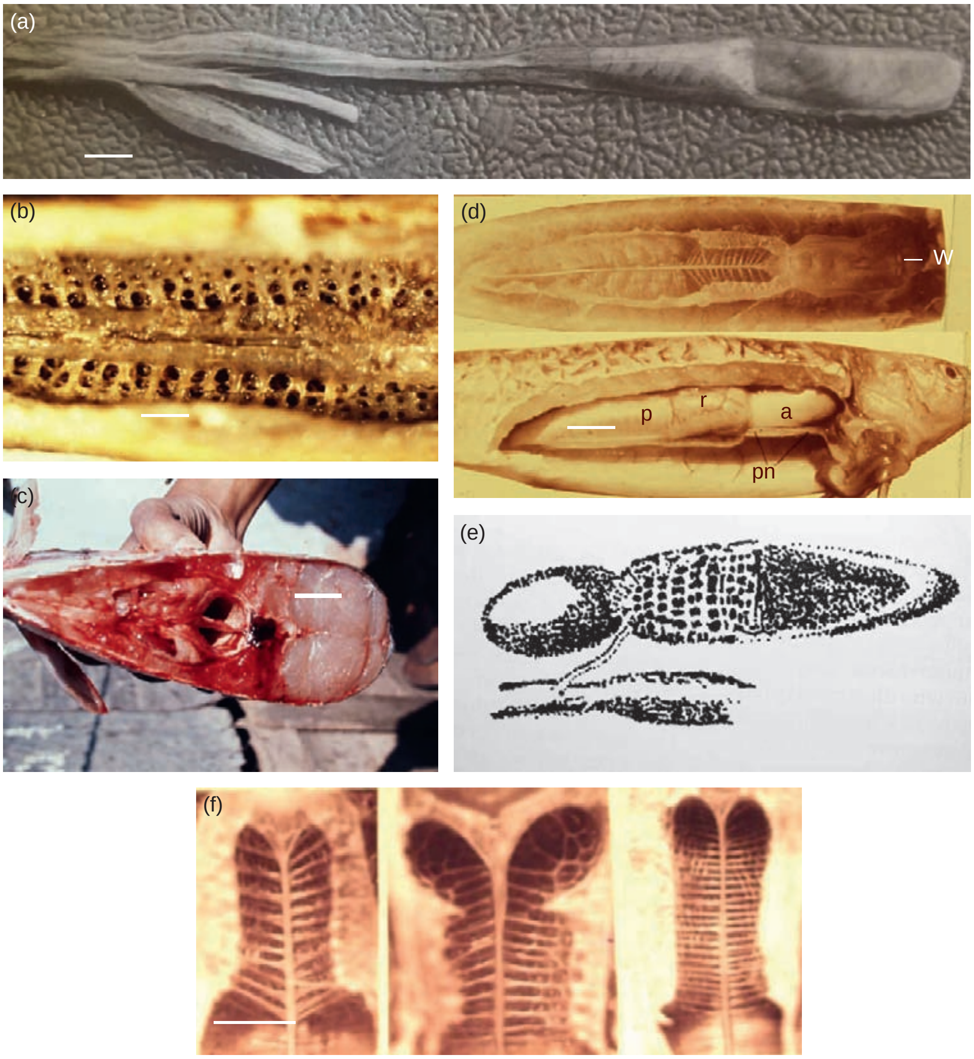

Figure 3 Lungs and respiratory gas bladders of some air-breathing fishes. (a) *Polypterus* sp.; note shorter left lung and expanded posterior section of right lung. Scale = 1 cm. (b) *Arapaima gigas*, ventral view; note kidneys contained within the gas bladder. Scale = 0.5 cm. (c) *N. notopterus*; note vertical septum in the respiratory region. Scale = 2 cm. (d) *Piabucina festae* showing side and ventral (cut away) views of the three chambers of the respiratory gas bladder; p, posterior; r, respiratory; a, anterior; pn, pneumatic duct. (f) Comparison of the respiratory sections of *Piabucina* (left), *E. erythrinus* (center), and *Hoplerythrinus unitaeniatus* (right). Scale = 1 cm. Reproduced from Figs. 3.7, 3.10, 3.13, 3.14, 3.16, and 3.17 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation.* San Diego, CA: Academic Press, with permission from Elsevier.

does not extend into the lumen and there are prominent concentrations of ciliated cells in and among the type I and II cells (**Figure 4**(**a**)).

Variations in the structural complexity of the respiratory surfaces of gas bladders are detailed in **Figures 1–5**. Highly compartmentalized and septate ediculae occur in the respiratory gas bladders of *Arapaima*, *Amia*, *Lepisosteus*, *Megalops*, *Phractolaemus*, *Piabucina*, *Erythrinus*, *Hoplerythrinus*, *Pangasius*, and other genera. The retroperitoneal expansion of the gas bladders of *Arapaima* (**Figure 3**(**b**)) and *Pantodon bucholzi* encompasses the kidneys and in *Pantodon*, which floats at the surface, air spaces penetrating the vertebral column add buoyancy. The respiratory gas bladders of the characins *Erythrinus*, *Hoplerythrinus*, *Lebiasina*, and *Piabucina* (**Figure 3**(**d**)–**3**(**f**)) have three chambers: the complex honeycomb of the respiratory section differs markedly among the genera, the posterior section has linear tendons that aid in organ contraction for exhalation, and the anterior chamber, which is partially divided from the respiratory section, attaches to the Webberian ossicles for transmission of sound vibrations to the brain. Like characins, the anterior section of the gas bladder in *Megalops* (two species) contacts the brain's sound-reception center (**Figure 4**(**c**)). In

addition to its respiratory section, the gas bladder of the featherback (*Notopterus* and other genera in this family, **Figures 1** and **3(c)**; **see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) has buoyancy and both sound-reception and production functions. By contrast, the respiratory gas bladder of *Umbra limi*, one of the most derived teleosts using a respiratory gas bladder, has relatively simple epithelium that does not project into the lumen (**Figure 1**).

Other ABOs

The evolution of the physoclistous gas bladder occurred independently in many teleosts; it eliminated the pneumatic duct and largely ended gas-bladder utility for air breathing. However, as teleosts continued their radiation, additional requirements for amphibious and aquatic air breathing resulted in novel ABOs and, while diverse, these share common features of an enclosed space that can be ventilated and a respiratory epithelium with ample blood supply.

Head Region

The simplest ABO in the head region forms through augmentation of the respiratory function of the buccal, pharyngeal, branchial, or opercular chambers with a covering of respiratory epithelium. The next complexity is to add more air volume, done by the addition of accessory chambers, sacs, or pouches, usually in the branchial chamber. Further refinements involve reshaping of the ventral skull bones to allow an even greater air volume, and further augmenting these spaces by filling them with multiply branched or faceted structures covered by respiratory epithelium.

Modified Chambers

Species in several families have independently converged on the use of the mouth, branchial chamber, and opercular chamber as ABOs and all of these fishes have relatively large buccopharyngeal chamber volumes (**Figure 6**). *Electrophorus electricus* has reduced gills and is an aquatic, obligate air breather. An extensive respiratory epithelium covers nearly the entire interior of its mouth, from the jaw to the pharynx, and also covers the branchial arches and the inner walls of the operculum. The mouth epithelium is formed into rows of vascularized tufts that extend from both the dorsal and ventral sides. When the mouth is closed, these rows are interdigitated and fill the buccal space with an absorptive epithelium.

All of air-breathing gobies hold air in their mouths. *Gillichthys mirabilis* is both a facultative and amphibious air breather. It has vascular surfaces on the roof of its mouth and tongue. All four mudskipper genera (*Periophthalmus*, *Periophthalmodon, Scartelaos,* and *Boleophthalmus*, about 25 species total; **see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) have exceptionally large (up to 17% relative to mass) buccopharyngeal chamber volumes. In these and other closely related species

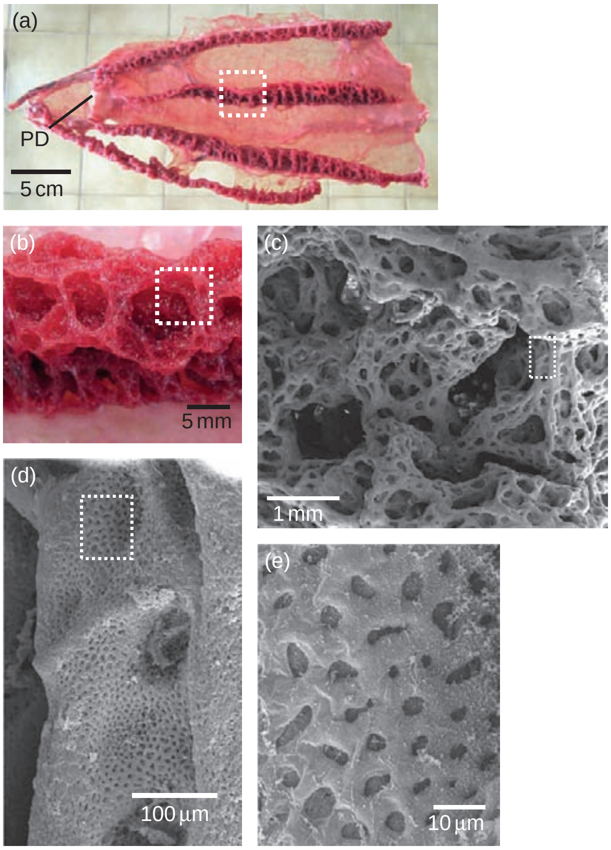

Figure 5 (a) Respiratory gas bladder of a 13.7-kg *Megalops atlanticus* opened along its dorsal side to reveal the internal surface and show the four ridges of respiratory tissue extending along its length. The dorsal ridge (at bottom) extends anterior of the pneumatic duct (PD) into the organ's narrow projection under the skull (augmenting sound reception). (b) Enlarged section of the box in (a) showing the faveolate surface surfaces of the respiratory ridge. (c) SEM of the box in (b) showing interconnection of septa forming faveolae and ediculae of different size. (d) Magnification of the box in (c) showing the respiratory surface of a septum. (e) Enlargement of the box in (d) showing the respiratory epithelium. Reproduced from Fig. 1.6 in Seymour RS, Wegner NC, and Graham JB (2008) Body size and the air-breathing organ of the Atlantic tarpon *Megalops atlanticus*. *Comparative Biochemistry and Physiology* 150A: 282–287.

(e.g., *Pseudapocryptes lanceolatus*) in the subfamily Oxudercinae, a vascular epithelium lines the surfaces of the mouth, pharyngeal, branchial, and opercular chambers. The relative area of these surfaces has not been determined and this would need to be known to determine the relative contribution of each to O_2 uptake. The expanded branchiostegal membrane and reduced opercular opening of mudskippers help to ensure air-breath retention.

Air held in the buccal chamber of the eel goby (*Odontamblyopus lacepedii*) envelopes the gills and contacts vascular beds on the inner wall of each operculum and other buccopharyngeal surfaces, all of which are functional for aerial O_2 uptake. A facultative, aquatic air breather, *Odontamblyopus*, gulps a large enough air volume to float its head and anterior body, and completely empties its ABO during exhalation.

The swamp eel, *Synbranchus marmoratus*, is both an aquatic and an amphibious air breather. A respiratory epithelium extends throughout the buccal and opercular chambers; however, this fish has a complete set of gills and is a facultative air breather. Its buccopharyngeal chamber is large and during air breathing it also holds sufficient air to float its head and upper body. The opercular openings are combined and reduced to a single ventral port which aids in air retention.

Suprabranchial Chambers

A sac or space extending from the top of the branchial chamber, the suprabranchial chamber (SBC), enhances the ABO volume and surface area. The SBC has independently evolved in species of four different families. The swamp eel, *Monopterus cuchia*, a close relative of *Synbranchus marmoratus* (above), is also an amphibious and aquatic air breather with a large buccopharyngeal chamber covered by a respiratory epithelium. However, *Monopterus* differs from *Synbranchus* in having a pair of small, respiratory epithelium-covered SBCs extending in a dorsal-posterior direction from the branchial chamber (**Figure 6**). *Monopterus* is similar to *Electrophorus* in having no gills on its branchial arches and unlike *Synbranchus* it is an obligate air breather.

Species in three clariid catfish genera (*Clarias, Heterobranchus,* and *Dinotopterus,* about 40 species in total, **see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) have large, paired SBCs extending from the skull to beyond the pectoral girdle (**Figure 7**). Contained within these are respiratory trees or dendrites that emerge from the epibranchials of two gill arches. In addition, gill filaments at the dorsal end of all four gill arches are fused to form fans that partially seal the lateral side of the SBC and serve as valves for ventilation. The gill epithelium covering the SBC, the fans, and the entire surface of the dendrites is formed by gill filaments that unfold, lose their cartilaginous supports, and undergo modification in aspect ratio, but retain their signature pillar cells (**Figure 7**). A muscle sheet surrounding the posterior SBC compresses it for exhalation.

The Indian catfish (*Heteropneustes fossilis*) also has large, paired SBCs bordered by gill fans (**Figure 8**). No dendrites are present but SBC area is expanded by paired tubes that extend into the body musculature to a distance of about one-half body length. The respiratory epithelium covering the SBC and the inner surface of the fans are also formed by modified gill lamellae. Contraction of muscle sheets surrounding the SBC projections causes exhalation.

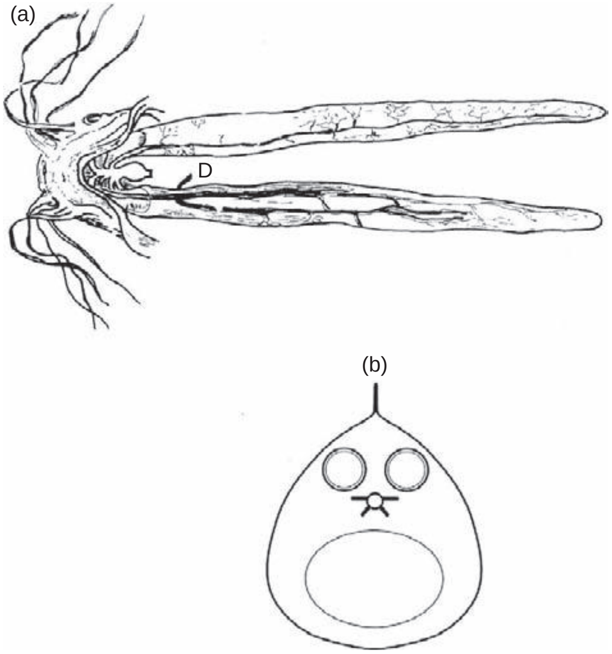

Figure 8 (a) Modified drawing of the SBC of *Heteropneustes fossilis* made by J. Hyrtl in 1854. (b) Transverse body section showing air-sac penetration into the body myotomes. Reproduced from Fig. 3.30 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation.* San Diego, CA: Academic Press, with permission from Elsevier.

The large, paired SBCs of the anabantoids extend from behind the eye to the pectoral girdle. Protruding into each is the labyrinth, a bony element formed by the epibranchial of gill arch 1 (**Figure 9**). Labyrinth size and complexity relate to air-breathing capacity. In the obligatory air breather *Anabas testudineus*, this structure fills the SBC and has ridges that amplify its surface (**Figure 9**). The labyrinth and SBC form a rigid structure that cannot be compressed for exhalation. However, like the threads on a screw, the labyrinth's surface is continuous with the SBC contour, which means that water pumped through the chamber will not stagnate or pool. This is important for ABO ventilation, which is done by forcing water through the chamber to displace stale air and then refilling it with fresh air. The respiratory epithelium covering the labyrinth and the SBC forms parallel rows of capillaries having ring-shaped endothelial cells. Although similar to the respiratory surface in clariids and *Heteropneustes*, this epithelium does not have pillar cells.

The large channid SBC is covered by a respiratory epithelium as are bony surfaces extending into it from the first branchial and hyomandibular arches and the parasphenoid bone (**Figure 10**). The vascular structure of this epithelium, however, differs from the anabantoids; it forms islets, featuring rosettes of spiraling capillary loops, different segments of which emerge into the ABO. This epithelial structure is similar to *Monopterus* (**Figure 7**). The channid SBC is similar to the anabantoid SBC in being largely incompressible, thus requiring water flow for ventilation.

Digestive Tube

Esophagus

The amphibious blenny *Lipophrys* (=*Blennius*) *pholis* holds air in its esophagus, which has longitudinal folds containing many capillaries. There are no respiration data.

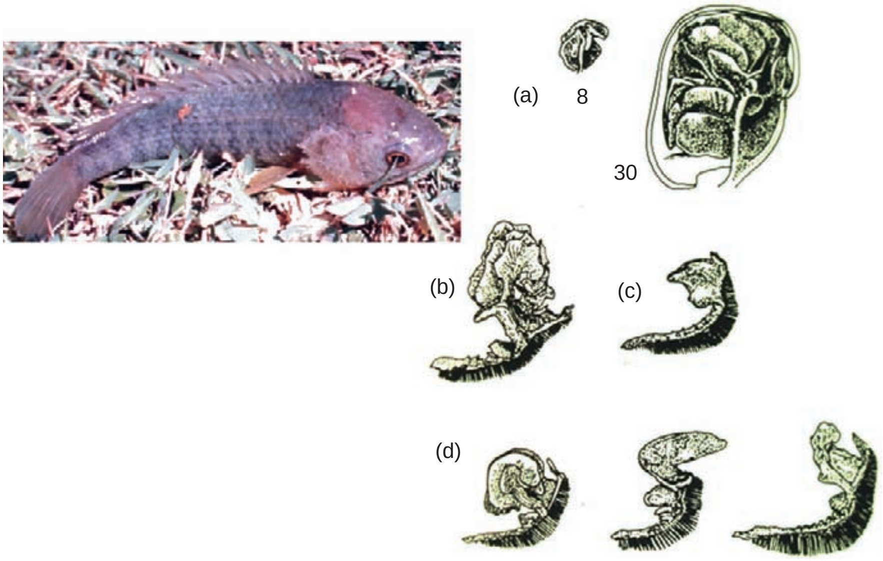

Figure 9 (Top left) *Anabas testudineus* and drawings of the labyrinth structure of several anabantoids. (a) *Osphronemus goramy* 8 cm and 20 cm total length; (b) *Anabas*; (c) *Sandelia*. Figure 10 (a) Ventral view of the SBC of a 30-cm *Channa micropeltes*. Head was sectioned at level of the esophagus (E) and roof of mouth to show openings into the SBC. O, operculum; G, gill arches; D, dendrites on arches 1 and 2. Dendrites also on hyomandibular (H) and parasphenoid (P) bones. Scale = 1 cm. (b) Side view showing dendrite penetration into the SBC. (c) Detail for the capillary rosettes and spiraling. Reproduced from Figs. 3.23 and 3.24 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation.* San Diego, CA: Academic Press, with permission from Elsevier.

The esophagus of the blackfish, *Dallia pectoralis*, is richly endowed with capillaries positioned within 1 μm of the surface along area-increasing micro-ridges formed by cuboidal epithelium. *Dallia* has a gas bladder that does not function for air breathing. Compression of striated muscle surrounding the esophagus and gas bladder drives exhalation by this fish.

Pneumatic Duct

The gas bladder of the eel *A. anguilla* (also other species) is physostomous; however, it also has a gas gland, the vascularized area within the gas-bladder wall that slowly secretes O_2 into the organ for buoyancy. While *Anguilla* has a pneumatic duct, this structure's esophageal opening is gated by a sphincter valve, which may limit air ventilation. The pneumatic duct is richly vascularized, and absorbs O_2 from the gas bladder, which supplies respiration. While out of water *Anguilla* makes use of this oxygen supply and also breathes through its gills and skin.

Stomach

Stomach ABO function is documented for many loricariid species. Air is gulped and swallowed and, once O_2 is depleted, the breath is burped out and exits from the operculae. Volume measurements of expired air confirm that the stomach ABO is completely emptied after each air breath. Anatomical studies show a stomach ultrastructure comparable to lungs and gas bladders in having a large number of capillaries but relatively few digestive cells near the inner surface. In *Liposarcus spinosus* (= *Ancistrus* sp.), a dense capillary mesh forms in the corpus region but not in either the cardiac or pylorus regions (**Figure 11**). A survey of over 40 loricariid genera indicates graded character states in stomach size and, in some species, accessory air chambers that function for buoyancy surround the respiratory stomach and always contain air. Stomach air breathing has also been confirmed in two other South American catfish families (Trichomycteridae, *Pygidium striatum*; Scoloplacidae, *Lithoxus lithoides*; **see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction).

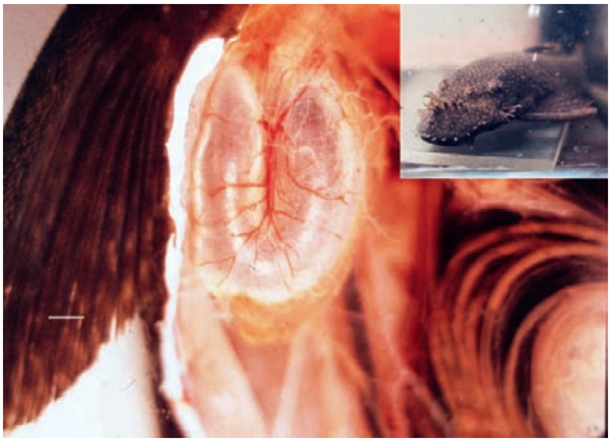

Figure 11 Air-filled stomach ABO of *Liposarchus* (= *Ancistrus*) *spinosus* on the right side of the abdomen. Note right pectoral fin and spiral intestine. Scale = 0.5 cm. (Inset) Fish exhaling air. Reproduced from Figs. 2.6 and 3.37 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation.* San Diego, CA: Academic Press, with permission from Elsevier.

Intestine

Intestinal air breathing evolved independently in two groups, the New World catfishes (Callicthyidae, *Callichthys asper, Hoplosternum thoracatum*) and the Old World loaches (Cobitididae, *Lepidocephalichthys guntea*, *Misgurnis anguillicaudatus*). In both the groups, swallowed air is passed through the digestive intestine and into the posterior, respiratory section. Once O_2 is removed from this gas, it is ejected from the anus, usually at the same instant that new air is gulped. In both the families, the digestive intestine has the important added function of compressing and then enclosing the feces in mucus clumps to minimize their size and maximize air contact in the respiratory surface. The respiratory intestine, normally inflated in both these groups, has thin, complaint walls and a high capillary density with diffusion distances ranging from less than 1 to 3 μm. In *H. thoracatum*, the respiratory intestine is perfectly aligned with the body axis and functions in buoyancy control. During air exposure, the intestine of the amphibious marine Chilean clingfish (*Sicyases sanguineus*) contains air and the vessels of this organ are engorged with blood; there are no respiratory data.

Gills

Respiration

Although the walls of the branchial chambers of the amphibious blennies (*Entomacrodus nigricans*) and rockskippers (*Dialommus macrocephalus*) lack a prominent respiratory epithelium, oxygen partial pressure (P_{O_2}) measurements indicate that branchial oxygen consumption rate ($\dot{V}_{O_2}$) takes place in air, which implicates the gills in this process. The contribution of gills to aerial respiration cannot be quantified because most species that hold air in their branchial chambers also have a respiratory epithelium lining that chamber's surface.

Modifications Related to Air Breathing

Respiratory modifications of gills for amphibious air breathing include larger cartilaginous support rods in the filaments, which are often curved to reduce contact with adjacent filaments and thus lessen the chance of coalescence and collapse out of water (**Figure 12**). Relative to other species, mudskippers have a smaller gill area, which is compensated by the respiratory epithelium contained in their expanded buccopharyngeal chambers. This is important for *Periophthalmodon*, in which a cell matrix covering the interlamellar spaces of its filaments greatly reduces gill respiratory function and makes it an obligate air breather (**Figure 12**).

Among aquatic air breathers, reductions in gill area resulting from the diminution or the complete absence of filaments from some branchial arches are a specialization that increases air-breathing efficiency and is most common in species that use continuous aquatic air breathing or are obligate air breathers. In *Electrophorus*, *Monopterus*, and anabantoids, the lungfish *Lepidosiren* and *Protopterus*, and other species, some or all of the branchial arches extending from near the heart (ventral side of the body) to the dorsal aorta (which supplies the systemic circulation from the dorsal side of body) do not have functional gill filaments and function solely as circulatory conduits (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes).

On the other hand, the gill area of many facultative air breathers is not reduced and comparable to the gill areas of non-air-breathing species. Among loricariids, the gill areas of a 100-g *Rhinelepis strigosa* (20 000 mm^2) and a 100-g *Hypostomus plecostomus* (9000 mm^2) are both within the range of most non-air-breathing freshwater fishes and higher than values for most air-breathing fishes. Similarly, the facultative Australian lungfish (*Neoceratodus*) has gills on all branchial arches and its estimated total gill area of about 2500 cm^2 in a 6-kg fish (= 417 $cm^2\ kg^{-1}$) is comparable to that of non-air-breathing freshwater fishes (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics).

Skin

Cutaneous respiration is documented for most of the major fish groups and only a few differences distinguish the air-breathing species (**see also Gas Exchange**: Respiration: An Introduction). Many developing fishes breathe exclusively through their skin prior to gill development. Larval *Monopterus* respire through extensive subepithelial capillary networks. Posthatch *Neoceratodus* have a ciliated respiratory epithelium covering their body surface.

Fish skin is a less effective gas-exchange organ than either the gills or ABO because of its greater thickness, the added diffusion barriers of scales and mucus, and low perfusion and ventilation potentials. Among species shown to have cutaneous respiration, water–blood diffusion distances range from 50 to 400 μm, and there is no consistent relationship between features such as scales, epidermal thickness, or amount of vascularization, and the rate of cutaneous O_2 transfer. For example, a cutaneous $\dot{V}_{O_2}$ of 32% of total $\dot{V}_{O_2}$ was measured for the heavily scaled *Erpetoichthys calabaricus*. Fish skin is metabolically active; the epidermis contains a living epithelium as well as sensory and secretory cells, all of which receive nutrition via dermal capillaries. Cutaneous respiration may serve the skin but not deeper aerobic

requirements. Such a function would, however, be limited in hypoxic or stagnant water, which minimizes diffusion.

Specializations for skin respiration in amphibious air-breathing fishes include the presence of epidermal capillaries (reduce air–blood diffusion distance) along the dorsal body surface (this area is readily exposed to air and makes less contact with the substrate). In mudskippers, which obtain about half of their O_2 via the skin, air–blood diffusion distances can be less than 5 μm along the dorsal-body surface but as much as 150−200 μm at other sites. In *Kryptolebias* (= *Rivulus*) *marmoratus*, which is totally reliant on skin respiration in air, capillaries on its dorsal body surface are within 1 μm of the body surface. Among aquatic air breathers, the most dramatic application of cutaneous respiration occurs in the eleotrid, *Dormitator latifrons*. In hypoxic water, this fish hyperinflates its physoclistous gas bladder and becomes positively buoyant, thus emerging its forehead to expose a dense capillary network that is engorged with blood and functions for aerial respiration (**Figure 13**).

ABO Ventilation

Ventilation of lungs and respiratory gas bladders involves the combined actions of the buccal force pump and swallowing for inhalation, and a combination of hydrostatic pressure and the contraction of muscles within the wall of the ABO or around it for exhalation. Many lung breathers exhale prior to inhaling. However, many gas-bladder air breathers inhale first and then exhale, which results in some mixing of the new and

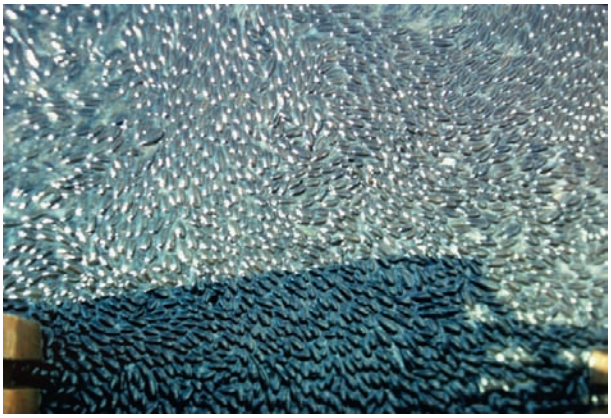

Figure 13 Overhead view of a large number of *Dormitator latifrons* aggregated at a dam in Panama. Each fish is positively buoyant and has its aerial-respiratory frontal skin patch exposed to air. Reproduced from Fig. 2.9 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation.* San Diego, CA: Academic Press, with permission from Elsevier.

stale air. In the case of the *Hoplerythrinus* (**Figure 3(f)**), new air is sequestered into the anterior chamber of the gas bladder and only after O_2-depleted air in the respiratory and posterior sections is ejected is the new air pushed into these chambers.

Polypterids are distinguished from all other lung or gas-bladder air breathers in using recoil aspiration in which contraction of muscles within the lung forces exhalation and also causes inward flexion of the thickly scaled body walls as well as the generation of a negative intraperitoneal pressure. Inhalation is then driven by the vacuum generated by the recoil of the body walls. New data from this laboratory document that aspiratory air breathing by *Polypterus* is coupled with the use of the spiracles for air intake. These structures, which are vestiges of the hyomandibular gill opening, are covered by spiracle bones that function as valves and are opened during the few milliseconds when the fish is at the surface for an air breath (**Figure 14**). This finding has implications for the early evolution of breathing mechanisms in the Tetrapodomorphs, which also had spiracles.

Both gulping and swallowing are required for the sequestration of air in the stomach and intestinal ABOs. For loricariids, ABO emptying is via emesis followed by the release of air bubbles from the operculae; this ensures complete turnover of the ABO volume. Nonmixing of the old and new air is also achieved by intestinal air breathers, which rely on the indelicate action of flatulence to vent old air. While discretely masked by simultaneous occurrence with a new air gulp, this is also a necessary contingency for buoyancy control.

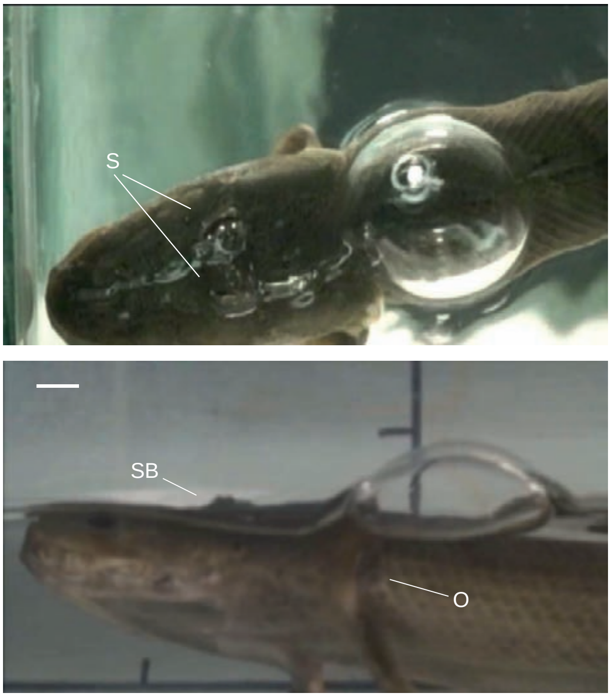

Figure 14 Top and side views of *Polypterus delhezi* at the instant in the air-breathing cycle when it is at the surface with the spiracles open for recoil-aspiration filling of the lungs. Spiracles (S) appear as dark crescents in top view. Side view showing erect spiracle bone (SB), the valve that covers the spiracle. Bubble is previous breath just released from the operculum (O). Scale = 1 cm.

The SBCs of clariids and *Heteropneustes* are filled by aspiration and buccal force and readily emptied by the action of muscles enclosing the posterior sectors of these chambers. In contrast, the SBCs of anabantoids and the channids are situated high above the gills, are intimately connected to the skull bones, and are noncompliant. The purging of an exhausted air breath from these organs requires the complex action of reversed water flow, analogous to the fish coughing reflex used to void debris from the gills. Reversed and fast water flow through the SBC, orchestrated by as many as four different hydraulic pulses initiated using different combinations of jaw and opercular actions, effectively floods out the old air and then displaces the water with new air, also resulting in a 100% breath replacement.

Glossary

Bimodal respiration The capacity to exchange respiratory gases with either air or water and to do so either simultaneously or sequentially.

Bradycardia A slowing of normal heart rate. In fish, this condition is often associated with hypoxia (low environmental oxygen levels).

Circulatory shunt Characterizing the presence of vessels that permit blood to bypass a particular organ. The term 'gill shunt', for example, indicates that conditions can occur in which blood normally destined for the gills bypasses that organ.

Diffusing capacity The rate of transfer, expressed in terms of the partial pressure diffusion gradient, of the respiratory gases O_2 or CO_2 between an external medium such as air or water and the blood.

Ductus arteriosus The blood vessel connecting the pulmonary artery and the dorsal aorta that, when dilated, shunts blood from the lung to the systemic circulation.

Enforced unsaturation A reduction in blood P_{O_2} caused by the convergence of two vessels, one carrying oxygenated blood and the other deoxygenated blood.

Pulmonary vasomotor segment (PAVS) Vasoactive section of the lungfish pulmonary artery that, through either vasoconstriction or vasodilation, regulates blood flow into the lung.

Respiratory sinus arrhythmia Central control mechanism integrating heart rate with the respiration cycle.

Tachycardia Increased heart rate.

Transbranchial deoxygenation A phenomenon associated with in-series circulation in which, during the transit of blood through the gills, the oxygen acquired in the ABO undergoes outward diffusion to ambient, hypoxic water.

Introduction

This article examines the patterns of blood flow to and from the air-breathing organs (ABOs) of fishes. It builds on information about the diversity and the phylogenetic relationships of the bimodally breathing fishes (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) and on their ABO structure (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes). The independent origin of air breathing resulted in a diversity of ABO types as well as a range of patterns for the flow of blood to and away from these organs (**Figure 1**). Fishes have an in-series circulation pattern in which blood flows in a single circuit from the heart to gills to the systemic circulation and back to the heart (**see also Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns). Because all air-breathing fishes have functional gills, the addition of an ABO to the in-series flow introduces problems for both the conservation and effective delivery of the aerially acquired O_2 to the systemic circulation and for ensuring sufficient contact between the blood and water in the gills needed for the vital ancillary gill functions of ion regulation, nitrogen excretion, and the release of respiratory CO_2 (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion, **Gas Exchange**: Respiration: An Introduction, and **Control of Respiration**: The Ventilatory Response to CO_2/H^+).

Since the earliest studies of air-breathing fish circulation nearly 200 years ago, emphasis has been given to identify the afferent and efferent blood vessels of the ABO. This standard was established by the nineteenth-century anatomist and physiologist Johannes Müller who, with knowledge of the blood flow pattern of light and dark blood in mammals, noted the paradoxical flow for some fishes possessing air-filled organs that were thought to function for auxiliary respiration. Müller observed that these organs often received blood that had just passed through the gills and wondered how additional oxygenation would be possible. He also noted that blood leaving a putative auxiliary breathing organ went back to the heart, mixing along the way with other venous streams of deoxygenated blood also headed to the heart. Müller reasoned that, if this blood had in fact become more oxygenated in an air-filled auxiliary breathing organ, then it would surely be deoxygenated when it mixed with the venous blood streams coming from the systemic organs. Müller's paradox and his use of the comparative approach to mammal and fish circulation serve as the starting points for this article.

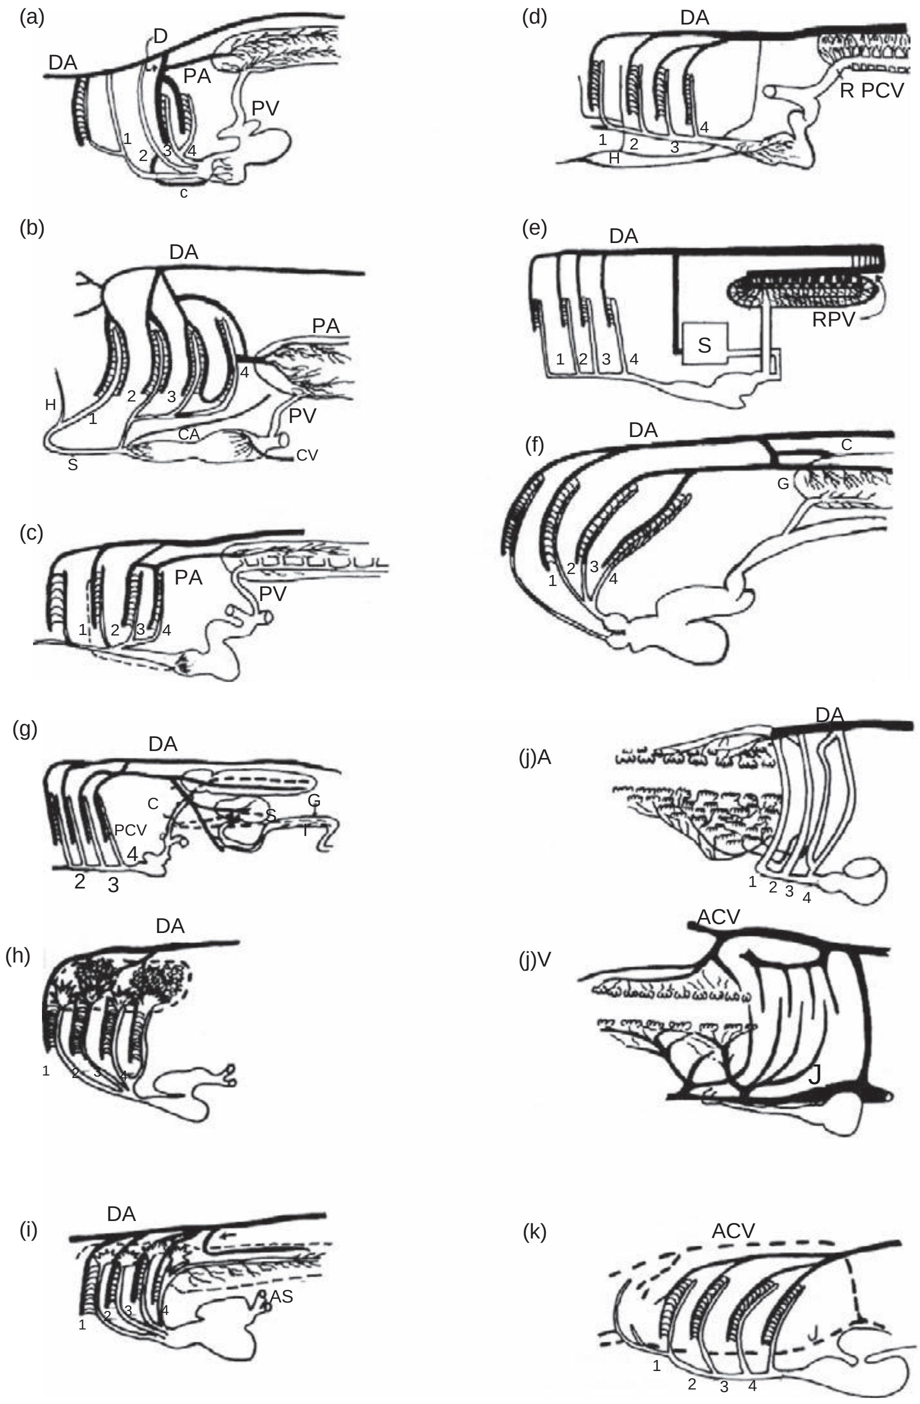

Figure 1 (Continued)

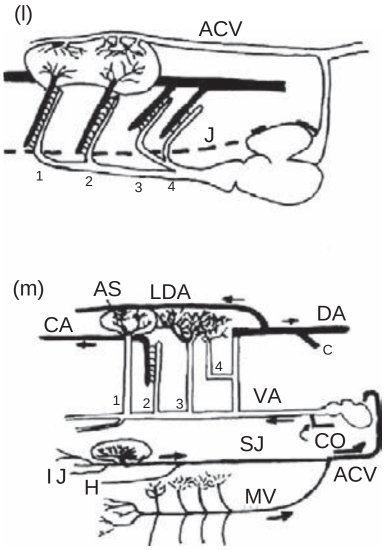

Figure 1 Circulation patterns of air-breathing fishes viewed from left side and showing tracts of major vessels to and from the ABO and their relationships to the branchial arches (1–4) and the heart (H). (a) *Protopterus*. Note pulmonary circulation and absence of gill filaments on arches 1 and 2. Coronary artery (C) branches from the hypobranchial which originates on arch 2. DA, dorsal aorta, D, ductus arteriosus; Pa, pulmonary artery; and PV, pulmonary vein. (b) *Polypterus*. Arches 3 and 4 contribute to PA formation. S is approximate position of the ventral aortic strap (**Figure 5**). Note coronary artery (CA) origin from the subclavian artery and vein (CV) drainage from ventricle. (c) *Amia*. PA originates from arches 3 and 4. PV enters left side of duct of Cuvier. Coronary supply from hypobranchial and efferent side of arch 2. (d) *Lepisosteus*. ABO drainage to right post cardinal vein (RPCV). Both subclavian (SC) and hypobranchial (H) arteries form coronary artery. (e) *Arapaima.* Afferent supply via renal portal vein. S, systemic circulation. (f) *Gymnarchus*. Note anastomoses between DA and celiac (C) and gas bladder (G) arteries (see **Figure 6**). (g) Generalized ostariophysan inter-renal vein tracks (dashed line) showing connections from the gas bladder, stomach, and intestinal (G, S, I) ABOs to the PCV. (h) *Clarias*. Dashed line marks the periphery of the ABO. Note the presence of fans on each branchial arch and that ABO efferent flow is into DA. (i) *Heteropneustes.* Dashed line marks periphery of the ABO. Note gill fans on each branchial arch and modified bulbous (**Figure 7**). Afferent 4 goes to the air sac (AS = SBC) and efferent drainage (arrow) is into the DA. (j) *Electrophorus*. A. Branchial arch arteries give rise to small superior and inferior vascular epithelial branches but are essentially ventral-dorsal conduits. V. Venous drainage is into the systemic circulation via the jugular (J) and anterior cardinal (ACV). (k) *Boleophthalmus*. Branchial circulation similar to most non-air-breathing fishes, with systemic capillaries being the site of O_2 uptake and venous return (dashed lines) occurring via the ACV and J. (l) *Anabas* and *Channa*. Efferent branchials 1 and 2 go into the ABO and ABO drainage is systemic (ACV and J, dashed line). Note reduced gills on arches 3 and 4. (m) *Monopterus.* Arrows show flow direction. (Top part of diagram) Arterial outflow from heart through elongate ventral aorta (VA) to branchial arches. Arch 1 serves SBC air sac (AS), arch 2 traverses a small gill and forms the carotid artery (CA). Arches 3 and 4 branch into the respiratory epithelium (note that arch 4 forms as a side branch of the ventral-dorsal aortic conduit). Blood supply to head is also via paired lateral dorsal aortae (LDA). The coronary artery (CO, curved arrow) emerges from the ventral aorta just beyond the bulbus. C. celiac. (Lower diagram) Venous return to the heart is via the superior jugular (SJ), and median (MV) veins into the ACV. Defining the Problem

Comparative Circulation: Mammal and Fish

Mammals (and birds) have two separate circulatory loops (pulmonary and systemic) serially linked at the heart, which is subdivided to form parallel left and right pumps (**Figure 2**(**a**)). The oxygenated blood exiting the lungs enters the left side of the heart from which it flows into the systemic circulation and returns to the right heart from where it is transported to the lungs. The respiratory and systemic circulations are then said to be in parallel. In contrast, fish circulation is but a single loop in which flow exiting the heart goes to gills and the systemic tissue beds before returning (**Figure 2**(**b**)). The respiratory and systemic circulations are then said to be in series (**see also Circulation**: Circulatory System Design: Roles and Principles).

The ABO Problem

Figure 2(**c**) shows the diverse ways that the insertion of an ABO (boxes with diagonal lines) complicates an in-series flow in which gills are also present. If, as Müller had observed, O_2 gained in the ABO enters the venous circulation, then it is at risk of forced partial unsaturation caused by mixing with other venous (hypoxic) blood streams. In the case of ABOs near the gills, if ABO blood flow bypasses the gills, this potentially eliminates the pre-ABO contact between blood and water that takes place in the gills, a step that is

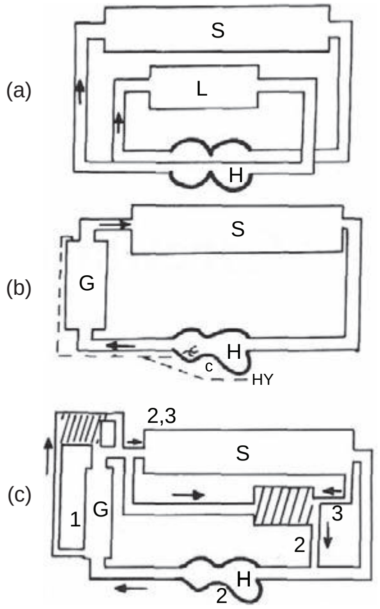

Figure 2 (a) Double-loop circulation of mammals. (b) In-series circulation loop of fishes. Dashed line shows efferent branchial origin of hypobranchial (HY) and coronary (C) arteries. (c) Three potential consequences of ABO (box with diagonal lines) placement: 1. O_2 loss across gills; 2. enforced partial unsaturation; 3. pressure drop. Arrows indicate flow direction. S, systemic circulation: G, gills; L, lung; H, heart. Reproduced from Fig. 4.1 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation*. San Diego, CA: Academic Press, with permission from Elsevier.

generally regarded as important for increasing respiratory efficiency by lowering blood CO_2 prior to its entering the ABO (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion, **Gas Exchange**: Respiration: An Introduction, and **Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System). Alternatively, if blood flow is to both the gills and the ABO, then a larger, stronger ventricle might be required for perfusion; however, if the efferent flows from these two organs mix, forced partial unsaturation would occur and result in a lower blood partial pressure of oxygen (P_{O_2}) to drive diffusion into the tissues.

Assuming that the water contacting the gills lacks sufficient O_2 for respiration, then **Figure 2(c)** shows that the first part of Müller's paradox (i.e., the apparent redundancy of double oxygenation, first in the gills and then in the ABO) is not a problem because blood in the gills would not be saturated with O_2 and an auxiliary ABO would be required. However, this solution immediately raises the inverse problem about gill function: If O_2-saturated blood passes through gills bathed in hypoxic water, what prevents the diffusive loss, termed 'transbranchial deoxygenation', of this blood?

Solutions

The recurring theme of this article is that the potential for transbranchial O_2 loss, together with the second part of Müller's paradox – the downstream mixing of ABO blood with deoxygenated venous blood results in forced partial unsaturation which lowers systemic P_{O_2} – remains central issues influencing the design and regulation of aquatic air-breathing fish circulation. This article further shows that the solutions to the related problems of conserving and effectively utilizing aerially acquired O_2 involve a suite of independently evolved adaptations to establish and modulate the degree of isolation between the ABO flow stream and other flows, and permit the strategic shunting (i.e., the detouring of blood from its normal destination to an alternative one) from one or the other respiratory organ in phase with the air-breathing cycle.

Structural and regulatory features known to play a role in blood-flow separation and shunting in different air-breathing fishes are summarized in **Table 1**.

Specializations that lessen contact between the ABO and other venous streams and decrease the potential for transbranchial O_2 loss are signature features of the heart, gill structure, and circulation patterns of two extant lungfish genera (*Lepidosiren* and *Protopterus*) and a few actinopterygian genera (however, none to the same extent, morphologically as lungfish) including *Polypterus* and *Erpetoichthys* (bichirs and ropefish), *Gymnarchus* (African knifefish), *Amia* (bowfin), and the teleosts *Heteropneustes* (Indian catfish), *Anabas* (climbing perch), *Channa* (snake head).

Major among these modifications is shunting to enhance separation of the oxygenated and deoxygenated streams (e.g., flow from the lungfish pulmonary vein into the left atrium) and the sequestration of O_2-rich blood from hypoxic water in the gills (e.g., using recessed lamellar vascular channels isolated from branchial water flow). Reducing total gill area also lessens the potential for transbranchial O_2 loss; some continuous air breathers have such small gill areas that they are obligatory air breathers.

Another O_2-conserving mechanism involves modulation of the relative rates of gill water flow ($\dot{V}$) and blood flow ($\dot{Q}$) through the gills during the period that air is held. Over the air-breathing cycle, many fish display considerable heart rate variability (HRV), as well as a prominent respiratory sinus arrhythmia (RSA, an integrated heart-rate (HR) response linked to the breathing cycle) characterized by a significant increase (tachycardia) in HR just as or slightly before an air breath is taken, a gradual HR reduction during the time the breath is held, and an abrupt drop in HR (bradycardia) when the breath is exhaled. HRV is often accompanied by inverse fluctuations in $\dot{V}$. Thus, as air-breath tachycardia increases $\dot{Q}$ a reduced gill ventilation frequency lowers $\dot{V}$ and the resultant drop in the $\dot{V}$:$\dot{Q}$

Table 1 Structural modifications in the circulatory anatomy of air-breathing fishes, possibly related to the shunting or selective perfusion of the ABO, systemic, or branchial vascular beds during bimodal respiration

Genus	*Structural feature*	*(Possible?) Action*
Protopterus, Lepidosiren	Ductus arteriosus	Lung shunt to dorsal aorta
	PAVS	Regulate pulmonary artery flow
	Afferent branchial arch shunts	Regulate branchial flow and pulmonary perfusion
	Incomplete ventricular septum	Balance pulmonary and systemic pressures
	Spiral and ventrolateral folds in bulbus cordis	Guide flow to systemic and branchial arches
Polypterus	Analog to ductus arteriosus	Lung shunt?
	Ventral aortic strap	Anterior branchial shunt?
Amia	Analog to ductus arteriosus	Allow ABO shunt?
	Recessed lamellar channels	Gill shunt
Gymnarchus	Dorsal aortic-efferent branchial arch junction	ABO shunt?
	No ventral aorta; four separate valved arteries	Selective branchial arch perfusion?
	Muscle insertions on pericardium	Heart torsion related to arch shunting?
Arapaima	Valve on systemic veins near heart entrance	Control venous mixing?
	Thick layers of smooth muscle in afferent and efferent branchial arteries	Control branchial circulation?
	Valved and discrete lamellar blood channels that are recessed	Control branchial shunting?
Luciocephalus	Vessel connecting pre-branchial ventral aorta to intestine	Branchial shunt?
Hoplerythrinus	Ductus arteriosus analog junction between the dorsal aorta and coeliac artery	ABO shunt
	Vasoactive branchial resistance	Regulation of branchial shunts and ABO perfusion
Clariidae	Separated ventral aortic branches	Branchial arch shunts?
Heteropneustes	Manifold bulbus with separate ventral aortic openings and dead-end sac extension	Selective branchial perfusion? Pressure compensation?
Loricariidae and Callichthyidae	Inter-renal vein	Hepatic-portal vein shunt
Channa, *Anabas,* and other anabantoids	Anterior and posterior ventral aortae. Reduced gill lamellae on arch 4	Optimal routing of ABO and systemic flows. Branchial shunt
Channa	Vessel connecting arch 2 suprabranchial artery to lateral aorta	ABO shunt
Electrophorus and *Monopterus*	Ventral–dorsal aortic conduits	Branchial shunts

Modified from Table 4.2 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation*. San Diego, CA: Academic Press, with permission from Elsevier.

ratio would minimize transbranchial O_2 loss by rapidly pushing O_2-rich blood through under-ventilated gills. (**see also Gas Exchange**: Respiration: An Introduction, **Brain and Nervous System**: Autonomic Nervous System of Fishes, **Hypoxia**: Respiratory Responses to Hypoxia in Fishes, **Design and Physiology of the Heart**: The Coronary Circulation, and **Control of Respiration**: Generation of the Respiratory Rhythm in Fish).

This article discusses how the vascular network potentially combines with HRV to improve respiratory efficiency. It will also show how the phylogenetic progression of air breathing, from lungfish to the most derived teleosts, has been accompanied by the development of mechanisms allowing fine-scale and short-term regulation of both HR and peripheral vascular resistance, all in phase with the respiratory cycle. The sarcopterygian and primitive actinopterygian air breathers alter flow using structural features and use both hormonal and cholinergic neural regulation to alter HR and vascular resistance. By contrast, rapid changes in adrenergic and cholinergic tone associated with each air breath are distinguishing features of the teleostean air breathers and these bring about abrupt changes in both HR and vascular resistance (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels) and may to some extent supersede reliance upon the more obvious structural or mechanical features for controlling blood flow in lungfishes (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish, **Hormonal Responses to Stress**: Catecholamines, **Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System, and **Brain and Nervous System**: Autonomic Nervous System of Fishes).

Patterns of ABO Circulation: Lungs and Respiratory Gas Bladders

Lungfish

Relative to all other air-breathing fishes, the African (*Protopterus*, four species; **see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) and South American (*Lepidosiren paradoxa*) lungfishes most closely approach the separate, in-parallel pulmonary and systemic circulation pattern of mammals (**Figures 1**(**a**) and **3**). In these fishes, the pulmonary vein passes though the sinus venosus and empties into the left atrium of a nearly completely divided heart that, in combination with the septated and spiral bulbus cordis, ensures the distribution of (1) most of the oxygenated blood into branchial arches 1 and 2, which lack gills and are conduits to the systemic circulation, and (2) most of the deoxygenated blood into the pulmonary arteries after passing through arches 3 and 4, which have distinctive gill filaments. P_{O_2} measurements at strategic sites in the circulation, as well as the paths taken by India ink and contrast agents, confirm that, just after an air breath is taken, a remarkable 90% of the blood in the pulmonary vein enters the systemic circulation. Later, as lung P_{O_2} lessens, this fraction declines. Thus, while not anatomically separated the two circulations are functionally isolated.

Key to achieving this functional separation are structural elements such as the return of the pulmonary blood to the left atrium, the partial anatomical separation of the atrium and ventricle into right and left chambers, and the septated spiral bulbus cordis, which directs the pulmonary and systemic streams (**Table 1**). Regulating this are vasoactive sites controlling circulation in phase with the

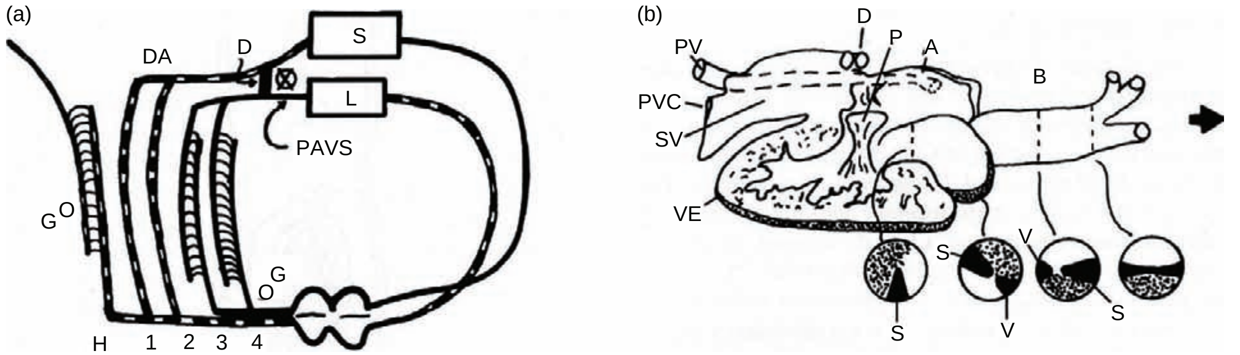

Figure 3 (a) Lung (L) and systemic (S) circulatory loops of *Lepidosiren* and *Protopterus*. Oxygen-rich blood (alternating black and while lines) leaves L, enters left side of the heart, and goes into the branchial arches (hyoid, 1, and 2) and then to either the head or the DA. Deoxygenated blood from the S loop (solid black line) goes through the right side of the heart to arches 3 and 4 and to the lung. Diagram shows location of the shunts (circles) and their configuration during air breathing: gills and PAV shunts are open and ductus arteriosus (D) is closed. (b) Right-side section view of the heart of *Lepidosiren*. Pulmonary vein (PV): dashed lines track PV advance to the anterior left atrium (A) which is obscured by the septum dividing it. PVC, posterior vena cava enters heart via the sinus venosus (SV). Circles are cross sections through the bulbus at different positions showing how the rotation of the spiral (S) and ventrolateral (V) folds affect the distribution of oxygenated blood (stippled area). Note that the two folds become fused at the end of the bulbus (arrow = rostral direction). D, ductus Cuvier; P, atrioventricular plug; VE ventricle; B, bulbus cordis (extending from VE to the arterial branches). Reproduced from Figs. 4.3 and 4.4 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation*. San Diego, CA: Academic Press, with permission from Elsevier.

air-breathing cycle. When a breath is taken, vasodilation (controlled by circulating catechols and vagal tone) increases pulmonary blood flow by channeling more blood through arches 3 and 4 and the pulmonary vasomotor segment (PAVS), and closing the ductus arteriosus (**Figure 3**(**a**)). *Lepidosiren* and *Protopterus* hearts lack adrenergic nerve fibers and HR is regulated by vagal tone (parasympathetic, cholinergic neurons) in combination with the level of circulating catecholamines (released from tissues and blood sinuses). (Because catecholamine levels are also stress related they can increase lungfish HR to a level where a lessening of vagal tone does not further increase HR; this may explain why in some experiments tachycardia is not always associated with taking a breath. In addition, unlike the situation in teleosts, catecholamines do not affect the hydration state of lungfish erythrocytes in a manner that alters hemoglobin (Hb)–O_2 affinity; (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect, Red Blood Cell Function, **Detection and Generation of Electric Signals**: Development of Electroreceptors and Electric Organs, and **Hormonal Responses to Stress**: Catecholamines.)

The gill circulation patterns of *Protopterus* and *Lepidosiren* were first detailed in the nineteenth century and all subsequent accounts consistently reported that the anterior gill arches (1 and 2) are totally devoid of gills and function as conduits for the passage of O_2-rich blood from the bulbus cordis to the dorsal aorta and on to the systemic circulation (**Figure 3**(**a**)). However, Marcos de Moraes and colleagues recently reported that *Lepidosiren* has small gill filaments on arches 1 and 2 as well as on arches 3 and 4, but that the total gill area and both the O_2 and CO_2 diffusing capacities (i.e., the transfer rate per mean effective partial pressure gradient between the external medium and blood) of this species are too small to significantly contribute to respiration. If confirmed, these facts contradict earlier reports for *Lepidosiren* gill structure and its similarities with *Protopterus*. Furthermore, if the gills of *Lepidosiren* do not contribute to aquatic respiration, then the perception that arches 3 and 4 play an important role in preconditioning deoxygenated venous blood (by removing CO_2 and equilibrating acid–base status) before it enters the lung is in doubt, as would be the mechanism by which *Lepidosiren* releases its respiratory CO_2 into water.

Relative to the obligate air-breathing *Protopterus* and *Lepidosiren*, the circulatory specializations of the facultative air breathing Australian lungfish (*Neoceratodus forsteri*) are less refined; it has functional gills on all of its branchial arches (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes) and its pulmonary vein enters an undivided sinus venosus. Septa within the atria and ventricle of *Neoceratodus* are also less complete and the septum within the spiral bulbus is smaller.

The Polypterids and *Amia*

In *Polypterus*, *Erpetoichthys*, and *Amia*, pulmonary arteries branch from the efferent side of branchial arch 4 (in some species arch 3 also contributes; **Figures 1**(**b**) and **1**(**c**)). Also present in these fish is a connection between the pulmonary artery and the dorsal aorta which, like the ductus arteriosus in lungfish, may act as an ABO shunt. A tendonous strap across the ventral aorta proximal to aortic arch 1 in *Polypterus* (**Figures 2**(**b**) and **4**) may play a role in phasically shunting flow away from arch 1. On the venous-return side, the degree of ABO and systemic separation is far less than in either *Lepidosiren* or *Protopterus* (**Figure 5**). In polypterids, the pulmonary and hepatic veins combine to form the hepatopulmonary which enters the sinus venosus. In *Amia*, the single pulmonary vein flows into the left duct of Cuvier. Thus, blood leaving the ABO would thus be subject to both enforced partial unsaturation as well as transbranchial O_2 loss. The hearts of these fish also lack the medial septation of lungfish hearts.

Gars and Primitive Teleosts

Inflow to the respiratory gas bladder of gars (*Lepisosteus* and *Atractosteus*; **Figure 1**(**d**)) is from multiple branches of the dorsal aorta and venous return is via the right post cardinal vein (**Figure 5**). There is no heart septation.

Osteoglossiforms

The Osteoglossiforms present three distinct patterns of circulation to their respiratory gas bladders. In *Notopterus* and presumably the other featherbacks (*Xenomystus* and *Papyrocranus*), the pattern is generally similar to most other teleosts; the afferent supply is via branches

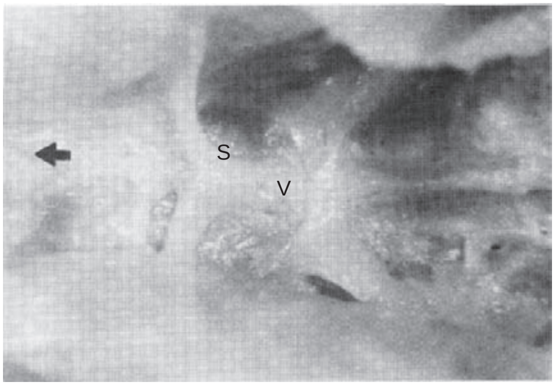

Figure 4 Ventral view of the strap (S) underlying the ventral aorta (VA) of *Polypterus bicher* (arrow = rostral direction). (**Figure 1**(**b**) shows strap position relative to anterior branchial arches.) Reproduced from Fig. 4.6 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation*. San Diego, CA: Academic Press, with permission from Elsevier.

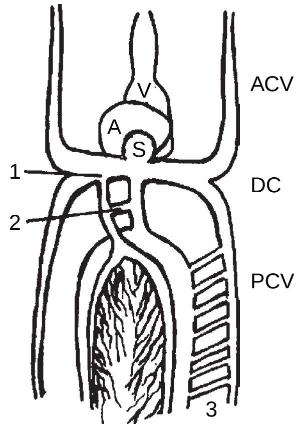

Figure 5 Generalized diagram of central venous return to the heart for three primitive actinopterygians 1. *Amia*: pulmonary vein (PV) empties into left duct of Cuvier (DC). 2. Polypterids: PV flows into hepatic vein. 3. Gars: PV flows into right post-cardinal vein (PCV). ACV, anterior cardinal vein; S, sinus venosus; A, atrium, V, ventricle. Reproduced from Fig. 4.5 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation*. San Diego, CA: Academic Press, with permission from Elsevier.

emanating from the dorsal aorta and venous return is into the post-cardinal vein.

In *Arapaima*, *Pantodon*, and *Heterotis*, the gas bladder completely encloses the kidneys and blood supply to the organ is via the renal portal system. Because virtually all of the blood returning to the heart from the posterior body flows through the renal portal system, having the ABO in series with this flow offers the potential advantage of oxygenating a large volume of the venous return and also lessening the proportion of deoxygenated blood that could mix with it to force unsaturation. Correspondingly, ventral aortic P_{O_2} measurements in *Arapaima* are high (45–50 torr; 80–90% saturation). Moreover, and unlike most other air-breathing fishes, *Arapaima* displays no air-breath-induced changes in dorsal-aortic pressure, pulse pressure, or HR; in most other species, these factors change over the time air is held in the ABO. This may be an experimental artifact or reflect the minimal effects that HR and blood pressure augmentation would have on the more remote venous system. Flow from the ABO of these three genera is more into the left than the right post-cardinal vein.

A remarkable series of circulatory specializations for air breathing in *Gymnarchus niloticus* (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes) were documented over a century ago by Richard Assheton (**Figures 1**(f) and **6**). The honeycombed respiratory gas bladder of *Gymnarchus* is supplied by pulmonary arteries arising from branchial arches 3 and 4 and venous return from this organ is via the left post-cardinal vein to the duct of Cuvier (flow from the anterior left side also enters here), which connects to the left side of the septated atrium (**Figure 6**). The heart structure of *Gymnarchus* is unique in featuring divided atria and, rather than a single ventral aorta with afferent branchial branches, there are four short, distinct ventral aortae, each with its own mini-bulbus capacitance chamber. The separate branches likely play a role maintaining the flow separation needed to enhance aerial respiration; however, there are no physiological studies with *Gymnarchus*.

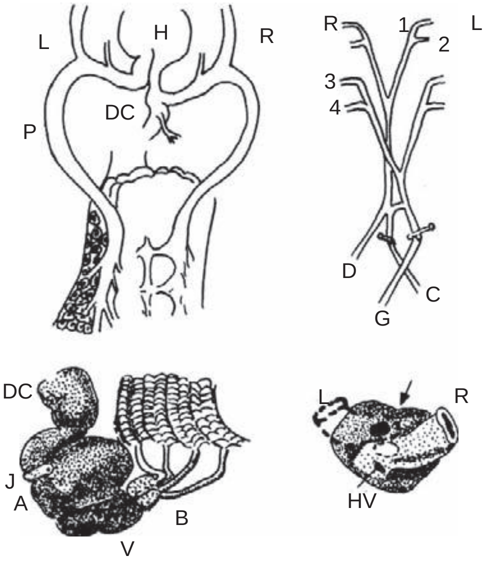

Figure 6 Redrawn detail of R. Assheton's (1907) illustrations of *Gymnarchus* blood flow. (Top left) Dorsal view of the central venous return showing the separated duct of Cuvier. H, heart (note the partial atrial septum); P, post-cardinal vein; L, left side; R, right side. ABO drainage is via the left P and into the left atrium. (Top right) Ventral view of the efferent branchial arteries (1–4) showing their connections to the dorsal aorta (D), the gas bladder (G), and the celiac (C) arteries. Note anastomoses between the three vessels. (Lower left) Right-side view of the heart showing the right ductus Cuvier (DC), jugular vein (J), the atrium (A), ventricle (V), and two of the four bulbus chambers (B) that lie at the base of each root artery. (Lower right) Posterior view of the atrium showing the left (L) and right (R) halves of the duct of Cuvier. The left duct is indicated by the dashed line and its entry port is shown as a black hole. The right duct is drawn and its entry port is shown as a white area outline by a dashed line. Note that the hepatic vein enters the right duct. Arrow shows position of the atrial septum dividing the two entry ports. Reproduced from Fig. 4.7 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation*. San Diego, CA: Academic Press, with permission from Elsevier.

Other Teleosts Having Respiratory Gas Bladders

For other species using a respiratory gas bladder such as the characins (*Lebiasina*, *Piabucina*, *Hoplerythrinus*, and *Erythrinus*) and other genera (*Phractolaemus*, *Pangasius Gymnotus*, and *Umbra*), afferent ABO circulation is generally via the dorsal aorta, celiac artery, or a branch of these, and venous return is most often into the post-cardinal vein (**Figure 1**(g)).

The characin *Hoplerythrinus unitaeniatus* has been the subject of several studies attempting to demonstrate the role HRV in facilitating aerial O_2 uptake. Flow measurements verify that postbreath tachycardia corresponds to increased flow into the ABO just after an air breath is taken. Studies using pharmacological agents to abolish inhalation tachycardia verify that both adrenergic and cholinergic tones increase simultaneously prior to each air breath, and then decrease, and that modulation of inhibitory cholinergic tone is responsible for the major proportion of HRV. However, that these interventions did not affect either air-breathing frequency or total oxygen consumption rate ($\dot{V}O_2$) indicates that even more intricate experiments of this type, in which additional factors such as the $\dot{Q}:\dot{V}$ ratio and transbranchial O_2 loss are also measured, will be needed to comprehend the functional significance of HRV for air breathing (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping, The Coronary Circulation, and **Hypoxia**: Respiratory Responses to Hypoxia in Fishes).

Circulation Patterns for Other ABOs

Mouth Breathers

The synbranchids *Monopterus* and *Synbranchus*, the electric knifefish *Electrophorus* (**Figure 1**(**j**) and **1**(**m**)), and several other species (*Hypopomus*) breathe air by holding it in their mouths and this reduces the problem of forced unsaturation and eliminates transbranchial O_2 loss. Whether or not the gills function in air breathing, surrounding them with air rather than hypoxic water ensures the accrual of O_2. Specifically, O_2 absorbed from air by the buccopharyngeal respiratory epithelium would flow into the venous circulation and quickly pass through the heart and gills to the dorsal aorta and then to the systemic circulation. Because the P_{O_2} of the air surrounding the gills is high, there would be not be transbranchial O_2 loss from the blood passing through the gills (moreover, this is a non-problem for the obligate air-breathing *Monopterus* and *Electrophorus* which do not have gills on their branchial arches). While, as shown in **Figure 2**(**c**), there is a potential for unsaturation due to the mixing of O_2-rich venous blood exiting the ABO and the less oxygenated venous return from the systemic circulation, the net result of an extended breath hold would be to elevate blood P_{O_2} throughout the body.

The downside of this air-breath-holding mode is that the interruption of gill contact with water interrupts the aquatic loss of respiratory CO_2 which, because of its effect on Hb–O_2 affinity, could adversely affect O_2 binding and delivery. The necessary solution is alternating periods of air holding, which oxygenates tissues, with periods of gill ventilation in water, which drives off blood CO_2 and conditions the blood for the next air breath. Another solution would be to have a relatively high blood Hb concentration (i.e., >12 g% in Synbranchids and *Electrophorus*), which would allow the storage of more O_2 and also buffer the acid effect of a rising blood P_{CO_2} on Hb–O_2 affinity.

Stomach and Intestinal Air Breathers

In species with ABOs located in the stomach or intestine, modified routes of venous return appear to lessen the effects of enforced partial unsaturation and circumvent the hepatic portal circulation, which is an O_2 sink. In *Hoplosternum thoracatum*, *C. callichthys* and *Lipophrys* (=*Ancistrus*) *spinosus*, and probably many other loricariid catfish, flow out of the ABO is into the inter-renal vein and then to the post-cardinal vein and thus bypasses the hepatic portal vein (**Figure 1**(**g**)). While the inter-renal and other vascular shunts potentially heighten the handling efficiency of ABO-obtained O_2, these modifications do not eliminate the problems of enforced unsaturation due to venous mixing, nor do they lessen the potential for transbranchial O_2 loss. Nevertheless, even with ABO drainage into the hepatic portal vein, species such as *Gymnotus carapo*, *Misgurnis anguillicaudatus*, and *Cobitis barbatula* breathe air effectively. Finally, a vessel transporting blood from the ventral aorta to the respiratory intestine has been reported for *Lepidocephalus guntea* but there are few details.

Suprabranchial Chambers

No fish, including the air breathers, can function without a gill circulation (**see also Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System and **Gas Exchange**: Respiration: An Introduction). However, as seen in **Figure 2**(**c**), some air-breathing species appear to lessen the separate problems of transbranchial O_2 loss and vascular-pressure depletion by arranging the ABO and gills as in-parallel circulations, and shunting blood to either one or the other organ in phase with air breathing. As shown earlier, species that hold air over their gills can, provided they hold it long enough, eventually increase the P_{O_2} of their entire circulation.

ABO circulation is different in species such as the clariids and *Heteropneustes* where the gills and the suprabranchial chamber (SBC) have a parallel circulation (i.e., both receive a fraction of the cardiac output). In clariids a fraction of the oxygenated SBC blood continues via the dorsal aorta into the systemic circulation, and in *Heteropneustes* most of the efferent SBC blood takes this course (**Figures 1**(**h**) and **1**(**i**)). For these fishes, downstream mixing of the gill and SBC blood will occur. It can be expected that the relative flow through these different circulatory patterns is regulated in phase with air breathing; however, there are no data for shunting or selective ABO perfusion for the clariids or *Heteropneustes*.

A possible mechanism for branchial shunting in these fish takes the form of their modified ventral aorta, which divides into separate branches serving the different arches (**Figures 1**(**h**) and **1**(**i**)). Detail for this in *Heteropneustes* shows that a highly modified bulbus arteriosus forms three ventral aortae (**Figure 7**). The smallest and most anterior-ventral of these originates on the left side of the bulbus and forms gill arch 1. The middle branch gives rise to arch 2, and the third and largest branch divides into arches 3 and 4. The side view (**Figure 7**) of this structure suggests that, with expansion, the bulbar area at the base of arches 3 and 4 can compress arches 1 and 2 to send more blood into the SBC. While partial occlusion of branchial arch 1 would appear to affect brain perfusion, this could be compensated by retrograde flow through the dorsal aorta.

In both *Channa* and the anabantoids (**Figure 1**(**l**)), circulation approaches the double-loop ideal. There are two ventral aortae: outflow from one passes through the two anterior gill arches and then into the ABO, while flow from the other circulates directly to the body via branchial arches having minimal respiratory surface area. For *Channa* small P_{O_2} differences in the two streams (i.e., less O_2 in the flow headed toward the gills) suggest there is ABO and systemic flow separation in the heart. This flow sequence also enhances ABO function by preconditioning blood (i.e., removal of CO_2 to water) for maximum O_2 absorption; however, efferent ABO blood also enters the venous circulation and, in the absence of a medially septated heart, maintenance of separate high and low O_2 blood streams remains problematic. Thus, optimal function of both the clariid and *Channa*-type circulations is dependent upon streamlined flow in the great vessels and heart, as well as on the neural-control capacity to selectively regulate branchial and ABO perfusion in phase with the air-breathing cycle.

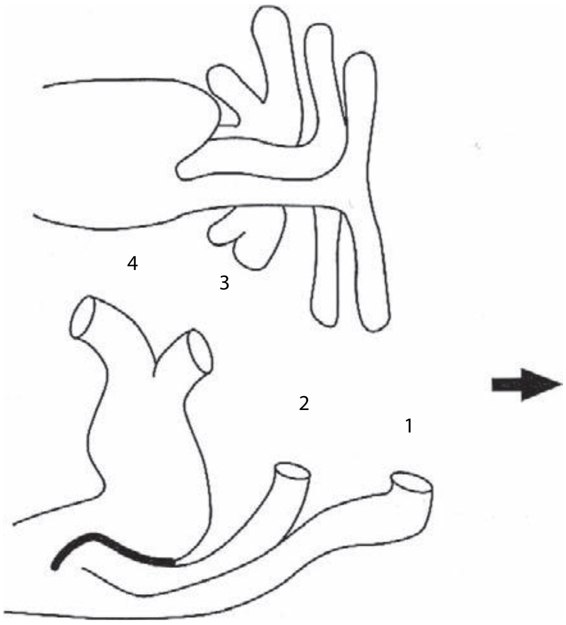

Figure 7 Bulbus arteriosus of *Heteropneustes*. (Top) Ventral view showing the displaced and tiered emergence of three ventral aortae. (Bottom) Right-side view showing how the lower bulbus section (thick line) giving rise to branchial arches 3 and 4 may compress aortae 1 and 2 to cause partial branchial shunting (arrow = rostral direction). Reproduced from Fig. 4.8 in Graham JB (1997) *Air Breathing Fishes: Evolution, Diversity and Adaptation*. San Diego, CA: Academic Press, with permission from Elsevier.

Coronary Circulation and Air Breathing

In most fishes, coronary perfusion supplies the outer compact myocardium layer, whereas the inner spongy endocardium is nourished by diffusion from venous blood circulating through the heart chambers (**see also Design and Physiology of the Heart**: The Coronary Circulation). The extent of coronary perfusion into the compact layer correlates with species activity. Little is known about how the epi- and endocardial layers of air-breathing fish hearts may differ from other species.

It has been suggested that air breathing evolved as a mechanism to oxygenate the endocardium. However, from a phylogenetic standpoint, this is not supported by the presence, in sharks, rays, and most non-air-breathing fishes, of a coronary artery that branches from the hypobranchial artery which originates on the efferent (oxygenated) side of, most usually, branchial arch 2. However, this is the pattern in *Neoceratodus* and both *Lepidosiren* and *Protopterus* have the same coronary origin; these fish lack gills on arch 2 which, due to separate pulmonary loop, contains oxygenated blood (**Figure 1**(**a**)). With few exceptions, the hypobranchial origin of the coronary artery is the most common source of ventricle oxygenation in most bony fishes. Two notable exceptions for coronary origin among the air-breathing fishes are the polypterids and gars (**Figures 1**(**b**) and **1**(**d**)) in which the subclavian artery is the sole (polypterids) or a partial (with the hypobranchial) contributor to the coronary circulation. While details are lacking for most air-breathing species, the arch 2 origin of the coronary circulation also occurs in *Channa* and this is noteworthy because the efferent branchial blood has yet to enter the ABO and is therefore not enriched with O_2. This implies that there is always sufficient O_2 within the venous circulation to sustain the heart and this is reasonable in view of the potential for axial-flow mixing and the presence of a significant ABO drainage into the systemic venous return (**Figure 1**(**l**)).

In *Monopterus*, the coronary artery originates on the ventral aorta just distal to the heart (**Figure 1**(**m**)). That blood at this site is sufficiently oxygenated to sustain the heart is attributable to the diffuse branchial circulation of *Monopterus* which feeds O_2-rich blood into the venous return.

Little data exist to show how the coronary circulations of most other air-breathing species might be modified to augment O_2 delivery during air breathing. Comparative data for the synbranchids having functional gills and for *Arapaima* and other osteoglossids having a large venous ABO flow can provide information on the roles of blood pressure and O_2 content in coronary perfusion.

Conclusions

Johannes Müller's contrast of fish and mammal circulation 170 years ago retains heuristic importance because of the focus it brings to the functional importance of ABO placement and the factors driving selection for adaptations to ensure the effective management of bimodally obtained oxygen. The vast phylogenetic gulf separating mammals and the fish-like Tetrapodomorpha of the Devonian (**Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) is filled with many examples of the progressive radiation of circulatory specializations among the vertebrate classes. In the case of mammals (and birds), selection for heightened metabolic performance and aerobic capacity resulted in the gold standard for optimal O_2 delivery featuring a double-looped and double-pumped continuous flow that separates the deoxygenated and oxygenated streams and re-pressurizes the latter prior to its dispersal into the systemic circulation.

Fishes occupy the base of the tetrapod phylogeny and were the first lunged vertebrates. It is likely that in its earliest iteration the lung operated within the limits of an in-series circulation. Lungfish are the closest living relatives of the tetrapodomorphs and the structural and functional similarities between the lung-circulation patterns of *Lepidosiren* and *Protopterus* (e.g., pulmonary return to the left atrium and the high degree of left–right heart flow separation) closely track the basic tetrapod features. However, no air-breathing fish has a completely separated left and right heart or circulation, nor can any species function without gills. The circulatory specializations occurring in the lungfish *Neoceratodus*, which is not an obligatory air breather, and the diverse but convergent circulatory modifications apparently contributing to oxygenated and deoxygenated flow separation in several teleosts (polypterids, *Amia*, *Gymnarchus*, *Heteropneustes*, *Channa*, *Anabas*, and others), suggest there was a strong selective premium placed on the separation, either or both in space or time, of the ABO and systemic flows of fish air breathing in water.

The presence of a higher capacity for right–left separation in *Lepidosiren* and *Protopterus* may reflect an even stronger selection for these features owing to the extreme environmental conditions in which they occur. Although these fishes are capable of living in mud without water and sustaining a low $\dot{V}O_2$ for long periods (*Protopterus* can estivate), these are not amphibious fish and their behavior is in no way comparable to that of terrestrial amphibians. This indicates that flow separation was driven by the respiratory inefficiencies of in-series circulation to both gills and an ABO during aquatic air breathing. It further implies that improving respiratory efficiency in water was a more likely causal factor for the structural changes in lungfish and that such changes preceded and likely facilitated the tetrapodomorph land transition in the Devonian.

Glossary

Aerobic Processes occurring without the need for oxygen.

Aerobic scope The capacity of an animal to increase its level of aerobic metabolism beyond that which is required for maintenance alone and thereby support activities such as muscular exercise, growth, or reproduction; it sets the capacity for oxygen-consuming physiological processes that an animal may perform at a given time. Aerobic scope is the difference between minimal and maximal oxygen consumption rate.

Anaerobic Processes occurring without the need for oxygen.

Anoxia (anoxic) Complete absence of dissolved oxygen in water.

Aphotic Conditions where ambient light is not present.

Arterial Adjective pertaining to blood that has been oxygenated.

Benthic Organisms living on, or near, the seafloor; lowest level of a body of water.

Buoyancy, positive and negative A positively buoyant organism is less dense than the surrounding fluid, so tends to rise to the surface. A negatively buoyant one is denser than the fluid and tends to sink.

Burst swimming Short-duration (s), high-energy swimming behavior used during predator avoidance or prey capture and powered by the white myotomal muscles using anaerobic metabolic pathways.

Cardiac output (V_b) Volume of blood pumped per unit time from the ventricle; the product of heart rate and stroke volume.

Closed-system temperature change A condition where blood-oxygen content remains constant, but the partial pressures of oxygen and carbon dioxide change with temperature.

Continuous swimming Long-duration (days–years) swimming behavior used during migrations or extended movements throughout the water column powered by the red myotomal muscles using aerobic metabolic pathways.

Coronary vessels Arterial vessels usually arising from the gills and directly irrigating the myocardial tissues with oxygenated blood.

Diel Pertaining to a 24-h period.

Drag (frictional and form) Resistance to the relative motion of an object through a fluid. Frictional drag refers to the resistance proportional to the wetted surface area of the fish and form drag refers to the resistance proportional to the cross-sectional area of the fish in contact with the water.

Ectotherm (adj. ectothermic) An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Elasmobranch The subclass of fishes (Elasmobranchii) found within the class Chondricthyes that includes sharks, skates, and rays, making up the Chondricthyes or cartilaginous fishes. Their bones are made up of cartilage rather than calcium found in all other vertebrates.

Endotherm An animal that uses its own metabolism as the major source of heat to maintain its body temperature greater than that of the surrounding environment.

Excitation–contraction (EC) coupling The physiological process of converting an electrical stimulus (an action potential) into a mechanical response (muscle contraction).

Hemoglobin A (usually) tetrameric, red blood cell-associated protein containing an iron core capable of reversibly binding oxygen.

Hypoxia (hypoxic) Conditions where dissolved oxygen is present at low levels.

Lactate Metabolic end product resulting from the catabolism of glucose under anaerobic conditions.

Muscle contraction When a muscle cell shortens and generates force.

Myocardium A general term for the cardiac muscle of the heart, which comprises several subtypes, including the compact myocardium and the spongy myocardium of fishes.

Myocyte An individual cardiac muscle cell.

Myoglobin An oxygen-binding protein in muscle that resembles hemoglobin in function, and enhances the rate of oxygen diffusion.

Myotomal muscle Segmented muscles along the body of a fish used for whole-body undulatory swimming.

Open-system temperature changes A condition where the partial pressures of oxygen and carbon dioxide are constant but the blood-oxygen content changes.

Oxygen minimum zone A zone in the water column (usually between 400 and 2000 m) where oxygen saturation is at its lowest.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

Photic Conditions where ambient light is present.

Ram ventilation Ventilation of the gills by swimming forward with the mouth open while suspending activity in the respiratory muscles.

Red myotomal muscle Slow-twitch muscle fiber type with a high aerobic capacity, mitochondrial density, and myoglobin concentration. Powers repeated, slow movements, such as continuous swimming.

Rete mirabile (pl. retia mirabilia) A vascular network, usually consisting of a parallel array of both arterial and venous vessels with countercurrent flow. Retia facilitate transfer of heat or oxygen between the arterial and venous vessels. Rete is Latin for ‘net or network’, mirabile for ‘wonderful’ or ‘miracle’.

Specific dynamic action The additional amount of oxygen or energy consumed above SMR as a result of feeding, measured during the period after feeding until metabolic rate returns to SMR; SDA represents the energetic cost of digestion, assimilation, and protein turnover.

Standard metabolic rate (SMR) The minimum metabolic rate of survival. Typically, SMR is measured on resting, unstressed adult animals in the post-absorptive state under normothermic conditions. For fish, normothermic is defined as a temperature well within the species tolerance limits for which the animals have had ample time to acclimate.

Stroke volume The volume of blood ejected into the aorta by a single contraction of the ventricle(s).

Teleosts A major group of ray-finned bony fish, including the most common fish.

Thermocline Zone of high rate of temperature change that separates a shallow, less dense, warm water layer (epilimnion) from a deeper, more-dense, colder-water layer (hypolimnion) in lakes, seas, and estuaries.

Thermal rate coefficient (Q_{10}) A unitless quantity that represents the factor by which the rate of a reaction is affected by a 10 °C change in temperature. A temperature-independent reaction would have a Q_{10} of 1.0 and a reaction rate that increases with temperature increase will have a Q_{10} greater than 1.0.

Upper uniform-temperature surface layers The surface layer of the open ocean that is a uniformly warm, well-mixed layer with abundant light penetration during the daylight hours and is limited vertically by the thermocline.

Ventricle A thick-walled chamber of the heart that is primarily comprised of cardiac muscle tissue.

Venous Related to deoxygenated blood.

Water column The representative three-dimensional column of water in the ocean environment spanning the surface to the sediments.

White myotomal muscle Fast-twitch muscle fiber type of large diameter with a high anaerobic capacity, large fiber size, low mitochondrial density, and myoglobin concentration; powers short-duration, high-power movements such as burst swimming.

Introduction

Fishes live in all ecosystems within the planet's oceans, ranging from shallow intertidal waters to the deep, abyssal oceanic plains and trenches (**see also Deep-Sea Fishes**), as well as in the vast open ocean. Pelagic fishes differ from other species (e.g., benthic or coastal species) in that they live in a three-dimensional environment without any discrete boundaries (i.e., not associated with bathymetric or coastal structures) that impede their horizontal and vertical movements through the water column. In general, the open-ocean pelagic environment occupies the majority of the volume of the oceans, and is characterized as being a vast, nutrient-poor expanse with distinct stratification of temperature, dissolved oxygen, and light intensity. In contrast to the neritic zone that is commonly associated with the continental shelf and thus is relatively shallow (<200 m), the pelagic zone includes all other open waters that are deeper than 200 m, where the bottom (bathymetry/structure) seldom has an effect on the surface layers and the water masses stratify due to their thermohaline properties (**Figure 1**). Moreover, the bathymetry of the pelagic zone does not have a pronounced influence on local oceanography (e.g., currents, thermal fronts, and upwelling) and light penetration does not have a direct effect on the benthos.

Many pelagic fishes often occupy the same geographic areas of the open ocean, but they really occupy largely separate ecosystems based upon their capacity to move vertically through the water column and tolerate different temperatures, oxygen concentrations, and light levels, which taken together result in resource partitioning. For pelagic fishes, the open ocean does not offer physical places to hide, and they must swim in order to avoid predators and find prey. For this reason, pelagic fishes have evolved a suite of morphological and physiological adaptations that (1) enhance their ability to swim continuously for extended periods of time while searching for prey or favorable oceanographic conditions and (2) retain their capacity for rapid bursts of speed for feeding or escaping. Overall, there are species-specific adaptations that allow pelagic fishes to inhabit overlapping yet distinct ecosystems within the pelagic realm. Several pelagic species have evolved physiological specializations that allow them to effectively pursue prey that are associated with the deep, cold, and hypoxic water layers. Others have the capacity to temporality venture into these deep layers, while still others lack such specializations and tend to remain in the upper uniform-temperature surface layers of the ocean. Taken together, pelagic fishes defy a strict categorization, having a wide diversity of morphological forms, physiological capabilities, and varied ecological preferences. In the pelagic realm, there are plenty of exceptions to the rules; however, all pelagic fish successfully exploit an environment that is often sparse in food and offers limited protection from predators.

With the exception of the high-latitude polar zones, the open ocean has two distinct water masses that separate the pelagic realm into two oceanographically (and potentially ecologically) discrete vertical zones: the warm surface layers and the cold deep waters (**Figure 1**). The surface layer is a uniformly warm,

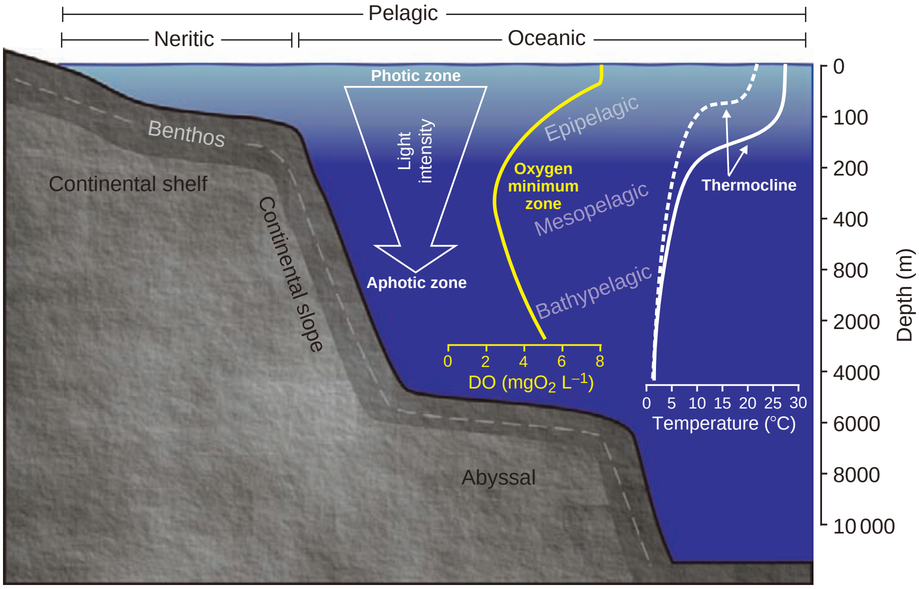

Figure 1 Classification of the pelagic environment showing the general depth-related patterns of light intensity, dissolved oxygen, and temperature in the oceanic zone. Note the oxygen-minimum zone is present at ~400 m and that the temperature–depth profiles vary by location (southern California (dashed line) and central equatorial Pacific (solid line)).

well-mixed layer of the ocean with abundant light penetration during the daylight hours and is limited vertically by the thermocline (an abrupt decrease in water temperature over a relatively small change in depth). The temporal persistence and absolute depth to which this warm, well-mixed layer penetrates vary due to local bathymetry, latitude, wind patterns, seasons, and thermohaline circulation. For example, between spring and fall, southern California waters have a thermocline between 30 and 60 m depth, whereas in the waters off Hawaii the thermocline is commonly as deep as 200 m and persists through most of the year. By contrast, the deep-water layer remains permanently and uniformly cold (2–8 °C) with very little, if any, light penetration (**see also Deep-Sea Fishes**). In addition, the lack of any measurable photosynthetic-based primary production and sparse vertical mixing in the deep-water layer (except during wind-driven upwelling events in coastal areas) results in the persistent decline in dissolved-oxygen levels leading to a marked hypoxic (i.e., oxygen-minimum) zone usually at mid-water depths (800–2000 m) (**Figure 1**).

Although the species diversity of fish inhabiting the upper 200 m of the pelagic realm (the epipelagic) represents a small fraction (~2%) of the approximately 28 000 described species, they are the most abundant fishes in the oceans. Pelagic fishes are morphologically diverse and range broadly in size (from the small anchovies Engraulidae to the whale shark *Rhincodon typus*, the largest fish in the ocean), body shape (from the elongate oarfish *Regalecus glesne* to the streamlined tunas Scombridae), coloration (from the whitish mola *Mola mola* to brilliantly colored mahimahi *Coryphaena hippurus*), swimming behavior (from schooling sardines Clupeidae to solitary oceanic whitetip sharks *Carcharhinus longimanus*), and feeding ecology (from the predatory swordfish *Xiphias gladius* to the planktivorous basking shark *Cetorhinus maximus*) (**Figure 2**). The ecology of pelagic fishes is also diverse, as some species spend only a portion of their life swimming in the open ocean (e.g., American eels *Anguilla rostrata*), others undergo diel migrations from the deep mesopelagic to the epipelagic (e.g., lanternfishes Myctophidae), while others are permanent residents of the epipelagic (e.g., tunas and jacks Carangidae). While some large pelagic species are strong swimmers and are known for their repeated, long-distance transoceanic migrations, other smaller species (e.g., American eel) also migrate over large distances (**Figure 3**) (**see also Fish Migrations:** The Biology of Fish Migration, Eel Migrations, and Tracking Oceanic Fish). It is impossible to paint an all-encompassing, generic portrait of the traits shared by all pelagic fishes, because, as always, the great diversity in fishes leads to exceptions to any biological generality. Nonetheless, the aim of this article is to provide the reader with a broad overview of the general morphological and physiological adaptations that make pelagic fishes distinct from their less-mobile, benthic, and coastal counterparts.

Numerous pelagic species co-inhabit the same geographical areas of the open ocean, but their depth distributions and vertical movement patterns vary significantly. This allows pelagic species to have a similar spatial distribution but results in marked differences in their diel utilization of the water column. We have just begun to understand the complex vertical and horizontal movement patterns of pelagic fishes and how these are influenced by regional oceanographic parameters (e.g., water temperature and light availability) and other factors such as reproduction and interspecific interactions. This article provides the reader with background information on the general adaptations that are present in pelagic fishes and then focuses on several unique physiological adaptations that allow some fishes to undergo large vertical (e.g., diving) movements through the water column.

General Adaptations for Life in the Pelagic Realm

Body Shape

Because pelagic fishes are not able to use fixed structures (benthic or otherwise) as a means of attachment or refuge, they must swim to escape predators and capture prey. The degree to which pelagic fishes swim ranges widely from relatively minimal swimming in nearly neutrally buoyant species to extensive swimming in negatively buoyant species. The latter commonly rely on continuous forward swimming to generate hydrodynamic lift (i.e., counteract their denser-than-seawater specific gravity) and to ram ventilate their gills. Due to their constant forward motion, most pelagic fishes have evolved morphological specializations that decrease both frictional and form drag (proportional to the surface area and cross-sectional area in contact with the water, respectively). These specializations include body streamlining (**Figure 2**), a high-aspect-ratio caudal fin, narrow caudal peduncles with one or two pairs of lateral keels, which decrease drag by reducing the turbulent flow across the stiff, nearly symmetrical caudal fin during the thrust-producing undulatory (side-to-side) movements, small finlets lining the dorsal and ventral margins along the posterior part of the body that help prevent flow separation at high speeds, and retractable fins. In general, pelagic fishes also possess large pectoral fins that provide additional hydrodynamic lift and a large dorsal fin that acts to minimize body rolling during swimming (**Figure 2**, **see also Buoyancy, Locomotion, and Movement in Fishes:** Maneuverability, and Undulatory Swimming).

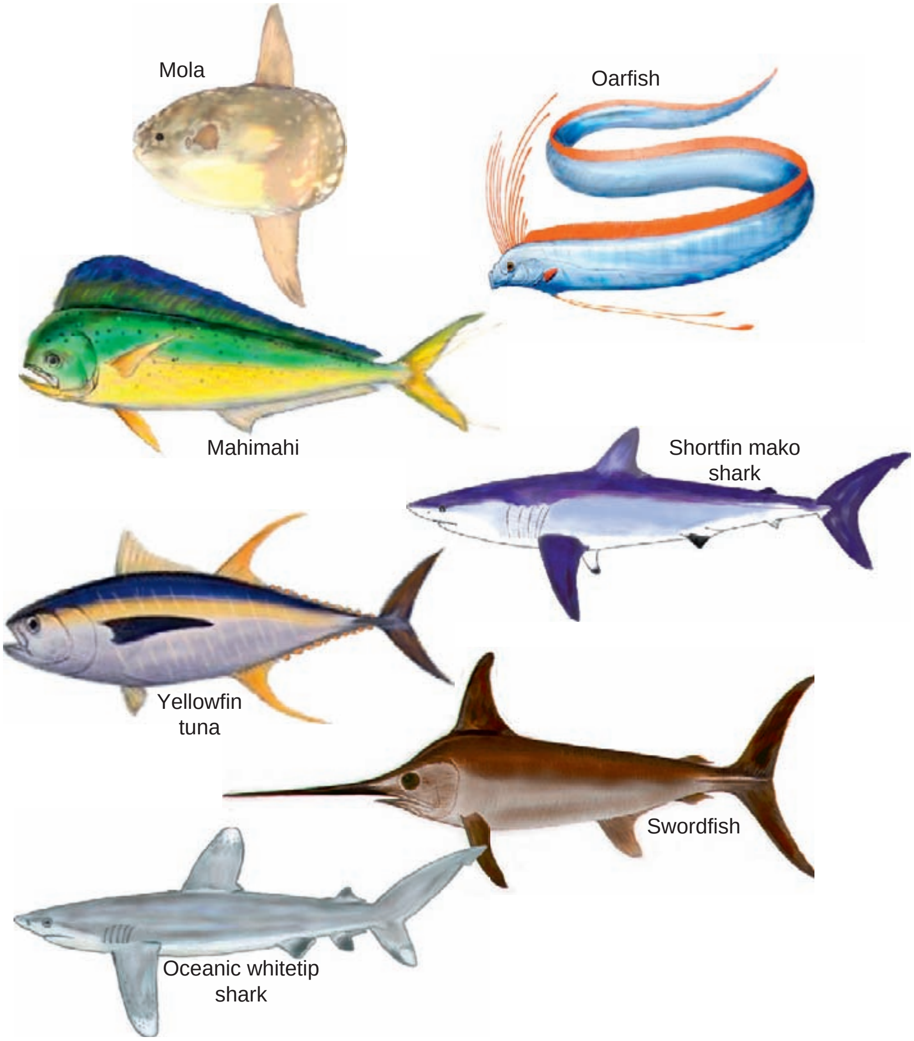

Figure 2 Representative examples of pelagic fishes showing the diversity of body shapes and colorations. Note the highly streamlined bodies and nearly symmetrical caudal fins of continuously swimming species (mahimahi, shortfin mako shark (*Isurus oxyrinchus*), yellowfin tuna (*Thunnus albacares*), oceanic whitetip shark, and swordfish).

Body Coloration

The lack of physical hiding places in the pelagic realm means that both predators and prey are easily visible in all three dimensions. Although a potential solution to this would be to have a transparent body, an adaptation present in many pelagic invertebrates and larval fishes, the combination of a large size and the use of muscles to power swimming limits this adaptation and renders pelagic fishes visible. Some fishes have evolved a laterally compressed body, making the body contour of these fishes, when observed from above or below, appear small. Other pelagic fishes that inhabit the well-lit surface waters have vibrant colors (mahi mahi) and dappling or barred patterns (mola, whale shark) that disrupt the body contour when viewed from the side. A more widely observed adaptation in pelagic fishes that inhabit the photic waters of the open ocean is to have cryptic countershading coloration in which the dorsal section of the body is darker (blue or green) than the much lighter (white) ventral side of the body (**Figure 2**). This allows the body to blend in with the blue or green water when seen from above and with the light surface waters when seen from below (**see also Vision**: Physiological Optics in Fishes, and Color Vision and Color Communication in Reef Fish).

Sensory Mechanisms

The perception of external stimuli by pelagic fishes is, as in other fishes, a complex assemblage of the visual, auditory/mechano, and olfactory systems (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction, **Hearing and Lateral Line**: Fish Bioacoustics: An Introduction, and **Vision**: Vision in Fishes:

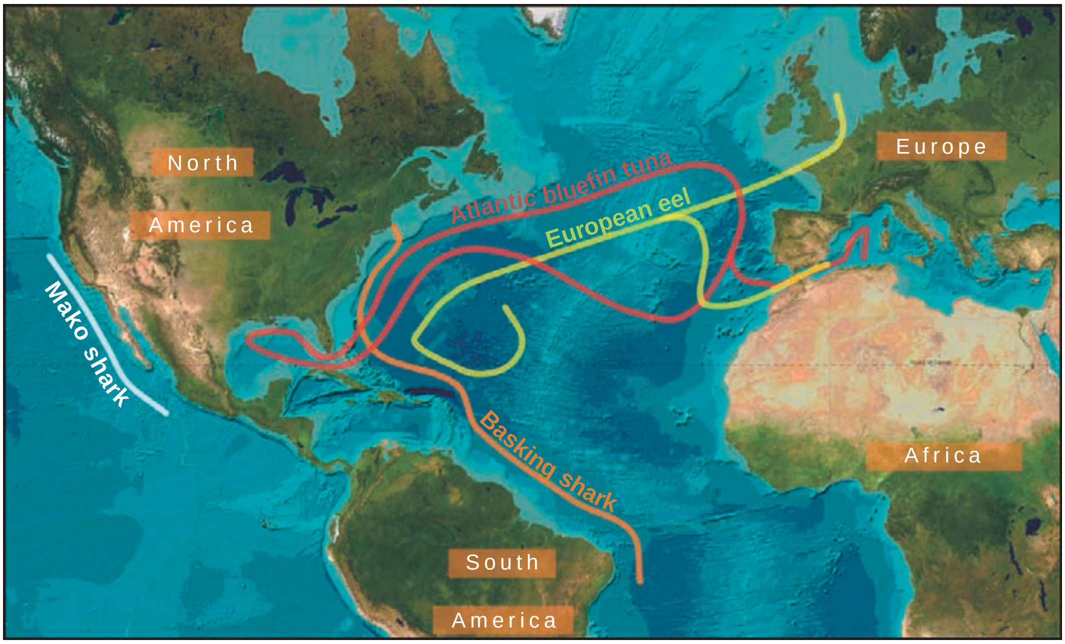

Figure 3 Horizontal movement patterns of selected pelagic fishes showing their long, trans-oceanic migratory patterns.

An Introduction). The ample light penetration during the daylight hours in the upper, photic layer of the pelagic zone has led most pelagic fishes to become visual predators. Thus, most have well-developed eyes that during the daylight hours, are light-adapted (allowing for vision in bright light). However, several pelagic species (e.g., swordfish and bigeye thresher shark *Alopias superciliosus*) that spend the daylight hours at depth (>300 m) and rarely encounter bright-light conditions have relatively larger eyes that remain constantly dark-adapted (allowing for vision under low-light levels). The extensive propagation of sound in the ocean has led pelagic fishes to evolve a complex auditory system capable of detecting sounds and vibrations across a wide range of frequencies that assist in finding prey and avoiding predators. Many small pelagic fishes form schools, which may allow hydrodynamic drafting (i.e., decreasing the metabolic costs of locomotion, through swimming in water that has been accelerated forward by preceding fish in the school) while serving as an antipredatory mechanism. This behavior relies extensively on the lateral-line (i.e., mechanoreceptor) sensory pathway, which detects pressure waves from surrounding conspecifics (**see also Hearing and Lateral Line**: Lateral Line Neuroethology). The lateral line is thus critical for the maintenance of a tight spatial formation during this grouping behavior. Unlike the keen sense of smell characteristic of benthic fishes, or those that inhabit environments with low or no light penetration (e.g., highly turbid waters, the aphotic zone) where vision is often impaired, pelagic fishes possess a modest olfactory capacity. A very small and select group of pelagic fishes (i.e., tunas, billfishes Istiophoridae, and lamnid sharks Lamnidae) have evolved the capacity for cranial endothermy, which allows for elevation of brain and eye temperatures (**see** section Regional Endothermy). This unique adaptation significantly influences the sensory capabilities of these species and increases the overall ability to locate and catch prey and avoid predation (**see also Smell, Taste, and Chemical Sensing**: Chemoreception (Smell and Taste): An Introduction, **Hearing and Lateral Line**: Fish Bioacoustics: An Introduction, and **Vision**: Vision in Fishes: An Introduction).

Buoyancy

In general, the bodies of pelagic fishes are made mostly of myotomal (i.e., swimming) muscles, bone or cartilage, and skin, which is usually covered with heavy scales. This results in an overall specific gravity (i.e., a measure of density) that is higher (~1.05–1.09 g cm^{-3}) than that of seawater (1.024 g cm^{-3}), resulting in negative buoyancy. Fishes have evolved adaptations to offset their high specific gravity allowing them to reach near-neutral buoyancy and ultimately decrease the potential cost of locomotion (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). The most obvious of these mechanisms in bony fishes is the swimbladder, which acts as a gas-filled flotation device. However, unlike the swimbladder of some shallow-water fishes, which have a pneumatic duct that is directly connected to the esophagus (physostomes), most pelagic fishes do not possess this duct (physoclists). In this case, the swimbladder is filled by transfer of dissolved gases in the blood through the gas gland and associated rete mirabile network (**see also Design and Physiology of Arteries and Veins**: The Retia). Interestingly, a swimbladder is not an essential structure for all pelagic fishes; for example, some closely related tuna genera have swimbladders and others do not. Nonetheless, the continuous rapid swimming in tunas allows the pectoral fins and body to produce hydrodynamic lift to offset the negative buoyancy. An additional benefit to the lack of the swimbladder in some of these species may be the ability to move freely up and down the water column without any adverse effect of a changing swimbladder volume, hence avoiding the overexpansion of this organ during a rapid ascent (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes and Buoyancy, Locomotion, and Movement in Fishes: An Introduction).

Another adaptation in pelagic fishes that increases their buoyancy is the presence of a large quantity of low-density lipids throughout their bodies (e.g., swimming muscles, body cavity, subdermal layer, and liver). In some species, there is a positive correlation between the overall amount of lipids and body size; that is, there may be a higher overall relative amount of lipids in the body as specific gravity increases due to their larger body mass. Unlike bony fishes, elasmobranchs do not have a swimbladder, and a principal mechanism to offset their negative buoyancy is to have a very large, oil-rich liver that decreases their overall specific gravity. In pelagic sharks, liver size ranges between 10% and 15% of body mass, but in some species (e.g., basking shark) the liver may be as large as 25% of body mass and occupy 95% of the visceral space. In addition, benthic sharks and rays have relatively smaller livers and are less buoyant than pelagic sharks, which allows them to sink and remain at the bottom.

Cardiorespiratory System

The ecology of many actively swimming pelagic fishes demands continuous locomotion during long-distance horizontal migrations and throughout repeated vertical oscillations. Because sustained swimming is powered by aerobic metabolism, the cardiorespiratory system needs to deliver ample supplies of oxygen and metabolic substrates (i.e., fuels) to the working tissues at all times. Although there are several marked differences between the cardiorespiratory systems of teleosts and elasmobranchs, continuously swimming pelagic fishes (e.g., compared with less-active species) have morphological and physiological specializations that enhance the transfer of oxygen across the gills (e.g., larger gill surface area and shorter blood–water diffusion distances), increase the quantity of oxygen transported by the blood (e.g., higher hemoglobin concentrations), elevate the delivery rate of oxygenated blood to tissues (e.g., increased capillary density and a complex capillary-muscle fiber geometry, resulting in an increased ratio of capillary surface area to muscle-fiber volume – **see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis), and facilitate the intracellular transport of oxygen to the mitochondria (e.g., increased myoglobin levels). In addition, relative to other fishes, the hearts of continuously swimming pelagic fishes have larger, more muscular ventricles that are perfused by an elaborate coronary blood supply providing the heart tissues with sufficient oxygen and metabolic substrates to sustain elevated aerobic activities (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping, and The Coronary Circulation). Pelagic fishes also have a more pyramidal-shaped ventricle that is hypothesized to enhance the effectiveness of blood outflow during systole. Taken together, these cardiorespiratory features appear to allow pelagic fishes to supply the continuously active, aerobic locomotor muscles with sufficient oxygen and metabolic substrates to sustain the high rates of intracellular adenosine triphosphate (ATP) production that power locomotor-muscle contraction during continuous swimming (**see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes, **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics, **Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin, and O_2 Uptake and Transport: The Optimal P_{50}).

Metabolic Rates and Swimming

Continuous swimming in pelagic fish requires a sustained supply of oxygen and metabolic substrates to fuel the aerobic myotomal muscles, and has resulted in a suite of morphological and physiological adaptations that augment not only the uptake and delivery of oxygen, but also the overall oxygen demand (i.e., aerobic metabolic rate). Although, in general, the aerobic metabolic rates of pelagic, obligate ram-ventilating fishes are usually elevated when compared to most other less-actively swimming fishes (e.g., benthic or mesopelagic), several species stand out even among pelagic fishes. For example, the swimming metabolic rates (e.g., including the maximum metabolic rates (MMRs)) of tunas and lamnid sharks (two groups of fish known for their highly migratory, and often rapid, swimming behavior) are 2–6 times higher than those measured in other actively swimming fishes (e.g., salmonids and carcharhinid sharks). These high metabolic rates have been commonly associated with the elevated maintenance costs (i.e., standard metabolic rate (SMR)) of the specialized cardiorespiratory system that allows for high rates of energy turnover as well as with the concomitant thermal effects of regional endothermy. (Although regional endothermy may increase metabolic processes (e.g., aerobic, red myotomal muscle contraction rates, and digestion), the morphological structures involved in heat retention only harness metabolically produced heat and by themselves they do not necessarily reflect any additional metabolic cost (excluding species that have thermogenic tissue); **see** section Regional Endothermy). However, the aerobic scope (i.e., MMR–SMR) is a more biologically relevant indicator than are the absolute values of metabolic rate and represents the potential capacity to handle multiple simultaneous aerobic demands (e.g., continuous swimming, recovering from oxygen debt, somatic growth, digestion of prey, and assimilation of nutrients). For example, in tunas, the MMR can be up to 18 times higher than the SMR, a markedly higher aerobic scope when compared with many other pelagic species. Similarly, the aerobic scope of lamnid sharks (e.g., MMR up to 6 times higher than SMR) is higher than that of other actively swimming pelagic shark species. Overall, the heightened aerobic scope in continuously swimming pelagic predators reflects their need for the capture of fast-moving prey and the physiological consequences (e.g., rapid recovery from burst activity and rapid digestion) of their swimming behaviors. In addition, some tropical, pelagic species (e.g., mahimahi and billfishes Istiophoridae) also have high MMRs, but this may reflect their rapid somatic and gonadal growth, a scenario not common for sharks, which have relatively low growth rates, mature later in life, and give birth to relatively few pups. (**see also Gas Exchange**: Respiration: An Introduction, **Ventilation and Animal Respiration**: The Effect of Exercise on Respiration, **Food Acquisition and Digestion**: Cost of Digestion and Assimilation, **Energetics**: General Energy Metabolism, and **Swimming and Other Activities**: Energetics of Fish Swimming).

The capacity to capture prey or escape predators is powered, largely, by the white myotomal muscles and fueled by anaerobic metabolism. Burst swimming relies on the rapid mobilization of muscle energy stores and results in the accumulation of lactate and protons. It is no surprise that pelagic fishes that routinely capture fast-moving prey not only have a higher capacity to burst swim, but also show a remarkable capacity to recover quickly from these anaerobically powered activities. Tunas, for example, have the highest known white-muscle lactate levels among vertebrates ($>100\,\mu\text{mol g}^{-1}$) and also have both high muscle and blood buffering capacities, which allows them to tolerate times of elevated proton loads during the time needed to process lactate to pre-exercise levels, a mechanism they can undergo more quickly than can other fishes. This is a consequence of tunas' cardiorespiratory system being able to deliver oxygen and metabolic substrates at rates far above those needed at routine activity levels. These adaptations appear to be a direct result of the selective pressures in the pelagic environment where food resources are aggregated, but widely scattered, and where no refuge exists for animals to hide and recover from a bout of strenuous activity.

Do Pelagic Fish Have a Depth Preference?

Many studies have hypothesized that there are species-specific depth preferences in pelagic fishes. However, it is unclear how fishes can perceive depth *per se*. That is, there is no known sensory mechanism that would permit a fish to detect the exact depth (e.g., 20 or 200 m) it is occupying. When fishes change depth, the swimbladder volume is altered, and this may be detected by the stretch receptors lining the swimbladder walls. However, it appears that these receptors only respond to acute changes in volume, and it remains to be seen whether they are able to determine the absolute depth. By contrast, elasmobranchs, which lack a swimbladder, therefore neither are subject to any volume-expansion limitations during their vertical movements nor can they rely on a change in gas volume to detect variations in hydrostatic pressure. Therefore, fish may not target a specific depth, but may associate with a depth range based on one or more environmental variables that correlates with depth, such as light, temperature, and prey availability. When viewed from an ecological perspective, it is difficult to perceive how depth itself can be relevant to pelagic fishes that inhabit an environment with dynamic oceanographic conditions such as the revolving water masses in the pelagic realm affect light penetration and water clarity, water temperature, deep-water mixing, and nutrient availability, and dissolved oxygen concentrations throughout the water column. For this reason, it is hard to associate any of these biotic and abiotic parameters to a particular depth because they are in constant flux throughout the open oceans. Because these oceanographic features appear to have a profound influence on the prey and predator distributions throughout the water column, it is clearly not the absolute depth that a pelagic fish targets. Rather, it is specific favorable environmental conditions and the associated organisms that influence the vertical (depth) movements of fishes.

Nonetheless, it is possible that the vertical movements themselves, not depth preference *per se*, may be physiologically constrained. In fishes that have a swimbladder, the range of depths they can occupy and the speed at which they can ascend or descend are limited by the capacity of this organ to adjust its volume (**see also Buoyancy, Locomotion, and Movement in Fishes**: Buoyancy in Fishes). Because any pressure change during the vertical movements will affect bladder volumes, it is critical that the time required for gas secretion (bladder filling) and resorption (bladder emptying) is less than that of the actual time of the vertical movement through the water column. If not, the effect of hydrostatic pressure on swimbladder volume could limit the extent of the vertical movements by, for example, the overexpansion of the swimbladder during rapid ascents. A solution to this would be that if pelagic teleosts, which undergo repeated and rapid movements up and down the water column, maintain a swimbladder volume that is equivalent to its maximum capacity when at the top of their vertical ranges, which would result in near-neutral buoyancy after the ascent.

An additional constraint exists as well. A direct effect of very high hydrostatic pressures (>1000 m in depth) is the alteration of the three-dimensional shape of enzymes and other proteins, which may ultimately affect biochemical function (**see also Deep-Sea Fishes**). However, few species of pelagic fishes dive to these extreme depths, and when they do, it is only for short periods of time (min–h). Hence, the overall vertical movements and depth ranges occupied for substantial periods of time by almost all pelagic fishes are above these potentially critical depths.

What May Limit the Vertical Movements of Pelagic Fishes?

There is a growing body of literature documenting how the vertical movements of predatory pelagic fish are influenced by the vertical movements of their prey. In order to decrease their exposure to predation, many prey species (e.g., cephalopods and crustaceans) have evolved greater relative physiological tolerances that allow them to diurnally invade deeper waters that have lower water temperatures, decreased dissolved oxygen levels, and lower light availability. Therefore, any pelagic predator that wishes to benefit from the concentration of the deep, hard-to-reach prey will have to maintain not only a functional suite of sensory systems associated with prey detection (e.g., sight, smell, and hearing) while in the deep, cold, hypoxic, and relatively dim-lit waters, but also sustain the swimming capabilities involved in the continuous search for prey and the bouts of burst swimming associated with prey capture. Because these environmental parameters appear to impose important limitations on the vertical movement patterns of large pelagic fishes, future work should focus on how oceanographic dynamics affect species-specific physiological adaptations to these conditions.

The vertical movements of pelagic fishes appear to be influenced not only by local oceanographic parameters that affect environmental conditions, but also by several biotic factors such as reproduction, interspecific (e.g., predator–prey) interactions, and ontogeny. Although how these factors influence vertical migrations within the water column is unknown, largely, the general movement patterns of pelagic fish still can be differentiated by comparing their diel vertical and thermal distributions. Specifically, during the daylight hours, when the water column has a distinct photic zone, many species reveal discrete vertical distributions due to their physiological tolerances to the depth-related reduction in temperature, oxygen level, and light intensity. By contrast, during the night when the entire water column is exposed to low light availability, many pelagic fishes migrate to or remain within the upper, warm, well-mixed surface layer resulting in a substantial overlap of their vertical distributions. This diel shift in the vertical distribution is most likely associated with the vertical migration of prey species associated with the deep-scattering layer.

Because the different physiological capacities of pelagic fishes to tolerate large and rapid changes in temperature, dissolved oxygen, and light levels are associated with their ability to move between the surface and deep-water layers, it is possible to group pelagic fishes into three broad categories that reflect their short-term (days–weeks) general vertical-movement patterns and hence their utilization of the water column:

- Group 1. These fishes are consistently found in the upper layers of the ocean where the water column is well mixed into a homogeneous thermal layer limited vertically by the thermocline. Although the depth within this layer that each fish routinely penetrates is species specific, the unifying theme for this group is that they rarely descend to water temperatures below 20 °C and thus are distributed both day and night in the relatively warm, photic, and well-oxygenated layers of the ocean. Some examples of genera in this group are: skipjack tuna *Kastuwonus pelamis*, wahoo *Acanthocybium solandri*, mahimahi, sailfish *Istiophorus*, silky shark *Carcharhinus falciformis*, oceanic whitetip shark, sunfish (*Mola*), whale sharks, and manta rays *Manta* (**Figure 4**).
- Group 2. Fishes in this group venture below the warm, surface layer and undergo regular, but short-lived, diurnal excursions into depths at or below the thermocline. Although the frequency and duration of these brief diving excursions are species specific, they may vary from a single event per day (e.g., striped marlin *Tretrapturus audax*, blue marlin *Makaira nigricans*, and black marlin *M. indica*) to several excursions per day (e.g., yellowfin tuna *Thunnus albacares*, shortfin mako shark *Isurus oxyrinchus*, and blue shark *Prionace glauca*) (**Figure 5**). Relative to group 1 fishes, this group has a broader vertical range resulting in their exposure to colder waters (even below 10 °C), lower levels of dissolved oxygen, and decreased light levels during the day.
- Group 3. Relative to all other pelagic fishes, this group (best exemplified by the bigeye tuna *T. obesus*, swordfish, and bigeye thresher shark (*Alopias superciliosus*)) exhibits distinct diurnal behavior patterns, making regular deep descents during the day and remaining in the upper uniform-temperature surface layer at night (**Figure 6**).

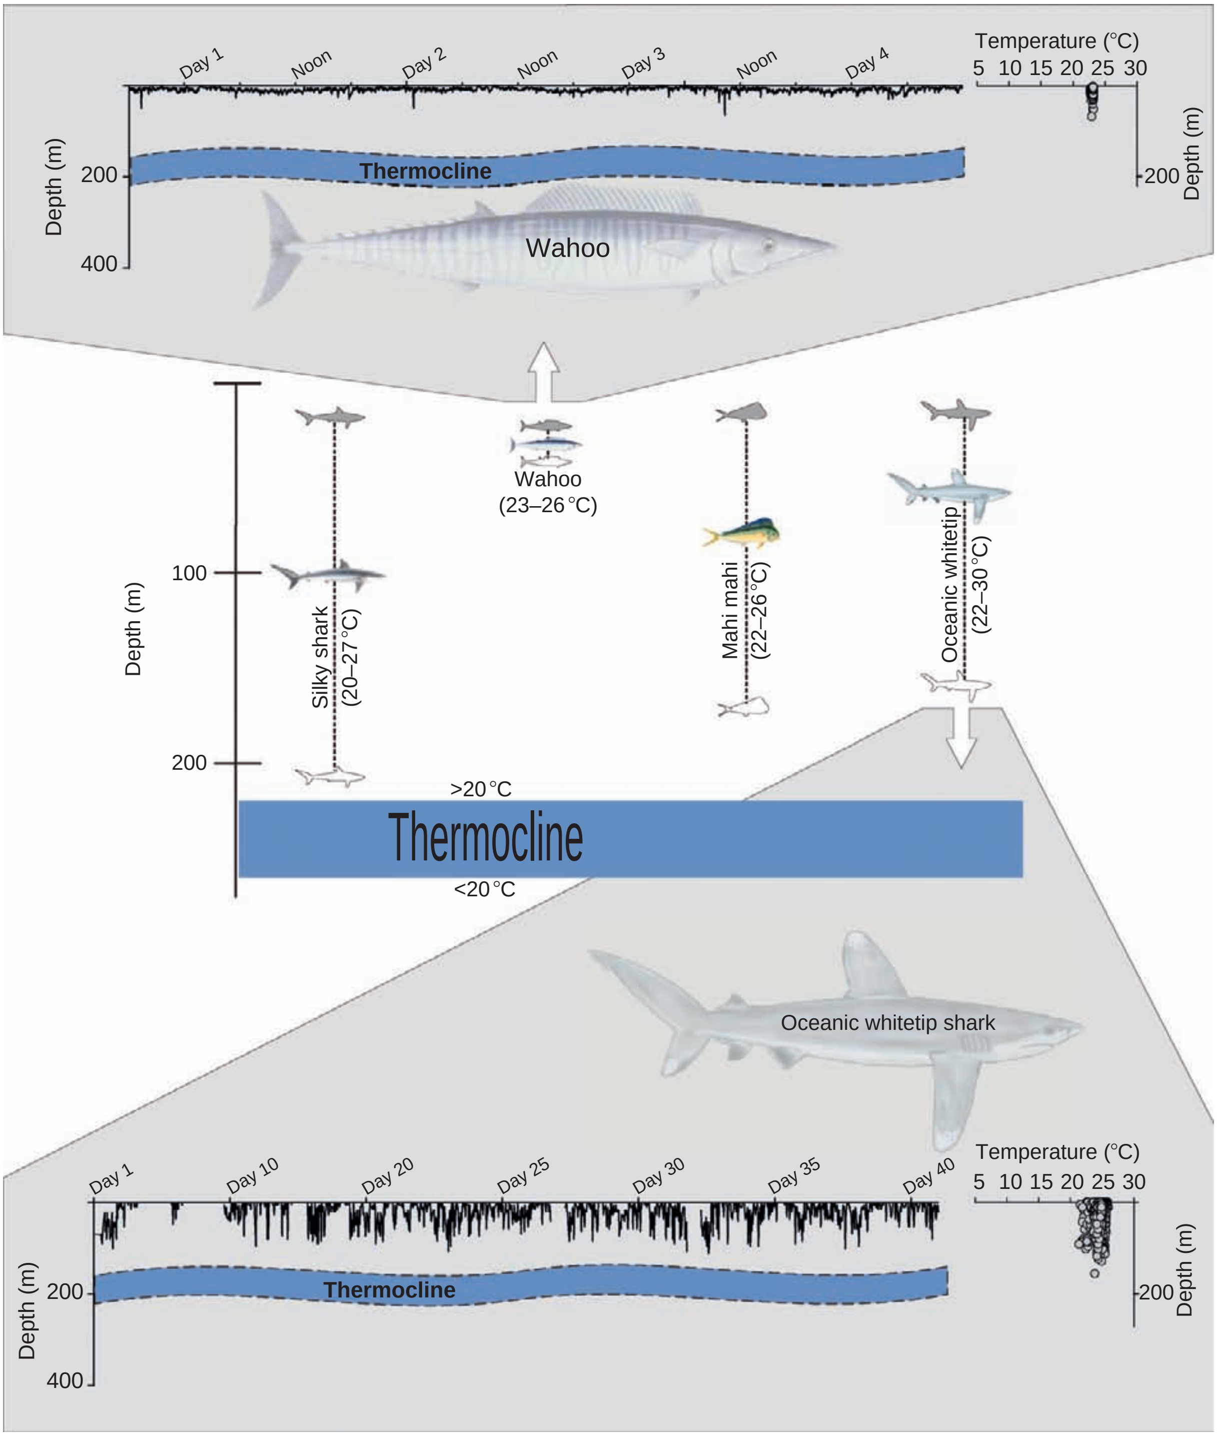

Figure 4 Representative vertical-dive profiles for group-1 pelagic fishes. Color fish images represent the average depth (combined night and day) for each species. Open and shaded fish outlines are the depths at which each species spent 95% of the time during the day and night, respectively. Values next to the name show the overall temperature ranges encountered. Blue-shaded bar represents the thermocline, separating water column into the upper warm, surface layer (>20 °C) and cooler deeper waters (>20 °C). Insets show the vertical movement patterns and temperature-depth profiles of wahoo and oceanic whitetip sharks. Day marks indicate midnight of that day.

This group has the widest thermal range and routinely descends to ~500–800 m, where water temperatures are below 5 °C and dissolved oxygen levels are low (<1 mg-O_2 L^{-1}) (**Figure 1**). In addition, this group experiences continuous low-light levels because they generally remain deep during daylight and occupy the upper water column at night. There are other species that also belong to this group because they are capable of

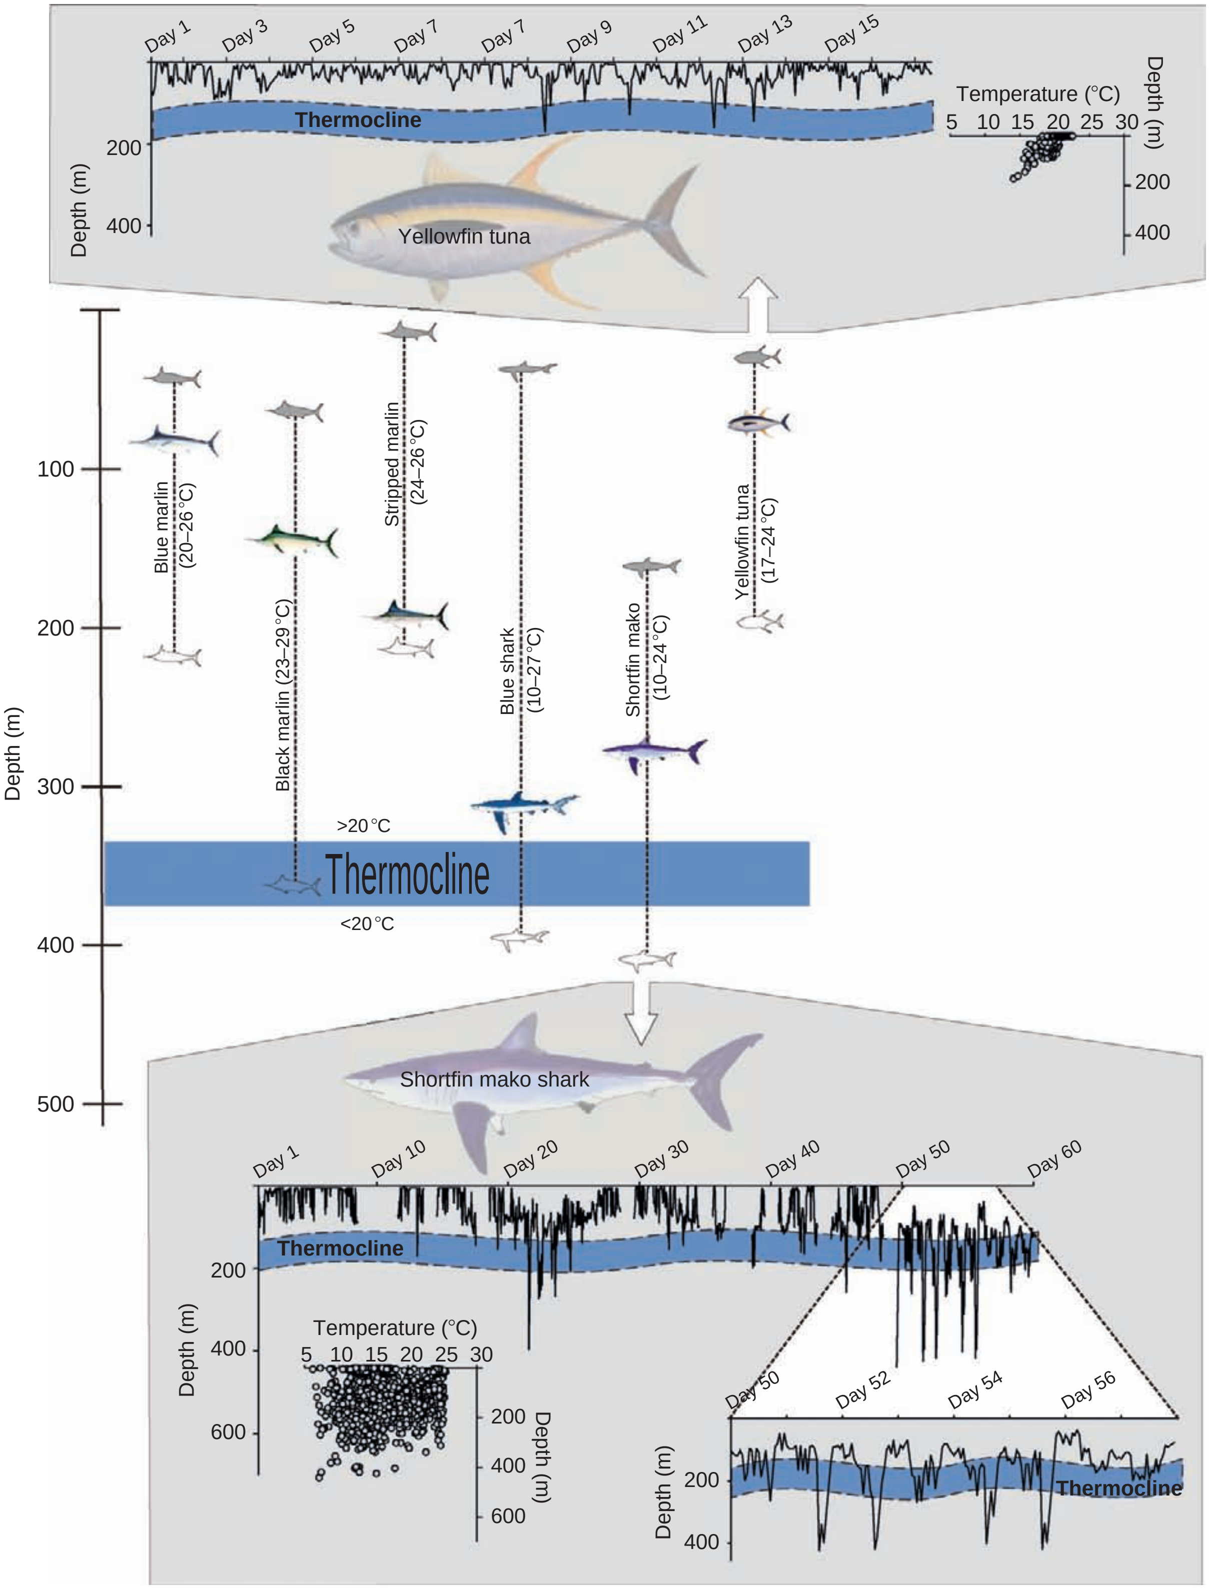

Figure 5 Representative vertical dive profiles for group-2 pelagic fishes. Color fish images represent the average depth (combined night and day) for each species. Open and shaded fish outlines are the depths at which each species spent 95% of the time during the day and night, respectively. Values next to the name show the overall temperature ranges encountered. Blue shaded bar represents the thermocline, separating water column into the upper warm, surface layer (>20 °C) and cooler deeper waters (<20 °C). Insets show the vertical movement patterns and temperature-depth profiles of yellowfin tuna and shortfin mako shark. Additional inset in the mako shark shows a finer timescale. Day-marks indicate midnight of that day.

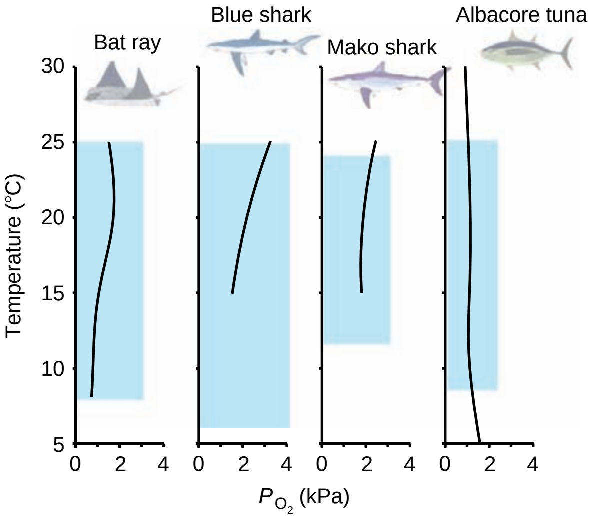

Figure 6 Comparison of the thermal effects on the oxygen-binding affinity of arterial blood at 50% saturation (P_{50}) during open-system temperature changes. Light blue shade shows the general range of ambient temperatures during their vertical movement patterns in the eastern Pacific Ocean. The bat ray (*Myliobatis californica*) migrates daily between 14 and 20 °C.

penetrating cold water during their extensive migrations to high latitudes (e.g., Atlantic bluefin tuna *T. thynnus*, porbeagle shark *Lamna nasus*, and salmon shark *L. ditropis*, basking sharks).

Physiological and Morphological Adaptations That Allow Some Pelagic Fishes to Undergo Rapid and Repeated Vertical Movements in the Water Column

Numerous species co-inhabit the same geographical areas in the pelagic realm; however, their depth distributions and vertical movement patterns vary significantly (**see** section What May Limit the Vertical Movements of Pelagic Fishes?). Thus, many pelagic species that have a similar spatial distribution have marked differences in their diurnal utilization of the water column, and hence, occupy distinct oceanographic ecosystems. For example, bigeye tuna and the yellowfin tuna, two closely related species, are often found, and targeted by the recreational and commercial fisheries, in the same geographical areas although their prey selection is clearly different (the former consumes prey from the deep layer, and the latter mostly feeds on species from the surface layer).

Pelagic fishes that undergo extensive vertical movements following their prey need to have physiological adaptations that allow for the uptake, and delivery of dissolved oxygen and metabolic substrates at rates that match whole-body metabolic oxygen demands. That is, these fishes need to be able to meet their metabolic demands during times of prey capture and predator avoidance, recovery from burst exercise, and digestion and assimilation, all the while being exposed to deep, cold, and potentially hypoxic waters. Because large pelagic fishes experience large and sudden changes in ambient water temperature during the rapid (~minutes) sojourns from the warm surface layers to the deep cold layers, they are unable to undergo temperature acclimation (e.g., synthesis of isozymes and modification of cell membrane structure). Thus, the reduction of ambient temperature and oxygen will undoubtedly alter cardiorespiratory function and ultimately restrict the swimming ability of the fishes and its capacity to undergo vertical movements through the water column.

Cardiac Function during Acute Temperature Changes

The hearts of all fishes receive blood from either the systemic venous system or the coronary circulation (**see also Design and Physiology of the Heart**: The Coronary Circulation, and Cardiac Anatomy in Fishes), which are at, or close to, thermal equilibrium with ambient temperature. Therefore, the temperature of the heart closely mirrors that of ambient conditions and immediately reflects changes in ambient temperature. Work on tunas has shown that a rapid 10 °C decrease in temperature lowers both heart rate and cardiac output, as stroke volume appears to be nearly fixed (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature). This change in heart rate appears to be independent of parasympathetic stimulation, which normally increases heart rate in fish, and thus the decline in heartbeat frequency appears to be the major contributor to the change in cardiac output. Recent work on Pacific bluefin tuna (group 3) found that a decrease in temperature from 25 to 10 °C lowered heart rate (thermal rate coefficient, $Q_{10} = 2.1$) to a lesser degree than that observed in other group 2 tunas ($Q_{10} = 3.1$) and that the heart rate, albeit low (<0.3 Hz), of bluefin tuna was maintained at temperatures as low as 2 °C, far below 10 °C at which other tuna hearts ceased normal function. This suggests that as tuna dive into colder waters at or below the thermocline, their slowing heart rate will result in a concomitant decrease in cardiac output and ultimately impair cardiorespiratory function. While tunas and other pelagic fishes still may meet their oxygen delivery requirements during slow swimming in colder temperatures, it is poorly understood how cardiac output is elevated in order to accommodate for the marked increases in oxygen demands associated with an increased swimming speed, recovery from burst swimming, and during digestion and assimilation.

Recent work on the excitation–contraction (EC coupling) dynamics in myocardium of group 3 (i.e., bluefin tuna and salmon sharks) and group 2 pelagic fishes has shown that, in the latter, a decrease in ambient temperature slows active calcium extrusion from the myocytes and prolongs relaxation times. Taken together, it appears that maintaining cardiac Ca^{2+} kinetics is critical to sustaining physiologically relevant heart rates (i.e., cardiac output) at low temperatures (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping, **Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels, **Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature, and **Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux.)

Regional Endothermy

Rapid and repeated vertical movements and movements across thermal fronts are a common trait of pelagic fishes, and regionally endothermic species are able to maintain a more thermally stable operating environment for their tissues (e.g., aerobic locomotor muscles, eye and brain, and viscera). Thus, for these unique pelagic fishes, regional endothermy provides an operating temperature that safeguards physiological function when exposed to cold ambient conditions.

The steady-state body temperature of most fishes is in equilibrium with that of ambient water temperature and all metabolically produced heat is rapidly lost either by convective transfer through the blood to the gills or by thermal conduction across the body surface. The capacity for aerobic myotomal muscle and visceral endothermy, defined as the capacity to conserve metabolic heat and maintain steady-state tissue temperatures that are above ambient, has evolved independently in several pelagic fishes (i.e., tunas and lamnid sharks). Regional eye and brain endothermy, some of which results from the transformation of eye muscles into thermogenic organs that warm the brain and eyes, has also been documented in the billfishes, opah *Lampris guttatus*, and possibly butterfly mackerel, *Gasterochisma melampus*.

Unlike the central circulation pattern in most fishes where the major vessels (i.e., dorsal aorta and the postcardinal vein) are found directly ventral to the vertebral column, the central circulatory pathway of some pelagic fishes (tunas, lamnid sharks, and the common thresher shark (*Alopias vulpinus*)) is reduced and blood flow to and from the myotomal muscles relies principally on a lateral circulation that gives rise to myotomal muscle-associated vessels. These vessels act as countercurrent heat exchangers and enable the conservation of metabolically produced heat allowing the aerobic myotomal muscles to maintain temperatures that are significantly above that of the ambient water (i.e., regional endothermy). In addition, these regionally endothermic fishes may have the ability to exert physiological control over routes and rates of heat transfer resulting in maintaining power output at high cycle (i.e., tail beat) frequencies when penetrating cooler waters. In addition, it has also been hypothesized that maintenance of elevated muscle temperatures allows these unique pelagic fishes to swim faster and to recover faster from anaerobic activity (**see also Design and Physiology of Arteries and Veins**: The Retia, **Pelagic Fishes**: Physiology of Tuna, and Endothermy in Tunas, Billfishes, and Sharks.)

The ability to maintain an elevated temperature of the central nervous system conserves sensory and integrative functions while in cooler and darker deep water, and warming of the brain and eye region enhances physiological processes (e.g., synaptic transmission and temporal resolution). For example, recent work on the swordfish eye shows that it is highly sensitive (Q_{10} of 5.1) to temperature changes and that warming the retina significantly improves temporal resolution. This suggests that a warm eye increases the fish's capacity to detect and capture fast-moving prey at both low temperatures and decreased light levels.

The capacity for visceral endothermy has been documented in all lamnid sharks and cold-water tunas, and is suspected in the common thresher shark. Although the structural specializations that allow for visceral heat conservation differ between these fishes, the unifying theme appears to be that heat produced from digestion is used to maintain elevated visceral temperatures. Data on free-swimming Atlantic bluefin tuna show that stomach temperatures increase by as much as 20 °C above ambient after prey is consumed and that this temperature excess

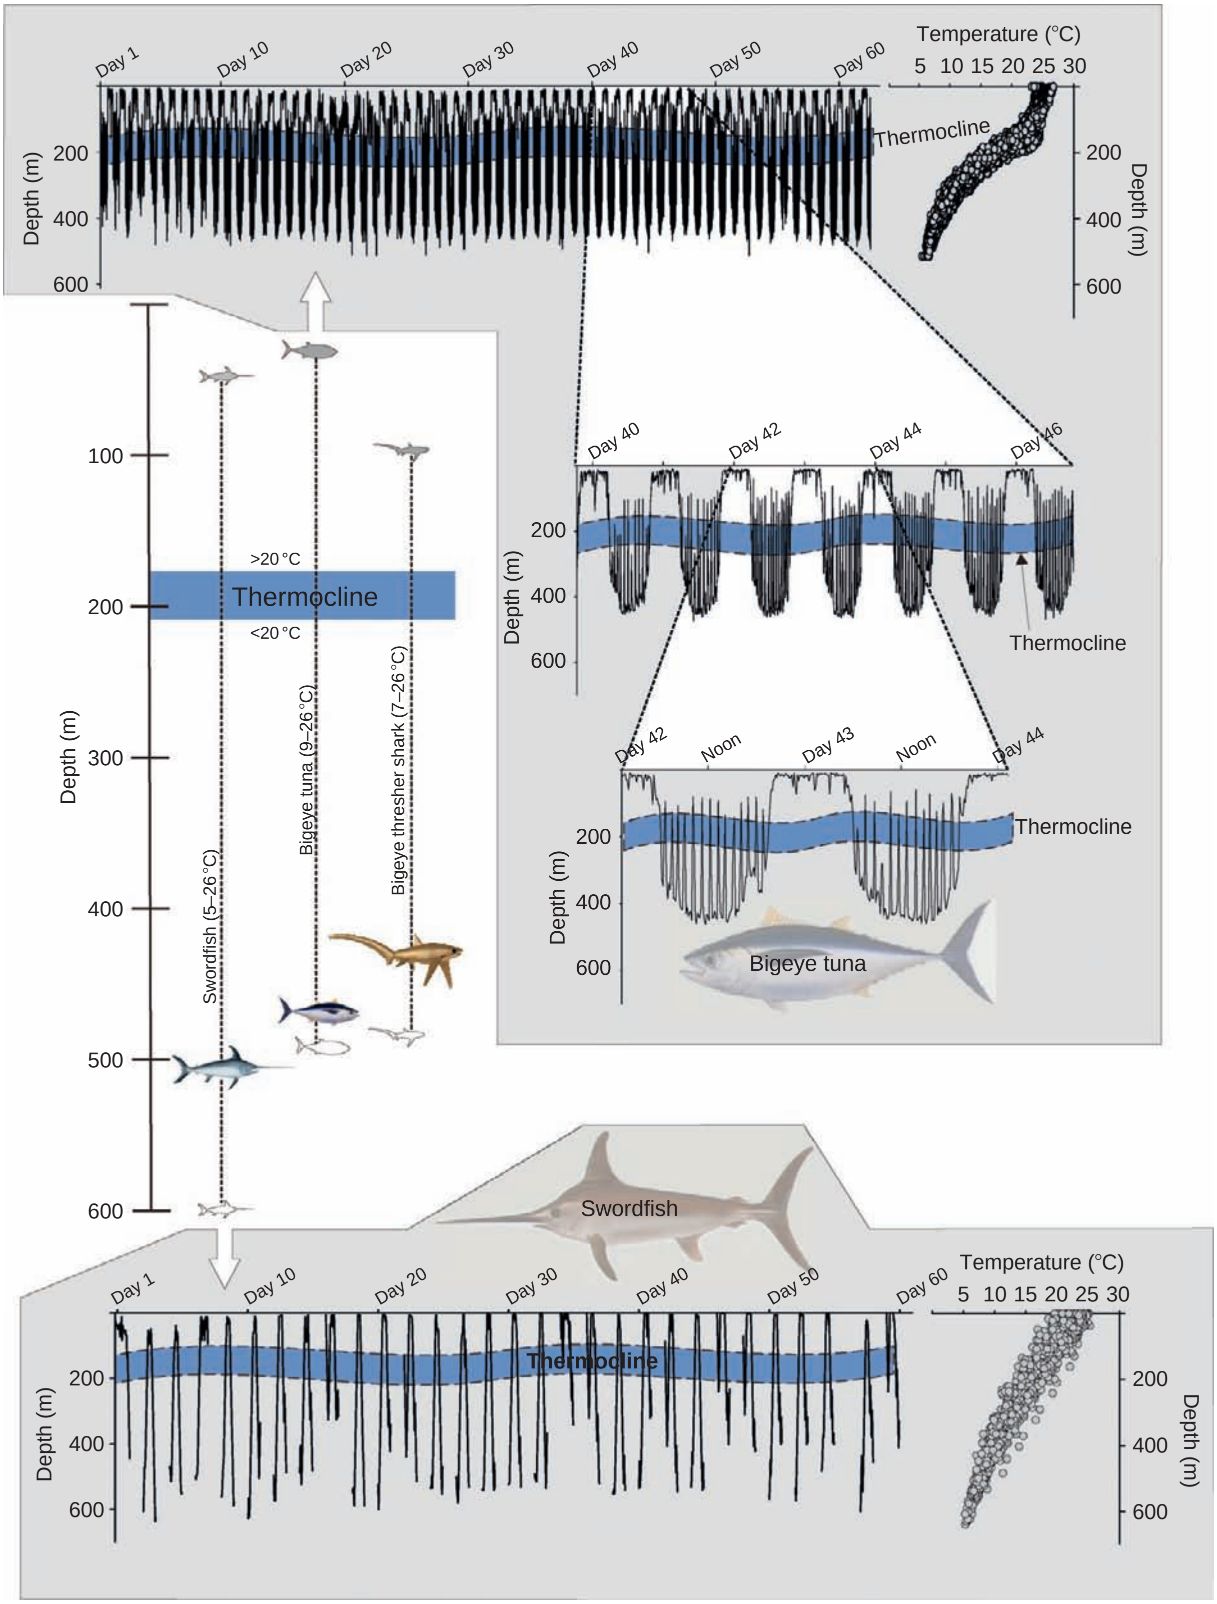

Figure 7 Representative vertical dive profiles for group-3 pelagic fishes. Color fish images represent the average depth (combined night and day) for each species. Open and shaded fish outlines are the depths at which each species spent 95% of the time during the day and night, respectively. Values next to the name show the overall temperature ranges encountered. Blue-shaded bar represents the thermocline, separating water column into the upper warm, surface layer (–>20 °C) and cooler deeper waters (<20 °C). Insets show the vertical movement patterns and temperature-depth profiles of bigeye tuna and swordfish. Additional insets in the bigeye tuna show finer timescales. Day-marks indicate midnight of that day.

slowly decreases back to the pre-feeding values over the next 20–30 h. By contrast, the stomach temperature of lamnid sharks remains continuously elevated (4–14 °C above ambient) and appears to be independent of ambient temperature. Regardless of the exact mechanism, heat production results from digestion and assimilation processes, and the presence of elevated visceral temperatures in these pelagic fishes is a potential mechanism to enhance specific dynamic action after prey is consumed.

Hypoxia and the Thermal Effects on Blood-Oxygen Binding

The extent and duration of the vertical movements in group 3 fishes routinely exposes them to low oxygen levels ($<1.5\ \text{ml-O}_2\ \text{L}^{-1}$) that appear to limit the vertical movements of fishes in groups 1 and 2. A comparison between yellowfin tuna (group 2) and bigeye tuna (group 3) shows that, in the latter, the onset of hypoxia-induced cardiorespiratory adjustments occurs at lower ambient oxygen levels (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia). In general, tolerance to low-oxygen conditions by any tuna seems to undermine their elevated metabolic rates (**see** section Metabolic Rates and Swimming), because the majority of hypoxia-tolerant fishes are generally characterized by sluggish behaviors and low metabolic rates. In addition, hypoxia-tolerant fishes usually have a high blood-oxygen-binding affinity, which could ultimately reduce oxygen off-loading and rates of oxygen delivery to the tissues, relative to blood with lower oxygen affinity (typically found in fish that need more oxygen delivery to their muscles). Not surprisingly, in bigeye tuna, the routine exposure to hypoxia has resulted in the blood having a higher oxygen affinity relative to yellowfin tuna; however, the metabolic rates of bigeye tuna are not lower than those of yellowfin tuna. Thus, bigeye tuna have evolved a unique ability that allows them to maintain elevated aerobic metabolic rates while remaining tolerant of low ambient oxygen levels (i.e., hypoxia, **see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion, Hemoglobin Differentiation in Fishes, and Hemoglobin).

During a sojourn into deeper waters, the blood in the gills of pelagic fishes in groups 2 and 3 are subject to rapid open-system temperature changes where the partial pressures of oxygen and carbon dioxide are constant, but the blood oxygen content changes. For this reason, blood passing through their gills must maintain its capacity to upload oxygen even when being exposed to a wide range of temperatures. In most fishes, an open-system change in temperature results in a lowering of oxygen affinity during warming and an increase in oxygen affinity during cooling. However, the blood of both tunas and lamnid sharks shows little or no shift in oxygen affinity when subjected to *in vitro* open-system temperature changes (**Figure 6**). These blood-oxygen binding properties are suggestive of the capacity to enable these unique pelagic fishes to be exposed to waters of very different temperatures without the adverse effect of changing the functional oxygen-binding properties of its hemoglobin.

The presence of regional endothermy in the aerobic myotomal muscles of tunas results in reduced rates of heat transfer with the ambient water that significantly slows the cooling of this tissue during rapid vertical movements. This elevated aerobic myotomal muscle temperature, which in some tuna can be as much as 20 °C above ambient, subjects the blood to a marked closed-system temperature change (i.e., blood oxygen content remains constant, but the partial pressures of oxygen and carbon dioxide change with temperature). As at the gills, the blood is at ambient temperature but quickly warms as it passes through the vascular countercurrent heat exchangers en route to the aerobic myotomal muscles. It is under these conditions that the blood of bigeye tuna (group 3) differs from that of closely related tunas in groups 1 and 2. *In vitro* studies using whole blood from bigeye tuna subjected to thermal conditions (i.e., warming) similar to that occurring *in vivo* during passage between the gills and aerobic myotomal muscles show that as the blood of the bigeye tuna is warmed, its oxygen affinity decreases to the extent that it closely matches that of other tunas in group 2.

Taken together, for bigeye tuna, the closed-system temperature changes induced a decrease in oxygen affinity, ensuring that oxygen off-loading in the swimming muscles is not compromised while the open-system thermal effects on blood-oxygen binding at the gills (i.e., high oxygen affinity) are maintained. However, this scenario leading to a unique hypoxia tolerance (enhanced oxygen uptake at the gills in hypoxic conditions and ample oxygen delivery to the warm myotomal muscles) requires the maintenance of elevated aerobic myotomal muscle temperatures and may explain bigeye tuna's regular excursions between the warm surface layers (where warmer ambient ocean temperatures will aid in whole-body warming) and cold, deep layers of the ocean (**Figure 7**).

Glossary

Aerobic scope The capacity of an animal to increase its level of aerobic metabolism beyond that which is required for maintenance alone and thereby support activities such as muscular exercise, growth or reproduction; sets the capacity for oxygen-consuming physiological processes that an animal may perform at a given time. Aerobic scope is the difference between minimal and maximal oxygen consumption rate.

Anaerobic Processes occurring without the need for oxygen.

Arterial Adjective pertaining to blood that has been oxygenated.

ATPase A protein whose activity is fueled by the hydrolysis of ATP. Key ATPases involved in excitation–contraction coupling are Ca^{2+} pumps and myosin ATPases.

Atrium A thin-walled chamber of the heart that is primarily comprised of cardiac muscle tissue.

Bohr effect Modification of the hemoglobin-oxygen affinity by the proton concentration (pH).

Buoyancy, positive and negative A positively buoyant organism is less dense than the surrounding fluid, so tends to rise to the surface. A negatively buoyant one is denser than the fluid and tends to sink.

Cardiac output The volume of blood pumped by the heart per unit time; it is the product of heart rate and stroke volume.

Cardiomyocyte Fundamental contractile cell of the working fish myocardium.

Clade A group consisting of a single common ancestor and all its descendants.

Citrate synthase Mitochondrial enzyme that catalyzes the first reaction of the citric acid cycle; citrate synthase activity correlates with mitochondrial density and is used as an index of a tissue's aerobic metabolic capacity.

Endotherm An animal that uses metabolic heat to achieve a body temperature greater than that of the surrounding environment.

Fast-glycolytic muscle fiber Muscle fiber type with fast isoforms of myosin, large diameter, high anaerobic capacity, and low mitochondrial density; it powers short-duration, high-power movements such as rapid acceleration.

Fork length Distance from the tip of the snout to the fork in the tail or caudal fin.

Gastric evacuation rate The rate at which the stomach is emptied postfeeding.

Hemoglobin An iron-containing oxygen-transport protein in the red blood cells of vertebrates and the tissues of some invertebrates.

Mitochondrion A cellular organelle that acts as the 'powerhouse', of the cell and produces the chemical energy source adenosine triphosphate, using oxygen as the final electron acceptor.

Muscle contraction When a muscle cell shortens and generates force.

Myocardium A general term for the cardiac muscle of the heart, which comprises several subtypes, including the compact myocardium and the spongy myocardium of fishes.

Myocyte An individual cardiac muscle cell.

Myoglobin An oxygen-binding protein in muscle that resembles hemoglobin in function, and enhances the rate of oxygen diffusion.

Net cost of transport The amount of energy above SMR required to move a given mass a given distance: [(swimming $\dot{M}_{O_2}$ – SMR)/(swimming speed × fish mass)].

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

Ram ventilation Ventilation of the gills by swimming forward with the mouth open while suspending activity in the respiratory muscles.

Rete mirabile (pl. retia mirabilia) A countercurrent system in which each arterial blood vessel is surrounded by several venous vessels and vice versa.

Ryanodine receptor Mediates the release of Ca^{2+} from the sarcoplasmic reticulum.

Sarcomeres The functional elements of a muscle cell responsible for shortening during a contraction.

Sarcoplasmic reticulum A specialized form of endoplasmic reticulum that acts as a storage site for Ca^{2+}.

Sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA) An energy-consuming Ca^{2+} pump located on the sarcoplasmic reticulum membrane that concentrates Ca^{2+} inside the sarcoplasmic reticulum.

Slow-oxidative muscle fiber Muscle fiber type with slow isoforms of myosin, high aerobic capacity, and high mitochondrial density; it powers repeated, slow movements such as sustained swimming.

Specific dynamic action (SDA) The additional amount of oxygen or energy consumed above SMR as a result of feeding, measured during the period after feeding until metabolic rate returns to SMR; SDA represents the energetic cost of digestion, assimilation, and protein turnover.

Standard metabolic rate Oxygen consumption rate or aerobic metabolic rate measured in resting, fasting individuals; it represents maintenance costs.

Stroke volume The volume of blood ejected into the aorta by a single contraction of the ventricle(s).

Teleosts A major group of ray-finned bony fish, including most common fish.

Ventricle A thick-walled chamber of the heart that is primarily comprised of cardiac muscle tissue.

Introduction

Tunas have been termed energy speculators because they require a high rate of energy input to support their high routine metabolic costs while gaining high energetic returns to allocate to activity, growth, and reproduction. There are five genera and 15 described species of tunas, which, according to morphological and some molecular data sets, comprise a monophyletic group within the family Scombridae (**Figure 1**). Tunas are active, pelagic predators and are important members of oceanic communities worldwide. They are specialized for high performance, with high aerobic and anaerobic metabolic capacities, high respiration rates, large branchial surface areas (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics) and large, muscular hearts (**see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes). In this respect, tunas are analogous to race cars; their high-performance level depends upon large quantities of high-octane fuel. Tunas are also among the very few fish species that can conserve metabolic heat using heat-exchanging retia mirabilia (**see also Design and Physiology of Arteries and Veins**: The Retia) to elevate the temperature of certain tissues above water temperature (i.e., regional endothermy; **see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks). This article summarizes key aspects of tuna physiology related to a high turnover rate of energy and the physiological consequences of both regional endothermy and diving behavior. It also emphasizes the key role that comparative studies of tunas and non-tuna scombrids – mackerels, Spanish mackerels, and bonitos (**Figure 1**) – have in identifying the unique physiological features of tunas.

Continuous Swimming

The life of a tuna centers on continuous swimming. Their ram-ventilation respiratory mode requires tunas to swim to force water over the gills. Furthermore, because tunas are negatively buoyant, swimming is needed to generate lift for hydrostatic equilibrium. Feeding also depends upon swimming because food resources are patchily distributed in both space and time in the open ocean where they live. Tunas necessarily swim long distances, including repeated dives in search of prey with some species making extensive migrations (**see also Fish Migrations**: Tracking Oceanic Fish). Once located, prey are consumed using a ram-feeding mode of capture (**see also Buoyancy, Locomotion, and Movement in Fishes**: Feeding Mechanics), coupled with bursts of high speed, powered by aerobic and anaerobic metabolism, respectively. Swimming is also a feature of tuna schooling, migratory, and spawning behaviors.

Continuous swimming is reflected in many morphological features of tunas that contribute to swimming efficiency, including a streamlined body shape, slots, or grooves into which fins can be retracted to produce a smooth body contour and reduce drag, a rigid, high-aspect-ratio caudal fin propeller, bony caudal keels that reduce resistance as the tail moves laterally, and a well-developed tendon system linking the locomotor muscle to the skeleton (**Figure 2**). Tunas swim using the unique Thunniform mode in which lateral undulation of the body is reduced and the caudal fin, moving at high frequencies, produces most of the thrust. Cruising at speeds with low transport costs or using kick-and-glide swimming behavior can also reduce energetic expenditures.

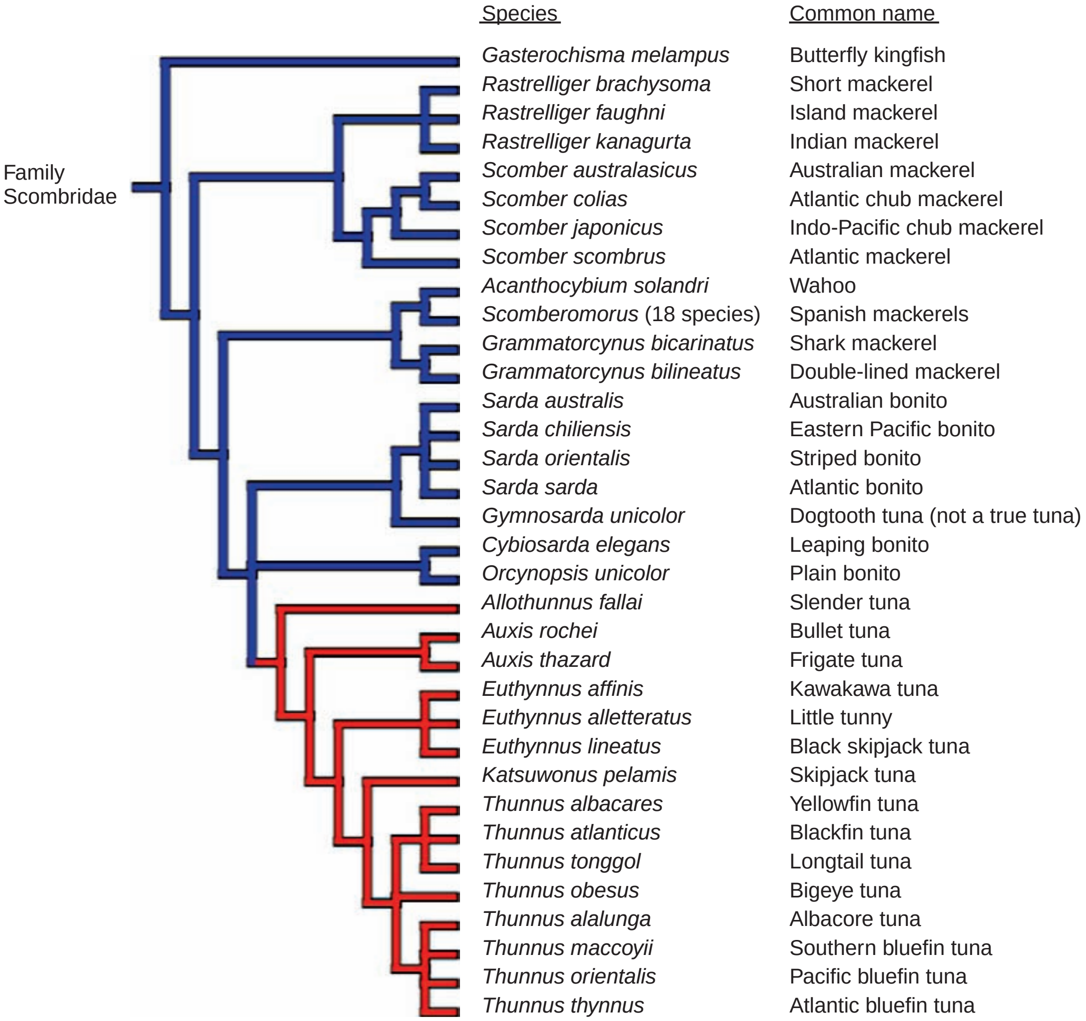

Figure 1 Cladogram showing hypothesized relationships among the 51 species in the family Scombridae, based primarily on *Fish Physiology*. All species except the 18 species of the genus *Scomberomorus* are listed, and common names are from *FAO Species Catalog*. In the text, species are referred to by scientific name. Red represents the clade of 15 tuna species and blue signifies non-tuna scombrids. Unresolved nodes of the cladogram are presented, with species listed alphabetically, if there is no published evidence to resolve relationships at the species level or if morphological and molecular data give conflicting or inconsistent results. Data from Colette BB, Reeb C, and Block BA (2001) Systematics of the mackerels and tunas (Scombridae). In: Block BA and Stevens ED (eds.) *Fish Physiology,* vol. 19, pp. 1–33. San Diego, CA: Academic Press and Collette BB and Nauen CL (1983) *FAO Species Catalog, Volume 2: Scombrids of the World. An Annotated and Illustrated Catalogue of Tunas, Mackerels, Bonitos, and Related Species Known to Date*. Rome: Food and Agriculture Organization of the United Nations.

High Metabolic Rates and Aerobic Scopes

In fish that never stop swimming, standard metabolic rates (SMRs), which represent maintenance costs, are determined by measuring oxygen consumption rate ($\dot{M}_{O_2}$) in immobilized individuals or by extrapolating $\dot{M}_{O_2}$ versus swimming speed relationships to zero velocity. SMRs measured in tunas using both methods are greater than in non-tuna scombrids when compared at similar sizes and temperatures (**Figure 3**). Tunas also have high routine and maximal oxygen consumption rates, and their capacity for exceptional performance is reflected in high aerobic scopes (the difference between maximum $\dot{M}_{O_2}$ and SMR), which allow several aerobic processes to occur simultaneously. How the maximal recorded $\dot{M}_{O_2}$ in tunas (2500–2700 $mgO_2\,kg^{-1}\,h^{-1}$ at 25 °C) can be allocated among several different activities is illustrated in **Figure 4**.

Cost of Continuous Swimming

The net cost of continuous swimming, powered by the contraction of the slow-twitch oxidative muscle, ranges from approximately 0.5 to 3.5 times SMR in tunas, depending on swimming speed and fish size. The net cost of transport is similar in tunas and in comparably sized

Ventricle

Figure 2 Photograph of a *K. pelamis* approximately 80 cm in length showing morphological features that affect swimming performance and aerobic capacity, including a streamlined body shape, fins that can be retracted into slots or adducted into grooves to produce a smooth body surface, high-aspect-ratio caudal fin, and well-developed caudal keel. Also shown are the heart removed from *Thunnus alalunga* magnified 3× relative to the fish, and a dorsal view of the horizontal septum of a *E. affinis* showing the tendons that transfer contractile force from the locomotor muscle to the vertebrae and caudal fin to power swimming.

Sarda chiliensis and *Scomber japonicus* at the same speeds and water temperatures (**Figure 5**). Even at maximal continuous swimming speeds, $\dot{M}_{O_2}$ in tunas is less than the total aerobic scope, allowing other aerobic activities to occur while swimming maximally (**Figure 4**), something that even salmonids are apparently unable to do.

Cost of Burst Swimming

Bursts of high speed used in prey capture, courtship, and reproduction require high rates of adenosine triphosphate (ATP) production via anaerobic metabolic pathways within the fast-glycolytic locomotor muscle (**see also Hypoxia**: Anaerobic Metabolism In Fish). Compared with that of non-tuna scombrids, the fast-glycolytic muscle of tunas has higher activities of the enzymes creatine phosphokinase and lactate dehydrogenase, which are required for anaerobic ATP production. This muscle comprises 46–55% of body mass in tunas and, during bursts, can accumulate and buffer large quantities of lactate (up to 100 μmol g^{-1} in *Katsuwonus pelamis*).

The aerobic cost of burst swimming occurs during the postburst recovery period when resynthesis of creatine phosphate from creatine and of glycogen from lactate occur within the fast-glycolytic muscle. Both processes require aerobic metabolism, elevating $\dot{M}_{O_2}$ by up to 840 mgO$_2$ kg^{-1} h^{-1} during the recovery period. Recovery from maximal burst activity takes less time in tunas than in other fishes (<2 h vs. 4–24 h), but nothing is known about recovery rates in non-tuna scombrids. Although the fast-glycolytic muscle of tunas has very low or no measurable activity of key enzymes required to convert lactate to glycogen, it does have a high aerobic capacity, which may contribute to rapid recovery.

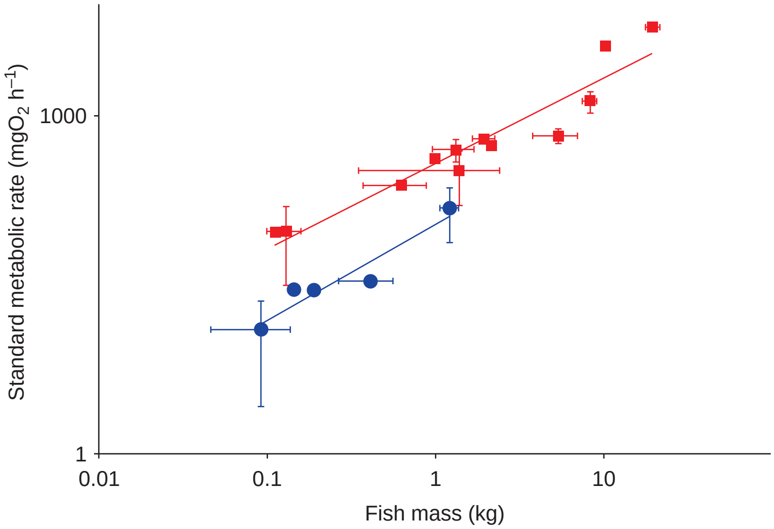

Figure 3 SMR (mgO$_2$ h^{-1}) at 25 °C as a function of fish mass (kg) in tunas (red) and non-tuna scombrids (blue), showing that SMR is greater in the tunas. If SMR was not measured at 25 °C, the reported value was adjusted to 25 °C using a Q_{10} of 1.8. Error bars represent ±1 standard deviation. Data are from six tuna species (*E. affinis*, *K. pelamis, T. albacares, T. alalunga, T. maccoyii,* and *T. orientalis*) and three non-tuna scombrids *(S. chiliensis, S. japonicus,* and *S. scombrus*). The best-fit power curves are: SMR = $372M^{0.76}$ for the tunas ($R^2 = 0.91$) and SMR = $108M^{0.85}$ for the non-tuna scombrids ($R^2 = 0.90$).

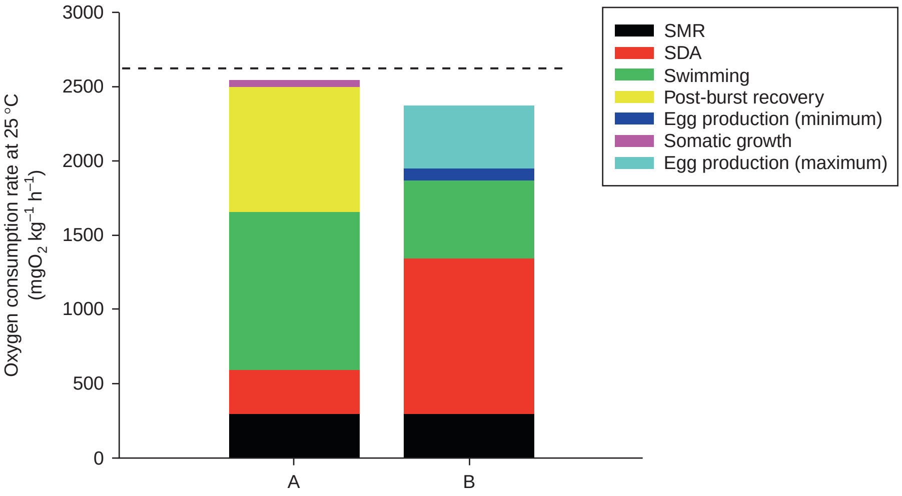

Figure 4 Two possible ways that tunas can partition aerobic scope to accomplish several different aerobic activities simultaneously. The maximal recorded $\dot{M}_{O_2}$ in tunas (2500–2700 mgO$_2$ kg^{-1} h^{-1} at 25 °C) is indicated by the dashed line, and other costs (see section High Metabolic Rates and Aerobic Scopes) were adjusted to 25 °C using a Q_{10} of 1.8, if necessary. A. Conditions within 1–2 h of feeding, with aerobic capacity supporting maximal postburst recovery costs, swimming at maximal sustainable speed, and the initial portion of SDA. B. SDA is the maximum value recorded in *T. maccoyii* at 3–7 h after consuming a large meal of sardines equivalent to 6–8.5% of body mass, postburst recovery is completed, and the costs of swimming at a speed of 1 length s^{-1} and of gamete production can be accommodated. Note that all activities cannot be conducted simultaneously at their maximal rate.

Cost of Feeding

Metabolic rate increases postfeeding due to recovery from any burst activity and as a result of specific dynamic action (SDA), the energetic cost of digestion, assimilation, and protein turnover (**see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation). Tunas consume large quantities of fishes, crustaceans, and cephalopods and have high rates of gastric evacuation and digestion and a high SDA. Gastric evacuation rates have been measured in three tuna and one mackerel species, and are greater in the tunas. The stomach was emptied within 12.0 and 10.4 h postfeeding at ~24 °C in *K. pelamis* and *Thunnus albacares*, respectively, compared with 30 h at 19 °C in *S. scombrus*; stomach contents were 90% evacuated at 4.5–6.5 h at 25 °C in *Euthynnus lineatus* versus 22 h at 19 °C in *S. scombrus*. In *T. maccoyii,* peak postfeeding metabolic rate was as high as 1290 mgO$_2$ kg^{-1} h^{-1} at 20 °C and

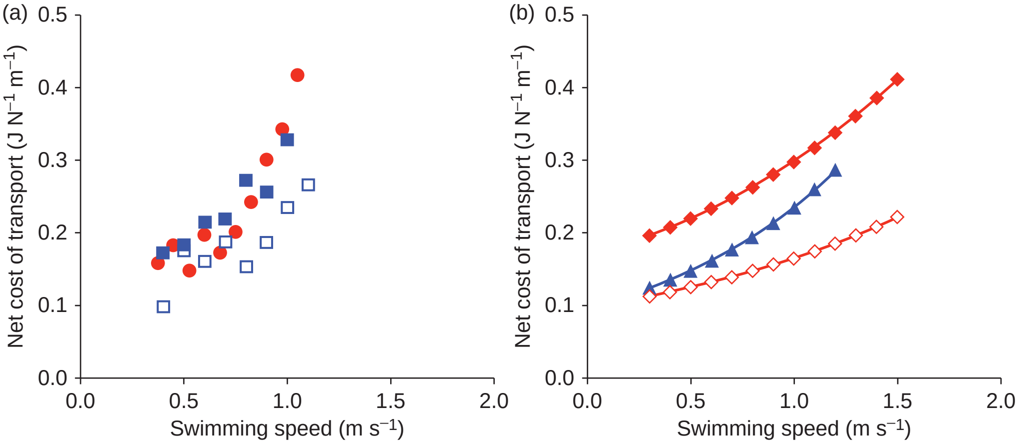

Figure 5 The net cost of transport at 24 °C (J N^{-1} m^{-1}) as a function of swimming speed (m s^{-1}), in (a) *E. affinis* and *S. japonicus* and (b) *T. albacares* and *S. chiliensis*, of approximately the same size. Data in (a) are derived from Sepulveda and Dickson for a 145 g, 22.0 cm FL *E. affinis* (solid red circles) and two *S. japonicus* 147 g, 23.4 cm FL (solid blue squares) and 156 g, 24.0 cm FL (open blue squares). Data in (b) are from Dewar and Graham for 51.3 ± 3.0 cm FL, 2.17 ± 0.5 kg *T. albacares* (open red diamonds) and 41.6 ± 2.7 cm, 1.1 ± 0.2 kg *T. albacares* (solid red diamonds), measured at 24 °C, and from Sepulveda *et al.* for 47.3 ± 1.8·cm, 1.24 ± 0.14·kg *S. chiliensis* (solid blue triangles); the bonito data were recorded at 18 °C and adjusted to 24 °C using a Q_{10} of 2.0. Data from (a) Sepulveda C and Dickson KA (2000) Maximum sustainable speeds and cost of swimming in juvenile kawakawa tuna (*E. affinis*) and chub mackerel (*S. japonicus*). *Journal of Experimental Biology* 203: 3089–3101; and (b) Dewar H and Graham JB (1994) Studies of tropical tuna swimming performance in a large water tunnel. I. Energetics. *Journal of Experimental Biology* 192: 13–31 and Sepulveda C, Dickson KA, and Graham JB (2003) Swimming performance studies on the eastern Pacific bonito *S. chiliensis*, a close relative of the tunas (family Scombridae). *Journal of Experimental Biology* 206: 2739–2748.

total SDA was 35% of the energy ingested, higher than the 5–20% reported for other teleost fishes.

A daily food consumption of 3.5% of body mass would be required to meet the energetic demands associated with maintenance metabolism plus the maximum SDA measured in *T. maccoyii*. Net energy gain requires a greater food intake, which is possible if a tuna fills its stomach once a day, given the stomach capacity of 7% of body mass (in *K. pelamis*) and maximum intakes of 8.5–8.6% of body mass per feeding measured in captive tunas. However, feeding rate also depends upon food availability. Feeding frequencies in tunas, estimated from visceral temperature changes recorded by data-logging tags, ranged from 0 to 10 meals per day in *T. orientalis* (mean + SD of 1.8 + 1.4 d^{-1}) and averaged 0.89 + 0.08 d^{-1} in *T. maccoyii*. It may be necessary for tunas to feed more frequently when food is plentiful and store the excess energy to mobilize during periods of low food availability. Tunas can store large quantities of lipid and glycogen, but how energy storage and mobilization are regulated is unknown for any scombrid fish.

Costs of Growth and Reproduction

Tunas have high rates of growth and reproduction, which can occur only if energy intake exceeds the energetic requirements of maintenance, continuous swimming, and feeding. Juvenile tunas grow rapidly, at rates similar to those of non-tuna scombrids. Early juvenile growth rates are up to 7.9 mm d^{-1} in laboratory-raised *E. lineatus* and 4.3 mm d^{-1} in field-caught *K. pelamis*, compared with 6.2 mm d^{-1} in *S. orientalis* and 3.7 mm d^{-1} in sierra Spanish mackerel, *Scomberomorus sierra*. Rapid juvenile growth rates require high feeding and food-processing rates. While high rates of feeding may increase predation risk, the resultant increase in growth rate reduces the time that juvenile fish are vulnerable to many predators as well as the time it takes to reach a size at which tissue temperatures can be elevated. Tunas can grow to very large sizes, although the maximum size of several tuna species is less than that of several non-tuna scombrids. The tuna that attains the largest maximum size (at least 315 cm and 685 kg), the *T. thynnus*, reaches a size of approximately 60 cm and 4 kg within the first year. The minimum energetic cost of this first-year growth, estimated from tuna caloric density, is ~50 mgO_2 kg^{-1} h^{-1}. As sexual maturity is reached, tunas allocate less energy to somatic growth and more to reproduction. Most tuna species have very high female batch fecundities, producing millions of eggs in a single spawning event, and spawning frequency ranges from daily to every 6 days. The cost of gamete production in tunas has been estimated to be 0.31–1.7% of body mass per day for females and 0.33% of body mass per day for males. Other reproductive costs, including those associated with migration and courtship, have not been quantified in any tuna.

Specializations Associated with High Aerobic Capacity

The large aerobic scope of tunas allows many, but not all, of the above aerobic activities to be conducted simultaneously (**Figure 4**) and depends on numerous physiological specializations for rapid rates of oxygen uptake and delivery to active tissues. Enhancing oxygen uptake at the gills, tunas have the highest gill surface areas, resulting from large numbers of gill filaments and lamellae, and the shortest diffusion distances reported for any fish group (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics). Tuna gills are structurally reinforced to withstand high-velocity ram ventilation, and the pathway for blood flow through the gill lamellae reduces vascular resistance and should enhance gas exchange (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy). Although resulting in high osmoregulatory costs (**see also Role of the Gills**: The Osmorespiratory Compromise), these adaptations allow tunas to process large ventilatory volumes while maintaining relatively high oxygen utilization rates (∼50%).

Tunas have thick-walled, pyramidal hearts (**Figure 2**) with a high percentage of compact myocardium and a well-developed coronary circulation (**see also Design and Physiology of the Heart**: The Coronary Circulation and Cardiac Anatomy in Fishes), as do other scombrid species. Heart mass as a percentage of body mass is high in tunas (0.28–0.81%), but values overlap with those of other scombrids (0.12–0.40%), and among scombrid species correlates with the percentage of body mass composed of slow-oxidative locomotor muscle (**Figure 6**). Tunas' muscular hearts produce high cardiac outputs (heart rate × stroke volume) and high blood pressures to propel blood through the gill and systemic circulations. In tunas, modulation of cardiac output while swimming and when exposed to hypoxia occurs primarily by altering heart rate (i.e., tuna hearts are frequency modulated), rather than stroke volume, because stroke volume is typically near maximal. At routine swimming speeds of 1–2 body lengths s^{-1}, heart rates in tunas were 62–97 beats min^{-1} at 25 °C in 1–2 kg *K. pelamis* and *T. albacares* and 20–50 beats min^{-1} at 18–19 °C in free-swimming, 10–21 kg *T. maccoyii*, compared with 80–140 beats min^{-1} in 0.4–0.6 kg *S. japonicus* at 16.1–21.8 °C. The highest reported heart rates for scombrids are >250 beats min^{-1} in *K. pelamis* and *E. affinis*, and 150 beats min^{-1} in *S. japonicus*.

A rapid heart rate requires rapid calcium cycling and ATP turnover (**see also Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux and Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element), and several characteristics related to these processes differ between tunas and other scombrids, reflecting the exceptional cardiac performance of tunas. In scombrids, the increase in intracellular [Ca^{2+}] required for cardiac muscle contraction results from Ca^{2+} release from the sarcoplasmic reticulum through ryanodine receptors, in addition to extracellular Ca^{2+} influx via L-type voltage-gated Ca^{2+} channels. For relaxation

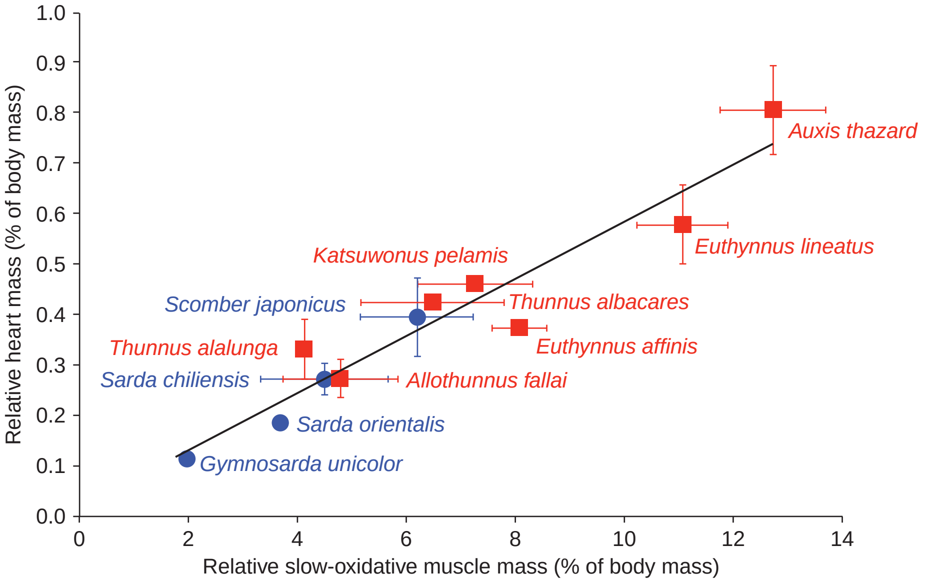

Figure 6 Relative heart mass (heart mass as a percentage of total body mass) correlates with relative mass of slow-oxidative locomotor muscle (muscle mass as a percentage of total body mass) in tunas (red) and non-tuna scombrids (blue). Error bars represent ±1 standard deviation. Black line is the best-fit linear regression ($y = 0.0567x + 0.0188$; $R^2 = 0.91$).

prior to the next heart beat, Ca^{2+} is rapidly removed by the sarcoplasmic–endoplasmic Ca^{2+}ATPase, SERCA2. Recent studies have compared these characteristics in the tunas *T. albacares*, *T. alalunga*, *T. obesus*, and *T. orientalis* and in the mackerel *S. japonicus*. Ca^{2+} influx via the L-type channel in myocytes isolated from the atria, but not ventricles, was greater in *T. orientalis* than in *S. japonicus*. Expression of both ryanodine receptor and SERCA2 proteins, and SERCA2 Ca^{2+} uptake rates and ATPase activity in microsomes prepared from both atria and ventricles, were greater in tunas compared with the mackerel. Cardiomyocyte mitochondrial densities are high in tunas (**see also Design and Physiology of the Heart**: Cellular Ultrastructure of Cardiac Cells in Fishes) and, although the activity of the mitochondrial citric-acid cycle enzyme citrate synthase is similar, activities of two key lipid oxidation enzymes are greater in tuna ventricles than in those of non-tuna scombrids.

Several features ensure that oxygen and fuels are supplied to all tissues at high-enough rates to meet their metabolic demands. Blood volume is not exceptional in tunas, but hemoglobin concentrations are higher in tunas than in non-tuna scombrids, meaning that more oxygen can be bound at the gills and transported to active tissues. Off-loading of oxygen from hemoglobin at active tissues is facilitated by a larger Bohr effect in tunas than in other active fishes (**see also Transport and Exchange of Respiratory Gases in the Blood**: Evolution of the Bohr Effect). In the slow-oxidative muscle that powers continuous swimming, capillary density is higher in tunas than in non-tuna scombrids and, in tunas, capillary tortuosity increases the surface area of contact between capillaries and muscle fibers (**see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis). The concentration of myoglobin, which facilitates the diffusion of oxygen from capillary blood to muscle mitochondria, is greater in tunas than in *S. chiliensis* and *S. japonicus*. However, slow-oxidative muscle mitochondrial densities, and citrate synthase activity measured at a common temperature, overlap in tunas and non-tuna scombrids. A key difference in tunas is that the slow-oxidative locomotor muscle is in a more anterior-medial position than in other fishes, and it is maintained at an elevated temperature (**Figure 7**), which results in higher *in vivo* enzyme activities. The diameter of slow-oxidative muscle fibers is restricted because these cells depend upon oxygen diffusing from capillary blood, and it may not be possible to increase the volume occupied by mitochondria without compromising contractile function. Maintaining this tissue at an elevated temperature will increase muscle contraction rate in tunas, and the higher myoglobin content would facilitate the resulting greater oxygen flux.

Physiological Consequences of Regional Endothermy

As regional endotherms, tunas maintain the temperature of the locomotor muscle and cranial region above ambient water temperature. Stomach, intestine, and cecal mass temperatures are also elevated in five species (*T. obesus*, *T. alalunga*, *T. maccoyii*, *T. orientalis*, and *T. thynnus*). Regional endothermy contributes directly to the high metabolic rates of tunas, but only by the amount associated with increased cellular metabolism due to warming of the specific tissues. Additional heat generation is not required for endothermy in tunas because the heat-exchanging retia retain heat that is produced by normal metabolic activity of the tissues and would otherwise be lost to the environment via conduction and convection (**see also Design and Physiology of Arteries and Veins**: The Retia). The only exception would be cranial endothermy in *Allothunnus fallai*, in which there is evidence that the four pairs of extraocular rectus muscles are modified to form a heater tissue that specifically generates heat.

Elevation of tissue temperatures increases rates of biochemical and physiological processes within those tissues (**see also Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks), but these rates do not always exceed those of non-tuna scombrids at *in vivo* temperatures. For example, contraction rate and power output of slow-oxidative muscle isolated from *T. albacares* increase with increasing temperature, but power is not higher in *T. albacares* than in *S. chiliensis* under *in vivo* conditions. Similarly, although digestive enzyme activities increase with temperature in tunas, they are no greater in *T. alalunga* or *T. albacares* than in *S. chiliensis* or *S. japonicus* at *in vivo* temperatures. Regional endothermy does stabilize tissue temperatures and physiological functions as environmental temperature changes rapidly during dives, and may have allowed some tunas to expand their thermal niche into cool waters at high latitudes and below the thermocline.

Tunas have some capacity to thermoregulate physiologically by reducing the rate of heat exchange with the environment in cool waters and increasing it when activity increases, especially in warm waters, as documented during repeated dives in *T. obesus* (**Figure 8**). The thermal coefficient in *T. obesus* was reduced during dives into cool water below the thermocline, thereby increasing heat conservation. In warm surface water, by contrast, the thermal coefficient was increased. In combination with vertical movements (behavioral thermoregulation) and thermal inertia, this physiological control of thermal conductance allows *T. obesus* to maintain internal temperatures above ~17–18 °C even though most of the day is spent in much cooler water (**Figure 8**). Thermal

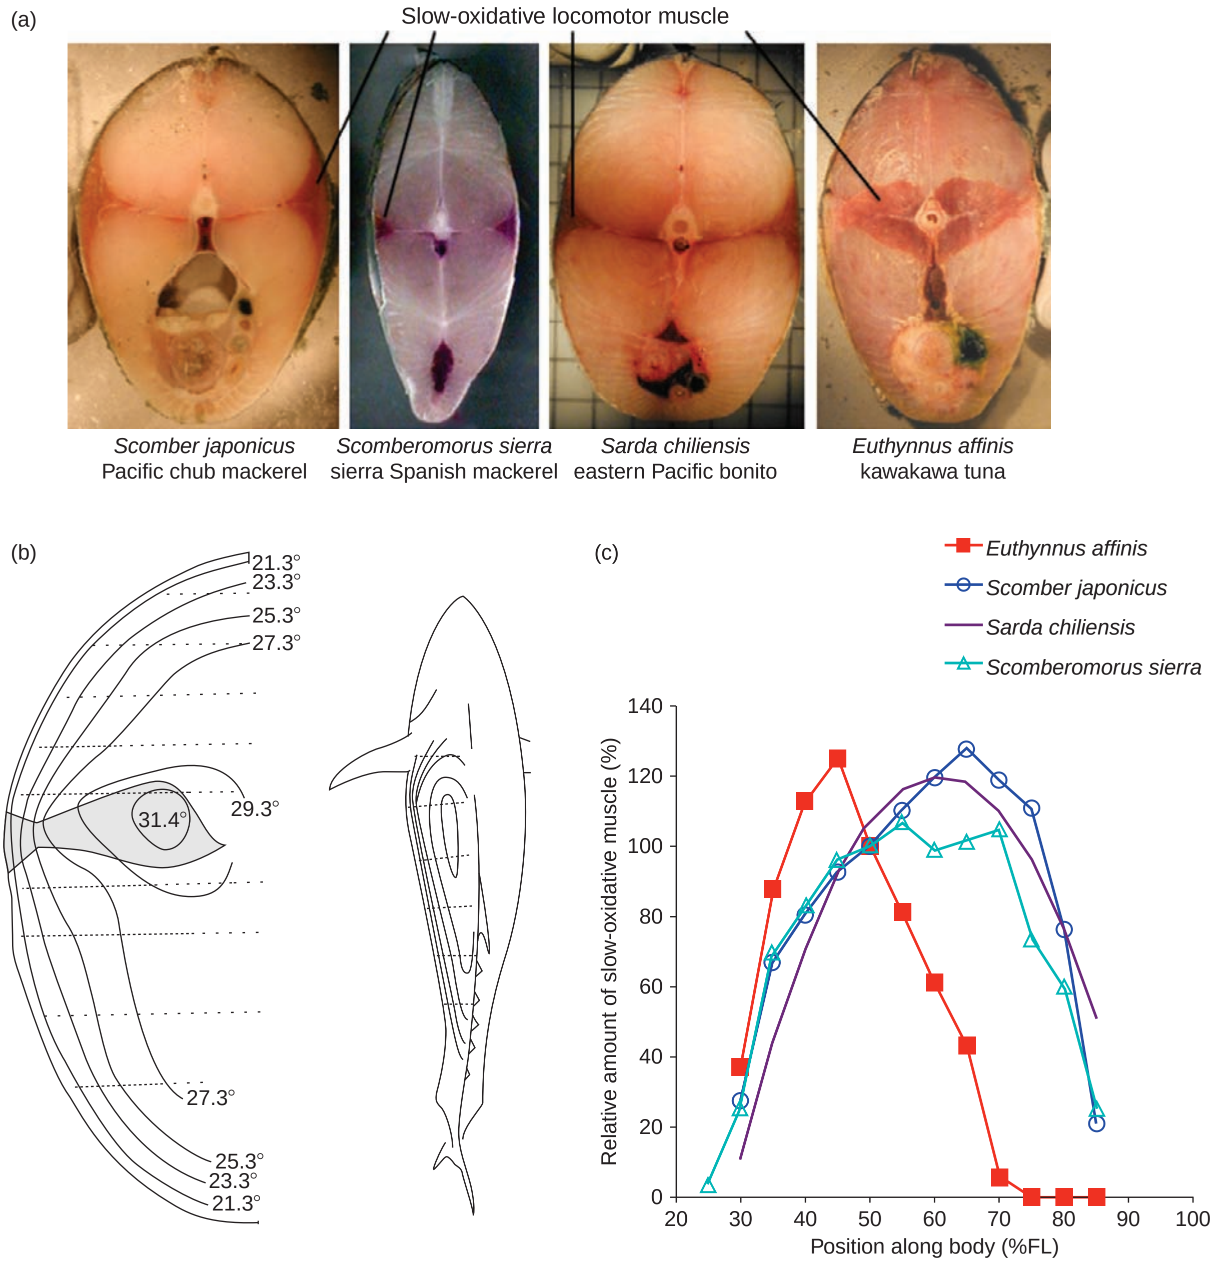

Figure 7 (a) Transverse sections, taken at a position along the body corresponding to 45% of fork length (FL), in representatives of four major scombrid groups (mackerels (*S. japonicus*), Spanish mackerels (*S. sierra*), bonitos (*S. chiliensis*), and tunas (*E. affinis*)). The unusual axial position of the slow-oxidative locomotor muscle (red tissue) in the tuna contrasts with the typical teleost distribution as a lateral wedge just beneath the skin in the non-tuna scombrids. (b) Thermal profiles of the locomotor muscle in a *T. thynnus* in cross section and frontal section from Carey and Teal. Temperature is highest (31.4 °C) in the core of the slow-oxidative locomotor muscle (stippled) and is up to 12.1 °C warmer than the ambient seawater (19.3 °C). (c) The relative amount of slow-oxidative muscle (as a percentage of the amount at 50% of FL) as a function of position along the body (% of FL) for the four scombrid species in (a). Because muscle amounts were not measured at exactly 50%FL in *S. chiliensis*, the position closest to 50%FL (50.3–52.6%FL) was assigned a relative slow-oxidative muscle value of 100%, and the curve represents the best-fit second-order polynomial for data from four individuals. The position of the slow-oxidative locomotor muscle is more anterior in the tuna than in the three non-tuna scombrids. (b) From Carey FG and Teal JM (1969) Regulation of body temperature by the bluefin tuna. *Comparative Biochemistry and Physiology* 28: 205–213.

conductance is most likely modulated in tunas by altering blood flow using vasoactive control mechanisms that involve sympathetic and endothelial-derived chemical messengers, as in other teleosts (**see also Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System), but this aspect of thermal physiology has not been investigated in tunas.

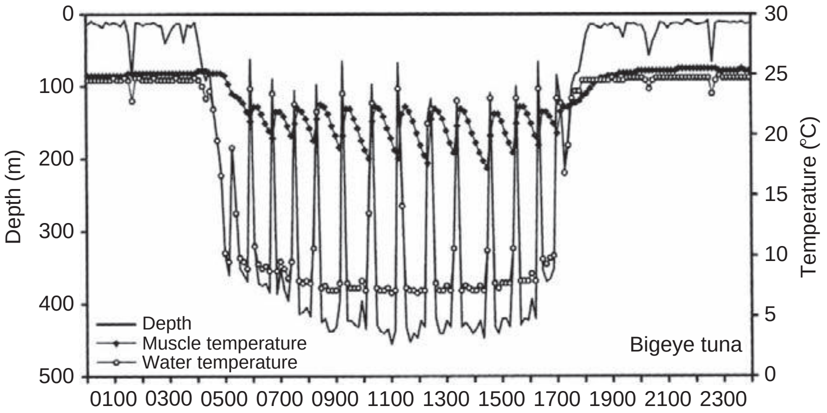

Figure 8 Repeated diving behavior in *T. obesus* documented in an archival tag record of depth, muscle temperature, and water temperature measured simultaneously over a 24-h period. Muscle temperature varies much less than does water temperature and is maintained above 17–18 °C by a combination of physiological and behavioral thermoregulation. The slope of the muscle temperature vs. time tracing is proportional to the thermal coefficient (*k*), which represents the rate of heat exchange with the environment. As the fish dives into cool water, *k* decreases, allowing heat retention, whereas *k* increases as the fish ascends into warm surface water. From Brill RW and Bushnell PG (2001) The cardiovascular system of tunas. In: Block BA and Stevens ED (eds.) *Fish Physiology,* vol. 19, pp. 79–120. San Diego, CA: Academic Press.

As a consequence of regional endothermy, blood in a heat-exchanging rete rapidly warms within the rete arterioles as it flows toward the warmed tissue and rapidly cools as it leaves the tissue within rete venules. Normally, increasing temperature decreases the binding affinity of hemoglobin for oxygen (increases the P_{50} value, the partial pressure of oxygen (P_{O_2}) at which the hemoglobin is 50% saturated with O_2), which facilitates delivery of oxygen to active tissues (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function and Hemoglobin). If this happened during the closed-system temperature changes within the rete arterioles, oxygen would be released from hemoglobin before it reached the tissue. The effects of closed-system changes in temperature on hemoglobin-oxygen binding affinity in whole blood differ interspecifically among tunas. Such changes have no effect on hemoglobin-oxygen binding affinity in *K. pelamis*, *T. thynnus* at $P_{O_2} < P_{50}$, and *T. maccoyii* at 23–36 °C, thus preventing premature off-loading of oxygen within the rete arterioles. The blood of *T. alalunga, T. thynnus* at $P_{O_2} > P_{50}$, and *T. maccoyii* at 10–23 °C shows a reversed temperature effect, in which increasing temperature increases binding affinity. That response would ensure that oxygen is tightly bound to hemoglobin at the gills in warm waters and remains bound as blood traverses the rete arterioles and reaches tissue capillaries, making it necessary for other mechanisms, such as a large Bohr effect, to release sufficient oxygen at warm, active tissues. However, the typical response to temperature occurs in *E. affinis*, *T. albacares*, and *T. obesus*, and these species must possess other mechanisms to ensure adequate oxygen delivery to the tissues that are perfused by heat-exchanging retia (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange).

Regional endothermy also results in thermal gradients within tissues (e.g., in locomotor muscle; **Figure 7**) and different tissues within the body experiencing different rates of temperature change and operating at different temperatures. For example, heart temperature rapidly equilibrates with water temperature, while temperatures of the warmed tissues can be as much as 20 °C greater and change much more slowly. Heart rate decreases with temperature (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature), but the heart must pump sufficient blood to support high rates of aerobic metabolism in the warmed tissues even in cold waters. Heart function may, therefore, limit performance of other aerobic tissues during dives, may limit the time a tuna can remain in cool water, and may explain interspecific differences in thermal ranges and diving behavior among tunas.

Physiological Consequences of Diving in Tunas

Tagging studies have documented long-distance migrations and repeated diving in tunas (**Figure 8**; **see also Fish Migrations**: Tracking Oceanic Fish), with dives to depths exceeding 1000 m recorded in several species. During migrations, there is time for acclimatization to environmental conditions, but during dives tunas must tolerate rapid fluctuations in water temperature, oxygen content, hydrostatic pressure, and light levels. Foraging in deep waters or diving repeatedly requires a number of physiological specializations, including sensory mechanisms to locate and capture prey, tolerance of low temperature and rapid temperature change in tissues such as the heart and gills that are not served by heat-exchanging retia, and coordinating the function of tissues operating at different temperatures. As blood flows through the gills, open-system temperature changes, in which O_2 and CO_2 can exchange with seawater, may occur, but this type of temperature change results in little to no effect on hemoglobin-oxygen binding in all tunas that have been studied. This response allows sufficient uptake of O_2 at the gills despite the rapid temperature changes that tunas experience during dives (**Figure 8**).

Heart function and molecular determinants of cardiac muscle Ca^{2+} cycling differ among tunas, reflecting interspecific differences in thermal ranges (**see also Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux and Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element). The heart of *T. orientalis* continues to beat and pump blood, albeit at a reduced rate, at temperatures as low as 2 °C. Cardiac muscle in *T. orientalis* has the highest levels of SERCA2, and greater rates of SERCA2 Ca^{2+} uptake than in *T. alalunga*, which are greater than in *T. albacares* and *T. obesus*. The Q_{10} for heart rate is lower in *T. orientalis* than in *T. albacares*, reflecting the greater thermal range of *T. orientalis*, but the temperature sensitivities of Ca^{2+} uptake and ATP hydrolysis by SERCA2 did not differ significantly among the tuna species studied. Some tunas, most notably *T. obesus*, dive into and spend significant amounts of time in waters of low oxygen, and thus must also tolerate hypoxia. The very high hemoglobin-oxygen binding affinity of *T. obesus* allows sufficient oxygen binding at the gills in hypoxic water. The ventricle of *T. obesus* has the highest proportion of compact myocardium (73.6%) measured in any fish, and thus can produce high contractile force. However, heart metabolic enzymes and myofibrillar ATPase in *T. obesus* did not show any apparent adaptations to temperature or hypoxia in comparison to those of *T. albacares* and *K. pelamis*. Interspecific differences in physiological capacities and tolerances are only beginning to be understood, but are thought to be the basis for different vertical mobilities and thermal niches, and for resource partitioning among tuna species inhabiting the same geographic area.

Glossary

Ectotherm (adj. ectothermic) An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Endotherm An animal that uses its own metabolism as the major source of heart to maintain its body temperature greater than that of the surrounding environment.

Rete mirabile (pl. retia mirabilia) A vascular network, usually consisting of a parallel array of both arterial and venous vessels with countercurrent flow. Retia facilitate transfer of heat or oxygen between the arterial and venous vessels. Rete is Latin for net or network, mirabile for ‘wonderful’ or ‘miracle’ (plural, retia mirabilia).

Thermogenic tissue A specialized heat-producing tissue.

Introduction

Powerful ocean predators such as swordfish, marlins, tunas, and some pelagic sharks are unique among fish for their capacity to maintain elevated temperatures of certain tissues even when swimming in cooler waters. Most fish are ectotherms, that is, their entire body temperature is the same temperature as the water in which they swim, primarily because they breathe with a gill. Body heat loss occurs as blood passes through the gills due to their large surface area optimized for gas exchange. Fish are surrounded by cooler ambient water, which has a much higher heat capacity than air. Thus, the core tissue temperatures of ectothermic fish are governed by the surrounding environment, not by metabolically derived heat production. Heat is rapidly and efficiently drawn out of the fish into the surrounding water, the gills acting as a convective cooling system.

Endothermy, the ability to maintain elevated body temperature by metabolic means, has been documented only within about 30 of the over 25 000 species of fishes. These remarkable examples illustrate the challenges of overcoming the physical constraints and are restricted to large, predatory, open ocean fishes – one assemblage among the teleosts the Scombroidei, which includes mackerels, tunas, and billfishes, and the other assemblage among the sharks of the family Lamnidae.

The evolutionary transition from ectothermy to endothermy required both an increase in heat production by elevating metabolic capacity plus the evolution of mechanisms to reduce the rate of heat loss. Among these endothermic fish, two distinct strategies for elevating tissue temperatures have evolved: systemic and cranial endothermy. Examples of systemic endothermy occur in the sharks of the family Lamnidae (white shark, makos, salmon shark, and porbeagle) and tunas (bluefins, albacore, and skipjack). Both groups have species that have expanded their range into northern waters, often swimming in frigid seas but can have regions of their body at temperatures 20 °C or more above ambient water temperature (**Figure 1**). An example of cranial endothermy is the monotypic swordfish (*Xiphias gladius*), where highly specialized extraocular muscles are modified into a thermogenic organ that warms just the brain and eyes up to 15 °C above ambient water temperatures.

Some of the literature refers to these fish as heterotherms rather than endotherms. Their point is that the entire body temperature is not constant (some tissues may be warm while others are cold) or temporally (the stomach may be warm only after a large meal). The use of endothermy herein stresses that the source of the heat is metabolic heat produced by the fish rather than from the environment.

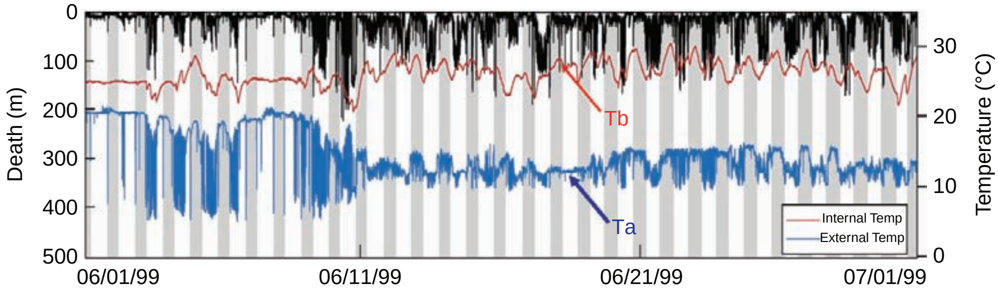

Figure 1 An archival tag record demonstrating endothermy over a 3-week period in an Atlantic bluefin tuna swimming in the North Atlantic. Modified from Walli A, Teo SLH, Boustany A, et al. (2010) Seasonal movements, aggregations and diving behavior of Atlantic bluefin tuna (Thunnus thynnus revealed with archival tags. *Plos ONE* 4(7): e6151 (doi:10.1371/journal.pone.0006151).

Systemic Endothermy

Endothermy in fish evolved in groups that attain large body size. A requirement of endothermy is an internal heat source, which occurs in some species as an increase in metabolic rate, or evolution of high aerobic capacity within a tissue. Countercurrent heat exchangers or retia mirabilia are required to conserve the metabolic heat (**see also Design and Physiology of Arteries and Veins**: The Retia). Tunas (Scombridae, Tribe Thunnini (*Katusuwonus, Euthynnus* and *Auxis*)) and sharks (Lamnidae) are unique among fishes because of their unique ability to maintain elevated tissue temperatures above ambient water temperatures in their locomotory muscle, viscera, brain, and eye muscles. Dr. Frank Carey of Woods Hole Oceanographic Institution was the first scientist to measure tissue temperatures in free-swimming tuna, and subsequently made major contributions to our understanding of endothermy in fishes. Some tuna species, similar to birds and mammals, have an elevated standard metabolic rate and numerous specializations associated with increased oxygen delivery to the tissues. The heat generated by this elevated metabolic rate is retained within these tissues with vascular countercurrent heat exchangers embedded in the systemic circulation.

Cranial endothermy in the tunas and lamnid sharks occurs through a heat exchanger retia located in the circulation to the eyes and brain. To date, there has not been a heater organ-like tissue for thermogenesis identified in tunas or sharks; the heat sources are the highly aerobic extraocular muscles as well as the brain, which thus far have been shown to occur in the bluefin tuna group only. Heat conservation mechanisms involving vascular retia are found in the lamnid sharks as well as closely related thresher sharks of the family Alopidae.

In tunas and lamnid sharks, endothermy in locomotory muscle is associated with two distinct anatomical changes: (1) the movement of the red slow-twitch aerobic swimming musculature internally and forward in the body plan and (2) the insertion of a complex countercurrent heat exchanger in the circulation to the oxidative muscle mass to reduce conductive and convective heat loss. Strong convergence in structure and function is seen in these two lineages. Both have a very streamlined shape and a shift in the body plan such that the red muscles that power endurance swimming have a central position near the vertebral column (**Figure 2**). This differs from most teleosts that have the aerobic red muscle located laterally near the surface of the fish, just beneath the skin. The central position of the aerobic muscle source facilitates heat retention as the red muscle fibers are continuously recruited, contracting and generating heat during the sustained locomotion characteristic of these lineages. The central positioning of the red muscle in tunas and lamnid sharks has received considerable attention as a result of its role in endothermy; however, it primarily reflects the evolution of a unique locomotor style. This stiff-bodied thunniform and lamniform swimming is more efficient for drag reduction (**see also Buoyancy, Locomotion, and Movement in Fishes**: Functional

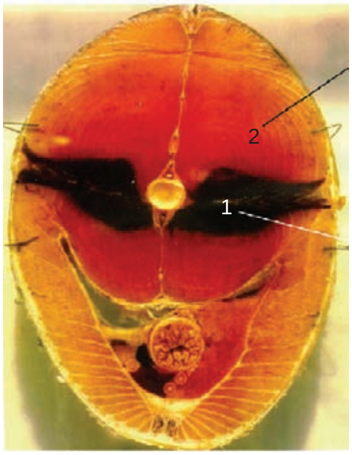

Figure 2 A cross section through a tuna that illustrates the internal location of the aerobic muscle that powers endurance swimming. This location differs from most teleosts that have the aerobic red muscle located laterally near the surface of the fish, just beneath the skin. 1, aerobic red muscle; 2, white muscle.

Properties of Skeletal Muscle: Work Loops and Undulatory Swimming). These fish generate thrust exclusively via the tail and restrict their propulsive movements to the caudal region rather than bending the whole body. Evolution of this locomotory form may be tightly coupled with the movement of the central aerobic muscle mass internally in addition to the use of this metabolic source of heat for endothermy.

In addition to the muscle heat, in some species of tunas and lamnid sharks the metabolic heat of digestive processes is conserved as well. Energy is expended (and heat is produced) during ingestion, digestion, absorption, and assimilation of a meal. When bluefin tunas digest a meal, they have a metabolic response that includes elevation of oxygen uptake called specific dynamic action (SDA) and the associated post-feeding thermogenesis (**Figure 6**; **see also Food Acquisition and Digestion**: Cost of Digestion and Assimilation). By having visceral retia mirabilia, the tunas and sharks retain the heat and warm the tissues involved in digestion of the meal. The entire muscle mass buffers visceral tissue from the surrounding aquatic heat sink to reduce conductive heat loss. Often, the muscle below the gut contains a very high fat content that probably adds to its insulative value.

An unusual aspect of endothermy in fishes is the requirement for a robust cardiac physiology as the hearts of all tunas operate at ambient water temperatures because they are not protected by retia mirabilia. The unusual physiological arrangement of endothermy in some tissues is unique among vertebrates and can result in a cold heart supplying the metabolic demands of warm tissues. In response to this, bluefin tunas and lamnid sharks have a higher capacity to cycle calcium ions in the heart cells that helps maintain beat-to-beat contraction at reduced temperatures. Results from molecular, structural, and physiological data indicate a significant role of mammalian-like calcium-induced calcium release in the cardiac myocytes of tunas and sharks. Thus, endothermic fish can protect their cardiac function in frigid seas using mechanisms that increase the capacity of the heart to function, ensuring delivery of oxygen to the metabolically active tissues required for warming the muscles, visceral, and cranial tissues.

Cranial Endothermy

The elevation of cranial tissue temperatures has the same two main requirements: (1) a heat source based on aerobic metabolism plus (2) vascular countercurrent heat exchangers to retain the heat. The main source of metabolic heat in the cranium is the extraocular muscles, the muscles that move the large eyes of these visual predators.

Cranial endothermy in tunas and sharks is not associated with a specific thermogenic tissue but with conservation of heat from continuously active red aerobic swimming muscle (lamnid sharks) or large extraocular muscles (tunas). In the case of the sharks, an unusual arrangement occurs whereby the vein coursing from the aerobic swimming muscle travels to the orbital sinus behind the eyes to bathe an orbital retia mirabilia with warm venous blood, the heat from which can be retained in the cranial region. That is, metabolic heat produced in the swimming muscle is used to warm the brain. Less complex is the situation in tunas, where the aerobic eye muscles are disproportionately large relative to eye size for ectothermic species. These extraocular muscles are among the fastest contracting muscles in vertebrates, and fiber populations are enriched with the cellular machinery for superfast contraction: the sarcoplasmic reticulum (SR) and proteins that cycle calcium. The presence of aerobic muscle fibers within the extraocular muscles, already specialized for superfast contraction, provides this muscle with relatively high thermogenic capacity and underlies the evolution of heat retention mechanisms in the circulation to the brain and eyes. The extraocular muscle of billfishes is similarly large and fast contracting, but has an additional feature, a heater organ.

Heater Organ Tissue

Some fish have evolved a heater organ for cranial endothermy. This thermogenic (heat producing) tissue, which warms only the brain and eyes, is found beneath the brain of all billfishes: swordfish, *X. gladius* (family Xiphiidae), marlins (*Makaira* sp.), spearfish *(Tetrapturus* sp.), and sailfish (*Istiophorous* sp.)(family Istiophoridae) and in one species of Scombrid fish, the butterfly mackerel (*Gastrochisma melampus*). It has also been reported in a monotypic genus, the slender tuna (*Allothunnus fallai*). The moonfish or opahs (Lampridae) have also been reported to have a countercurrent heat exchanger behind the eye, but it remains unresolved as to whether thermogenic cells are involved. Cranial endothermy in these species involves the presence of a specialized thermogenic heater organ tissue that develops from extraocular muscle and is located beneath the brain and near the eyes. The thermogenic capacity has been shown by direct telemetry in the swordfish to warm the cranial cavity up to 15 °C above ambient water temperature. The appearance of cranial endothermy independently of warming any other portion of the body indicates that there is a strong selective pressure for warming the brain and eyes.

The billfish heater organ is comprised of a mass of thermogenic tissue that is deep red in color with the appearance and texture of liver (**Figure 3**). It is associated with the superior rectus eye muscle in billfishes and with the lateral eye muscles in the butterfly

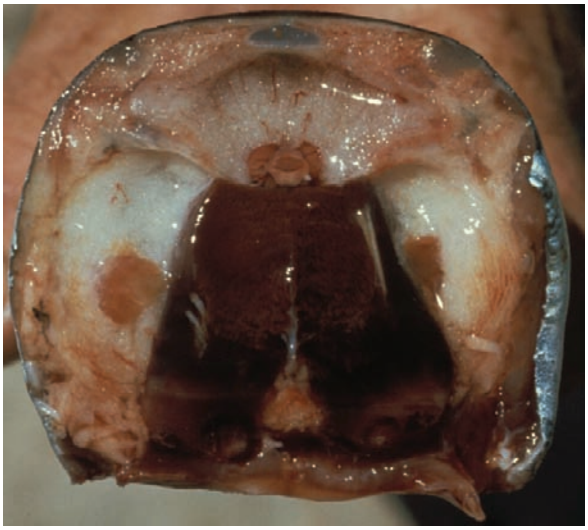

Figure 3 Transverse section through the head of a swordfish showing the position of the heater tissue beneath the brain and within the orbit. The head is packed with fat to reduce conductive heat loss.

mackerel, where modified muscles from both sides of the orbital cavity converge at the base of the braincase. In the swordfish, the brain is embedded in the dorsal surface of the heater, at the basisphenoid bone that forms the base of the braincase, which has been reduced to a membranous sheath. Large amounts of adipose tissue surround and insulate the brain, eyes, and heater organ. The major difference between heater organs in the billfishes is that of size; the heater organ is largest in the swordfish – the total mass of heater organ tissue exceeds the mass of the heart. The eyes of the swordfish are equivalent in size to small grapefruits. Both the eyes and the heater organ are surrounded by insulating fat.

In addition to the adaptation of the eye muscle to generate heat, these fish also have well-developed retia to reduce heat loss. At its base, a countercurrent heat exchanger is formed from the carotid artery and the venous return from the heater to retain the heat produced by the heater organ. Billfishes have two separate blood supplies to the brain and eyes: one supplying oxygen and the other retaining heat. The carotid circulation divides into numerous capillaries that bathe the oxidative heater cells with blood. In addition to this warm blood supply to the retina, the billfishes, like most teleost fishes, have a separate oxygenated source of blood to the retina by way of the choroid retia mirabilia. The choroid retia is extraordinarily enlarged in the marlins and other Istiophorid billfishes, and is supplied with blood via a pathway separate from the heater organ insuring a well-oxygenated blood supply to the eye. These fish have a separate circulation to the retina because the blood coursing through the heater organ is depleted in oxygen by the time the warm blood gets to the retina.

How Fish Have Built a Furnace Out of Muscle

The cells that make up the heater organ are modified skeletal muscle cells that are often called muscle fibers because they are multinucleate. They lack myofibrillar contractile proteins and are no longer involved in force generation but have an extremely high content of mitochondria and SR. In vertebrate skeletal muscle, contraction and relaxation are regulated by the concentration of calcium in the cytosol, which, in turn, is controlled by the SR and transverse tubule membranes. The SR of skeletal muscle cells is a highly organized intracellular membrane system that stores and releases Ca^{2+} in a highly regulated fashion. The SR has release channels (termed ryanodine receptors) that, when opened, allow Ca^{2+} to flow from the SR down its concentration gradient into the cytosol. Ca^{2+} is pumped back into the SR by the calcium ATPase (calcium pump protein), the major protein constituent of the SR bilayer. The calcium pumping consumes adenosine triphosphate (ATP) and heat is produced as a by-product of ATP production. If $Ca^{2+}$is cycled more than normal between the cytosol and the SR, then more ATP is consumed and more heat is produced. This is a key feature of the heater organ. In heater tissue and lacking extensive contractile protein, a thermogenic process is associated with Ca^{2+} cycling involving excitation–thermogenic coupling unlike the excitation–contraction coupling that normally occurs between the T-tubule, SR, and protein components of regular skeletal muscle.

Consistent with this role, certain morphological features stand out in all high power microscope pictures (electron micrographs) of heater tissue. The mitochondria of the heater cell are among the most densely packed in any cells in any animal, with as much as 63% of the cell volume being mitochondria. Also, located throughout the cytoplasm and in between the mitochondria is an extensive smooth membrane system comprised of tubules and membranous stacks. The tubules and membranous stacks are components of the two internal membrane components of muscle usually involved in excitation-contraction coupling, the SR. The very high oxidative capacity of the heater tissue also is reflected in high myoglobin concentration (400 μmol kg^{-1} wet weight) and in very high aerobic metabolic enzyme profiles.

Heater cells are innervated by a branch of the oculomotor nerve, and large clusters of acetylcholine receptors on the plasma membrane indicate that the cells are under nervous control similar to that in skeletal muscle. It is hypothesized that upon entering cooler water, nerve impulses to the heater cells result in depolarization of their cell membrane and that depolarization leads to Ca^{2+} release from the SR internal heater cell membrane

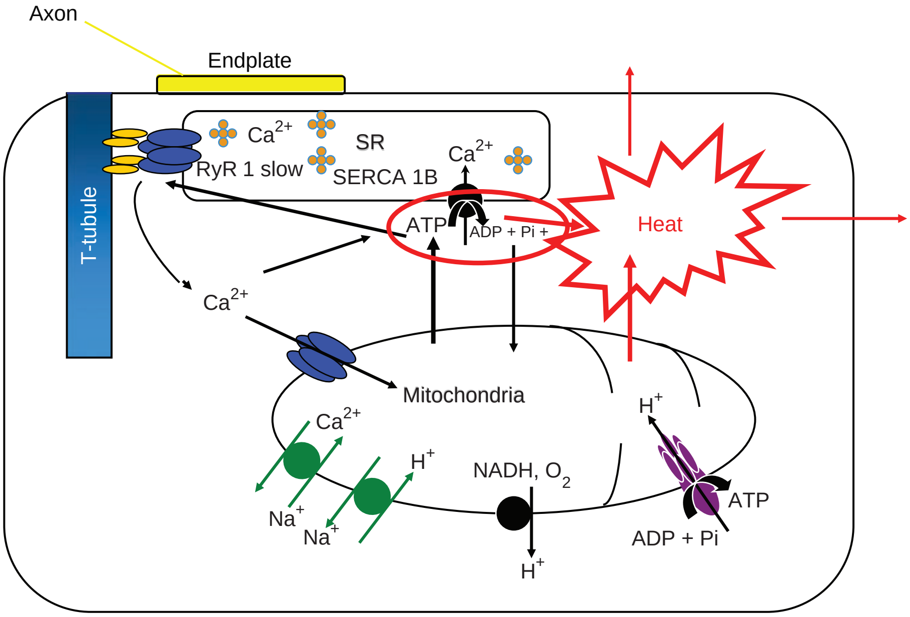

Figure 4 A model of excitation–thermogenic coupling in heater cells. Thermogenesis in heater cells is proposed to occur via depolarization-induced Ca^{2+}-release pathways. Nervous stimulation mediated by acetylcholine receptors at the endplate results in heater cell depolarization and DHPR–RyR1-mediated Ca^{2+} release from the SR. Increased cytoplasmic Ca^{2+} stimulates Ca^{2+} transport and ATP turnover by SERCA 1B and mitochondrial influx and efflux pathways. The physiological properties of the RyR1-slow isoform expressed in heater cells may facilitate prolonged channel openings under these conditions (high Ca^{2+}and the presence of adenine nucleotides) and promote further release of Ca^{2+} in a futile cycle that results in thermogenesis. Abbreviations: T-tubule, transverse-tubule; SR, sarcoplasmic reticulum; SERCA, sarco/endoplasmic reticulum Ca^{2+}ATPase; RyR, ryanodine receptor. Modified from Morrissette JM, Franck JPG, and Block BA (2003) Characterization of ryanodine receptor and Ca^{2+}-ATPase isoforms in the thermogenic heater organ of blue marlin (*Makaira nigricans*). *Journal of Experimental Biology* 206: 805–812.

system in much the same manner as occurs in a typical skeletal muscle through the Ca^{2+} release pathway (**Figure 4**). That is, depolarization leads to a conformational change in the voltage-sensitive dihydropyridine receptors (DHPRs) or L-type Ca^{2+} channels, which in turn induces the opening of SR Ca^{2+} channels and release of Ca^{2+}into the cytosol. Ca^{2+} release initiates a cycle of calcium-induced Ca^{2+} release. Similar to skeletal muscle, uptake of Ca^{2+} back into the SR requires energy in the form of ATP produced by the numerous mitochondria. The majority of energy used in generating ATP (and consumed by the Ca^{2+} pump) is released as heat – it is this heat that is used to heat the brain and eyes.

Telemetry of Brain Temperature

The best evidence for physiological regulation of brain temperatures comes from experiments with free-swimming swordfish conducted in the 1980s by Dr. Frank Carey. Swordfish have remarkable diel behavior, swimming to depths as deep as 600 m during the day in search of squid but spending most of the evening hours at the surface. During these vertical excursions, which primarily occur at dusk and dawn, the fish encounters rapid water temperature changes up to 19 °C in a short period. Measurements of cranial temperature provide direct evidence that the fish are able to warm the cranial cavity. Temperature in the cranial cavity remained about 28 °C for 36 h while the fish encountered water temperatures that ranged from 13 °C to 17 °C (**Figure 5**).

Why Be Warm?

The repeated evolution of endothermy in the scombroid fishes and lamnid sharks indicates that there is strong evolutionary selection for this energetically costly metabolic strategy. All endothermic lineages have species that have expanded their ranges into cool temperate waters and, in some cases, subpolar seas (Atlantic bluefin tunas and salmon sharks). This supports a niche expansion argument for the evolution of endothermy in fishes. There are several hypotheses on the advantages to warming of the brain, eyes, muscle, and visceral tissues.

In cranial endotherms such as swordfish, the warming of the brain and eye regions, the central nervous system and retina, is of key importance. Physiological processes such as synaptic transmission and the conduction of nerve impulses are temperature sensitive. Studies on the sensitivity of the retina indicate that vision and flicker frequency, as well as temporal resolution of a light flash,

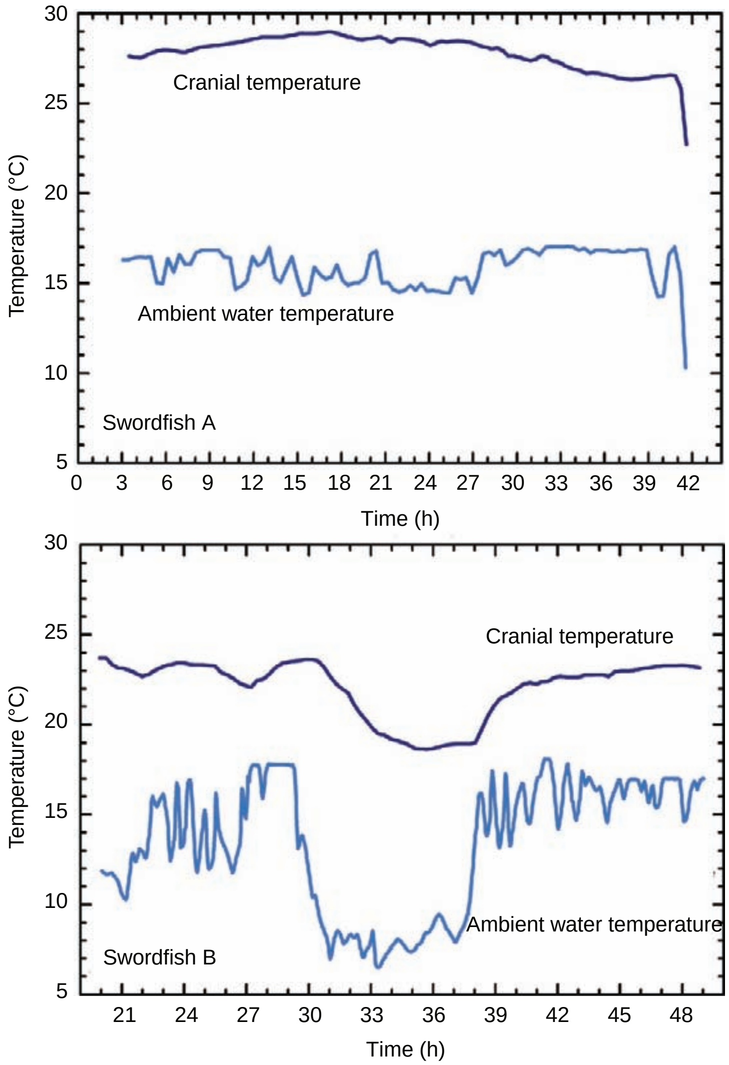

Figure 5 Telemetry record of cranial temperature and ambient water temperature from a free-swimming swordfish. Zero on the *x*-axis is midnight, top line is cranial temperature, and bottom line is water temperature. Swordfish swim to depths as deep as 600 m, typically at dusk and dawn. Modified from Carey FG (1990) Further observations on the biology of the swordfish. In: Stroud RH (ed.) *Planning the Future of Billfishes*. Savannah, GA: National Coalition for Marine Conservation.

are thermally sensitive. The warming of the eye and specifically the retina has been shown experimentally to significantly improve visual acuity, specifically the temporal resolution of nervous signals by the retina. Warming of the retina may improve the ability to detect prey in the dimly lit mid-waters (light penetration ceases around 1000 m; (**see also Deep-Sea Fishes**). Thus, fish with warm eyes can detect the rapid motion of prey species better than fish with cold eyes. Because these fish are fast-swimming predatory fishes, improvements in the temporal resolution mean that the swordfish eyes are operating faster than prey at the same temperature as the surrounding water. The convergence of cranial endothermy in several species indicates that there is strong selection for warming of the eyes and brain. Cranial endothermy has evolved multiple times in large predatory fish that experience cooler waters at high latitude distributions (temperate or subpolar seas) or at depth. Thus, warming of sensory structures in the cranium appears to be key to occupation of the colder (both at high latitude and at depth) as well as dimly lit environs.

Studies in tuna also indicate that warming of the swimming muscle permits them to generate more power that results in enhanced locomotory performance because power output of muscle is highly temperature dependent. A countercurrent heat exchanger that could maintain a 10 °C temperature differential would typically double maximum muscle power output and the frequency at which maximum power is generated. The deep slow muscle of a tuna operates at higher temperatures than slow muscle from ectothermic sister taxa such as bonito and has been shown to generate more power. However,

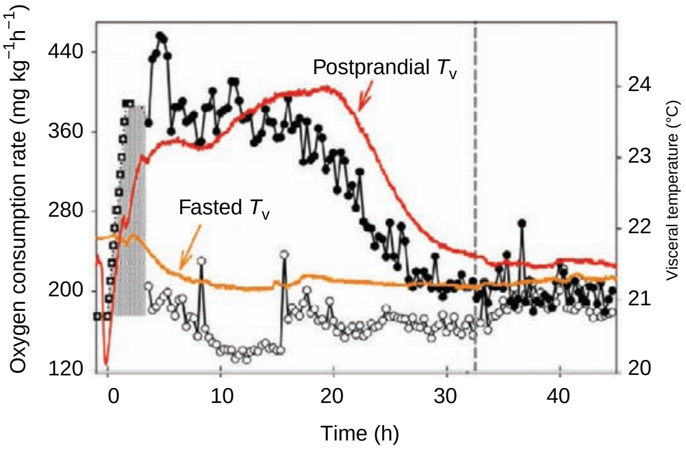

Figure 6 Traces of fasted and digesting oxygen uptake rate (MO_2; open and closed circles, respectively) and visceral temperature (T_v) from Pacific bluefin tuna (*Thunnus orientalis*) swimming at 1 BL s^{-1} at 20 °C. Spikes in MO_2 for the fasted trace resulted from short bursts of unsteady swimming. Modified from Clark TD, Brandt WT, Nogueira J, *et al.* (2010) Postprandial metabolism of Pacific bluefin tuna (*Thunnus orientalis*). *Journal of Experimental Biology* 213.

internal warm muscles are more thermally sensitive to temperature changes than more superficially located swimming muscles in tuna. This suggests evolutionary specialization for operation at higher, but also in relatively stable temperatures for function.

Digestion, like vision and muscle power, is temperature sensitive. An example of a tuna warming its viscera after a meal is shown in **Figure 6**. Food resources are ephemeral in the open ocean and often spread over large distances. Acquiring a meal quickly, digesting, and being able to take on more energy quickly is a matter of survival. Increasing the temperature of the viscera after a meal hastens digestion, largely because the action of enzymatic degradation of the meal is very temperature sensitive. Thus, when a tuna swimming in 10 °C water warms its gut from 10 to 30 °C after a meal, it decreases the time to digest the meal about threefold. Considered over a longer time period, for example, a week or a month, a tuna that warms its viscera can eat more if it can digest faster, , and thus grow more rapidly than if it did not warm its gut. That is, the advantage of the warm cecum is that protein is digested in about one-third the time so that these tuna can process about three times as much food per day.

In summary, these large, fast, oceanic predators have a number of specializations that permit them to achieve tissue temperatures higher than ambient water temperatures. Most important are the retia to conserve the heat, and an increase in metabolic heat production. Unique to a few of them is the evolution of a tissue specialized for the generation of heat to achieve high brain and eye temperatures, the heater organ.

Glossary

Amphidromy An uncommon subcategory of diadromy, in which there is a brief excursion from freshwater to seawater during the juvenile stage, but the majority of feeding and growth and spawning occur in freshwater.

Anadromy Life-history strategy entailing reproduction and early rearing in freshwater followed by a significant growth phase in seawater.

Catadromy A subcategory of diadromy, in which the majority of feeding and growth occurs in freshwater and the fully grown adult fish migrate to saltwater and reproduce.

Crepuscular Occurring during twilight (dusk and dawn). Daily pattern with two peaks of activity centered around dusk and dawn, though not excluding some activity in between these periods. From Latin ‘crepusculum’ (twilight).

Diadromy A category of migration, in which all migratory activity crosses the seawater/freshwater boundary.

Diel Pertaining to a 24-h period.

Fluvial Relating to a river, stream, or other flowing water.

Iteroparity A reproductive strategy whereby an individual reproduces more than once within its lifetime.

Lateral line Sensory structure consisting of a series of mechanoreceptor cells on the surface of the body of fishes and for detection of water motion relative to the body and low-frequency sound.

Migration A regular directed movement of a group of animals.

Navigation A mechanism whereby fishes plot a course to a particular location.

Oceanodramy A category of migration, in which all migratory activity occurs in saltwater.

Orientation A mechanism whereby fishes position themselves in a particular direction in response to an external stimulus.

Potamodromy A category of migration, in which all migratory activity occurs in freshwater.

Rheotaxis A directional preference to flowing water.

Semelparity A reproductive strategy whereby an individual reproduces only once within its lifetime.

What is Migration?

It is sometimes the case in fishes that the life history needs of a population (e.g., foraging and reproduction) cannot be met by a single habitat. This is due to variability in the habitat conditions (e.g., temperature), or to the changing needs of the population itself (e.g., foraging habitat vs. spawning habitat). In such cases, the fitness of individuals benefits from movement to an alternate habitat. As a result, many fishes have evolved a life history that includes coordinated movement from one habitat to another. This synchronous, directed movement of part or all of a population between discrete habitats is called 'migration'.

Approximately 2.5% of all fish species undertake migrations. The physical scale of migrations is highly variable and can range from hundreds of meters, as in some coastal and stream dwelling fishes, to thousands of kilometers, as in eels (*Anguilla* spp.; **see also Fish Migrations**: Eel Migrations) and tunas (*Thunnus* spp.; **see also Fish Migrations**: Tracking Oceanic Fish). The timing of migration typically occurs on a seasonal scale, though some species display coordinated daily movements (e.g., vertical or tidal migrations). According to some authors, this represents migratory activity and, to others, these movements are a specialized form of foraging. In this article, we focus on longer-distance migrations, not because short-distance and vertical migrations are ecologically or evolutionarily less important, but because long-distance migrations typically impose greater behavioral and physiological challenges on fishes than short ones.

Classifying Migrations

Fish migrations are typically grouped into three categories, based somewhat arbitrarily on their relationship to the seawater/freshwater boundary (**Figure 1**).

1. Oceanadromous migrations, such as those performed by tunas, white sharks (*Carcharodon carcharias*), and plaice (*Pleuronectes platessa*), occur entirely within seawater.
2. Migrations that occur entirely within freshwater are classified as potamadromous. Potamadromous migrations can occur solely in lakes (e.g., lake trout, *Salvelinus namaycush*), in rivers and streams (e.g., brook lampreys, *Lampetra* spp.), or can span both lake and fluvial habitats (e.g., white suckers, *Catostomus commersoni*).
3. Migrations that cross the seawater/freshwater boundary (e.g., Pacific salmonids, *Oncorhynchus* spp.) are classified as diadromous. There are three subcategories of diadromy – anadromy, catadromy, and amphidromy:

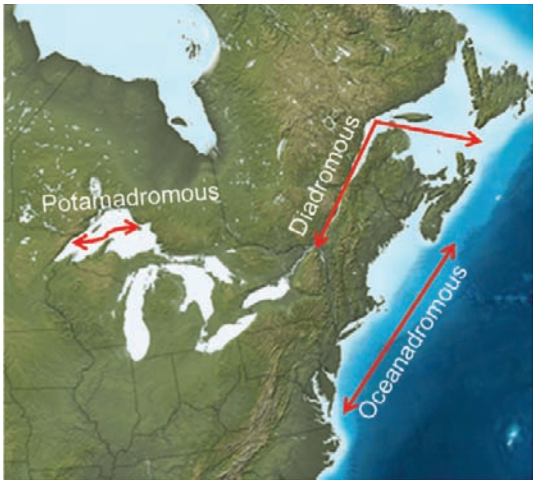

Figure 1 Map of the northeast coast of North America displaying example migratory patterns for the three major categories of fish migration. Migrations are categorized based on their relationship to the seawater/freshwater boundary – see text for details. Sources of map image: http://oversights.org.uk/.

   (a) Anadromy occurs when most feeding and growth occurs in saltwater and fully grown adults move back into freshwater to spawn (e.g., Pacific salmon).
   (b) Conversely, catadromy occurs when most feeding and growth occur in freshwater and the fully grown adults move into saltwater to spawn (e.g., eels).
   (c) The last subcategory, amphidromy, occurs when there is a brief excursion from freshwater to seawater during the juvenile stage, but the majority of feeding and growth and spawning occurs in freshwater. This last subcategory is most common in fishes inhabiting islands in the tropics and subtropics (e.g., sicydiine gobies, *Sicydium* spp.)

While it might be convenient to classify migrations, the above categories and subcategories do not provide any insights into the behavioral or physiological challenges involved in migrations, with the notable exception that diadromous migrants must contend with an osmoregulatory challenge as they move between the freshwater/seawater environments (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). As a result, this article focuses on the requisite properties for long-distance migration, rather than their categories.

Orientation and Navigation

There is a long history of interest in orientating and navigating mechanisms in fishes that stems from the discovery in the 1930s that salmon return from the ocean to their natal streams to spawn (termed 'homing'). Since then, homing has been demonstrated for numerous fish species. Originally, it was believed that the phenomenon involved a spectacular navigation mechanism. However, despite intensive research on the mechanisms of homing in fishes, no precise navigation ability has yet been demonstrated. This prompted researchers to test the hypothesis that homing is accomplished through random search. Not surprisingly, a random search model alone was insufficient to explain homing in salmon. However, when slight directional bias (orientation) was added to the model, the predicted return rate was similar to the observed return rate for these fish.

Several orienting mechanisms have been proposed, and it is likely that several different cues might be involved in orientation at various stages of migration. In particular, orientating behavior differs markedly between open water and fluvial migrations. In open water, fishes may migrate in any one of 360° of direction. By contrast, fluvial migrants are confined within a relatively narrow channel plus they have the added cue of migrating either with or against the current, termed negative or positive rheotaxis, respectively. Because of this dichotomy, we discuss the possible orienting mechanisms for open water and fluvial migrations separately.

Orienting in Open Water

Stemming from pioneering work by Hasler in the late 1950s, there is now considerable evidence that fishes use solar cues to orient during open water migrations. Fishes may orient using information derived from changes in the sun's azimuth (angle of the sun in the horizontal plane) and/or altitude (angle of sun in the vertical plane) (**Figure 2**). However, because these measures change on both a diel and seasonal scale, fishes that orient using the sun must possess an internal biological clock and calendar to compensate for these changes. For salmon that spawn on very precise dates of the year, the idea of an internal biological clock is not an unreasonable expectation. Indeed, laboratory experiments in a variety of species have demonstrated that fishes may be trained to use an artificial sun to orient in a particular compass direction. Moreover, fishes trained to orient in this manner can correctly compensate for diel and seasonal variation in the position of the sun.

The sun itself is often obscured and, thus, is not always a reliable orienting cue. Nonetheless, fishes may continue to orient when the sun is obscured by using polarized light as a directional cue. The ability to detect and discriminate planes of polarized light has been demonstrated in numerous species. However, there is some evidence that polarized light would be a reliable orienting cue only during crepuscular periods (dawn and dusk) when the percentage of polarized light is as high as 60–70%. During the day, the percentage is far lower (<40%), and may in fact be below the detection threshold of most fishes.

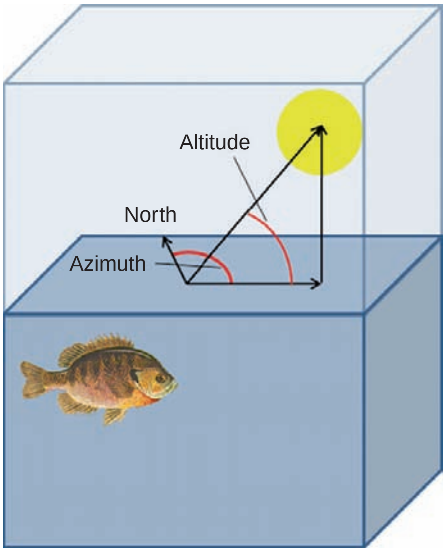

Figure 2 Solar information used by fishes for orientation in open water. Directional information is derived from changes in the angle of the sun in both the vertical (altitude) and horizontal (azimuth) planes. Fish possess a biological clock and calendar that allows them to compensate for diel and seasonal changes in these parameters.

There is a growing body of support for geomagnetic orientation, particularly in fishes such as Pacific salmon and eels (**see also Fish Migrations**: Eel Migrations), which undergo long-distance oceanic migrations. When water moves across the Earth's magnetic field, it induces a weak electric current that may be detected by fishes. In rainbow trout (*Oncorhynchus mykiss*), changes in the intensity of the Earth's magnetic field are detected by discrete magnetoreceptor cells located in the olfactory epithelium. These cells, which contain chains of magnetite crystals (biogenic Fe_3O_4) that transduce the induced electric current into a sensory signal, are innervated by a branch of the trigeminal nerve. There are, however, opponents to the theory of geomagnetic orientation in migrating fishes. The two main arguments against this type of orientation are that: (1) temporal and spatial variations in the magnetic field would make it difficult to form a useful magnetic map; and (2) there is as yet no evidence that fishes possess the ability to memorize such a map, even if they were capable of forming it (**see also Sensory Systems, Perception, and Learning**: Magnetic Sense in Fishes). Nevertheless, salmon can memorize the complex odors of a natal stream for their entire seaward migration, which can last several years.

The tendency to orient in a current is called rheotaxis. In open water, large-scale currents substantially influence the direction and speed of some migrations. For example, the ocean migration pattern of Pacific salmon from British

Columbia (Canada) is largely determined by interannual variations in the strength of the Alaskan Gyre, a counterclockwise current in the Gulf of Alaska. Smaller-scale currents can also be important. For example, models of the migratory behavior of Pacific salmon that encounter the Sitka Eddy (mesoscale eddy located northwest of the Queen Charlotte Islands, BC, Canada) suggest that salmon can exploit the rotational current of the eddy to increase speed and moderately reduce the energetic costs of migration. More recently, it has been hypothesized that even subtle currents may be important during the open water phase of migration of salmon to their natal streams.

Differences in water temperature and salinity create vertical layers and each layer has a distinct origin, presumably with its own unique home stream 'olfactory bouquet', which plays a dominant role during the final stages of locating the natal stream (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle). Behavioral studies have shown that both Pacific and Atlantic salmon tend to migrate within a single vertical layer, but make brief periodic excursions into adjacent layers. Salmon may use these excursions to determine the direction of the layer's origin by detecting the acceleration that occurs as they cross between adjacent layers. It is unlikely that the lateral line is sensitive enough to detect the subtle differences in velocity between adjacent layers. However, the otolith organs are capable of detecting minute accelerations and, depending on how quickly the fish move between adjacent layers, could be capable of detecting velocity differences as small as $1\ \mathrm{mm\,s^{-1}}$.

Orienting in Fluvial Habitats

Navigation in fluvial habitats is less complicated than in open water. Here, water current is the primary orienting cue – migration is the result of the tendency of animals to orient with the current (negative rheotaxis) or against it (positive rheotaxis). Studies that employed a combination of Co^{2+} and aminoglycoside antibiotics (streptomycin and gentamicin) to block various components of the mechanosensory lateral line system have demonstrated that the lateral line is involved in mediating rheotactic behavior. Specifically, a single class of lateral line organs located on the surface of the skin, superficial neuromasts, appears to be important. A second class of lateral line organs, canal neuromasts, are located within canals beneath the surface of the skin and may contribute to navigation in complex flows (**see also Hearing and Lateral Line**: Lateral Line Neuroethology). Nevertheless, the lateral line is incapable of mediating rheotaxis on its own. Rheotaxis depends on a fixed frame of reference from which the fish can determine both the speed and direction of flow. This is accomplished using either visual cues or through periodic contact with the substrate.

There is overwhelming evidence that olfactory orientation is an important component of navigation in fluvial migrants. The olfactory basis of upstream migration has been most extensively studied in Pacific salmon and sea lampreys (*Petromyzon marinus*). Upstream-migrating salmon home to a stream-specific set of olfactory cues that are imprinted prior to their emigration from the stream as smolts (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle). In sea lampreys, the situation is somewhat different. Spawning phase sea lampreys do not home to their natal stream. Instead, they are drawn to streams with suitable spawning habitat by a multicomponent bile acid pheromone released by larval lampreys, which they can detect at extremely low concentrations (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development and Lampreys: Environmental Physiology). Interestingly, while these navigation strategies differ significantly, the mechanism by which olfaction mediates upstream migration appears to be the same.

The general consensus is that olfactory cues induce upstream migration in fishes through olfactory-mediated rheotaxis. This conclusion is based on two main observations. First, fishes tend to display significantly greater upstream activity (positive rheotaxis) when the correct olfactory stimulus is present than when it is not. Second, upstream migrants that no longer detect the olfactory stimulus, such as when the stimulus is pulsed, the animal is anosmic, or when the animals pass upstream of the stimulus source, display significantly greater movements in the downstream direction (negative rheotaxis). Downstream migrations, like those of salmon smolts, could similarly be induced by olfactory-mediated rheotaxis in response to conspecific olfactory cues. However, there is as yet no experimental evidence to support this assertion (**see also Sensory Systems, Perception, and Learning**: Spatial Orientation: How do Fish Find their Way Around?). Clearly, aquatic pollutants that impair olfaction (**see also Toxicology**: The Effects of Toxicants on Olfaction in Fishes) could have catastrophic effects for these fishes.

Energetics of Migration

Long-distance migrations, especially upstream migrations in fluvial systems, are energetically demanding, and feeding during long-distance migrations is rare. The reason for this is that feeding imposes several constraints on migration, including foraging time and the reduced metabolic scope available for migratory activity when energy is reallocated for foraging and digestion. As a consequence, most species rely heavily on energy reserves that they accumulate in the months preceding migration. In fact, in semelparous species such as Pacific salmon and lampreys, the alimentary canal and digestive organs undergo atrophy so that precious energy reserves are not wasted in maintaining these inactive tissues. In fishes that do not feed during migration, the energy available for migratory activity is finite; thus, energy management is a primary factor determining the success of a migrant.

The degree to which fishes deplete their energy reserves is highly variable both among species, and among different populations within a species. In some anadromous spawning migrations, energy depletion can be remarkably high, ~85% of total energy stores. There is a correlation between the degree of energy depletion during migration and the prevalence of semelparity among fish populations – the more energy they deplete, the less likely they are to be repeat spawner. For example, there are no repeat spawners among American shad (*Alosa sapidissima*) migrating up the St. Johns River (Florida, USA), which deplete as much as 75–82% of their total stored energy reserves. However, American shad migrating up the more northern Connecticut River (New England, USA), which deplete only 35–60% of their stored energy, do repeat spawn. Nonetheless, while exhaustion of energy resources probably contributes to mortality in semelparous populations, it is not the only factor. This is evident by the fact that some semelparous populations migrate only a relatively short distance – not nearly far enough to exhaust their energy reserves, indicating that there are other genetic and/or environmental factors involved. Indeed, the mechanism of post-spawning death in semelparous species appears to involve a breakdown in glucocorticoid regulation, resulting in highly elevated levels of circulating corticosteroids and a consequent disruption of immune function. This may be part of a true but rapid senesence program.

Energy for migratory activity is stored as proteins, carbohydrates, and lipids. Lipids are the most energy dense form of energy storage, having an approximately twofold greater energy density (9.45 kcal g^{-1}) than both carbohydrates and proteins (4.1 and 4.8 kcal g^{-1}, respectively). Unlike higher vertebrates, which store lipids mainly in adipose tissue, fishes distribute lipid reserves among a variety of tissues, including adipose-like tissue in the viscera, muscle tissue, and the liver. Many fishes also possess a subcutaneous layer of fat. Studies of proximate tissue composition have demonstrated that both lipids and proteins are depleted during long-distance migrations. Carbohydrate levels tend to remain high, but this is because carbohydrates (glycogen and glucose) are used mainly to fuel short bursts of activity, and are then subsequently replenished through breakdown and conversion of lipids and/or protein.

The majority of energy mobilized during migration (excluding that used for gonadal development during spawning migrations) is used by the muscles for locomotor activity. In general, fishes have two types of muscles that are both anatomically and functionally distinct. Red muscle is organized into a thin longitudinal band beneath the lateral line and is ideally suited for powering slow and intermediate speed, high endurance swimming – the swimming that comprises most of a fish's routine activities. High-speed swimming is powered by white muscle, which comprises the bulk of the muscle mass, despite the fact that most fish species only occasionally invoke high-speed (aka burst) swimming. White muscle is fueled mainly by glycolytic (anaerobic) metabolism and is prone to fatigue (**see also Swimming and Other Activities**: Applied Aspects of Fish Swimming Performance). Moreover, during anaerobic swimming fish accumulate the metabolic by-product lactate, which can cause acidosis and even death. Reconversion of lactate to glycogen and rebalance of acid–base requires aerobic metabolism and can take as long as 24 h.

Environmental Factors That Influence Migration

Understanding how environmental variables influence migration is a popular theme in the study of migratory biology. The greatest challenge in studying how environmental factors influence migration is the fact that environmental variables are often highly correlated with one another, making it difficult to know which variables are the most relevant for influencing a migration. For example, in temperate climates there is a high degree of correlation between the length of day (photoperiod) and water temperature. Moreover, the relative importance of each environmental factor may be dependent on the local characteristics of the habitat in which the migration is occurring. Nonetheless, despite these challenges, a number of environmental factors have repeatedly been shown to influence migration in fishes.

Changing light levels are an important environmental stimulus for migratory activity. On a seasonal scale, changes in photoperiod provide calendar information that is used to initiate and synchronize the migratory activity of individuals within a population. Long-duration migrations such as the spawning migrations of Pacific salmon and Pacific lampreys (*Lampetra tridentata*) appear to be particularly dependent on photoperiod for synchronizing migratory activity. This probably reflects the fact that other environmental factors (e.g., temperature) that vary on a seasonal scale are more variable, and, therefore, less reliable. The daily (diel) alternation between night and day synchronizes migratory activity. Diel activity patterns fall into three categories – diurnal, nocturnal, and crepuscular. It is not clear for most fishes whether the diel pattern of migratory activity is a true endogenous circadian rhythm (**see also Sensory Systems, Perception, and Learning**: Circadian Rhythms in Fish) or a direct response to changing light levels. There is, however, evidence that fishes will adapt their diel activity to variations in light level. For example, nocturnal fishes often become active during the day when there is cloud cover, or when turbidity is high. Thus, the diel period in which a fish migrates appears to be related to its perceived risk of falling prey to visual predators.

Temperature can trigger and synchronize migratory activity in fishes. When temperature acts as a trigger, migration can be viewed as a form of behavioral thermoregulation (**see also Behavioral Responses to the Environment**: Temperature Preference: Behavioral Responses to Temperature in Fishes). This can occur under two conditions. First, in thermally heterogeneous environments, temperature may fluctuate beyond the range of thermal tolerance for a given population. Thus, the fish are forced to seek out a new thermal habitat. Second, the thermal requirements of the population may change. For example, the optimal temperature for growth may not be the same as for reproduction. In this example, temperature is the cause of the migration to spawning grounds. However, temperature is also a well-known synchronizing cue during spawning migrations. This is particularly true for migrations that are relatively short in duration. A good example of this is the springtime upstream migration of sea lampreys (*P. marinus*) in the Laurentian Great Lakes. Typically, the migration does not begin until temperatures in the streams exceed ~10 °C. Thus, the migration begins later in cooler than average springs and earlier in warmer than average springs. This type of thermal threshold for migratory activity in spawning phase fishes is common and seems to have evolved in response to the strict thermal requirements of the developing embryos. A related temperature effect is slowed growth at low temperature, which causes more northern populations of Pacific salmon to rear in freshwater for another year before migrating to the ocean.

In fluvial habitats, discharge-related events can also have a marked influence on migratory behavior. The effect of discharge on migration can sometimes be difficult to interpret because changes in discharge are often associated with changes in other environmental factors, such as temperature and turbidity. Nonetheless, there is evidence that periodic increases in discharge, such as those that occur during the spring snow melt and after rain events, are commonly associated with peaks in downstream migratory activity (e.g., Atlantic salmon smolts, *Salmo salar*). Perhaps more surprisingly, increases in discharge are also commonly accompanied by peaks in upstream migratory activity (e.g., spawning migrations of white suckers, *C. commersoni*, and brown trout, *Salmo trutta*). In these instances, the benefits of higher water levels (e.g., greater protection from visual predators and easier access to headwater rearing sites) seem to outweigh the greater energetic costs of swimming against greater velocity. Moreover, it has been shown in adult Pacific salmon that some fish can utilize small-scale reverse flow vortices to draft up-river with minimal swimming effort and thus can conserve high levels of energy during the migration. By contrast, in species with relatively poor swimming ability (e.g., American eels, *Anguilla rostrata*, and brook lampreys, *Lampetra planeri*), the cost-to-benefit ratio is apparently greater and increases in discharge may inhibit upstream migration.

There is fairly strong support for lunar phasing in some migrating fishes. In many cases, changes in migratory activity appear to be a direct response to variations in the intensity of moonlight. For example, upstream migratory activity in lampreys and eels is reportedly highest on nights with little moonlight. However, there is also evidence that some species may entrain to the lunar cycle. For instance, in masu (*Oncorhynchus masou*) and coho (*Oncorhynchus kisutch*) salmon smolts, circulating levels of the thyroid hormone thyroxin (T_4) peak during the new moon. This peak in T_4 is, in turn, a stimulus for downstream migratory activity. Lunar phasing has also been widely reported in diadromous species as they cross the seawater/freshwater boundary. However, in these cases, the relationship is generally believed to be indirect, and is likely a response to tidal variations, rather than changes in moonlight.

Anthropogenic Impacts on Migration

Human activities have a long history of interfering with fish migration. Probably, the most obvious way in which our activities disrupt migration is through the construction of dams and other structures (e.g., weirs and culverts) that act as barriers to migration in streams and rivers. Barriers disrupt stream continuity making it difficult, if not impossible, for fishes to reach upstream habitat (**Figure 3**). Even when a fishway is present at a barrier,

it is typically selective in the species that it passes, and those fish that do navigate the fishway usually incur high costs, in terms of both time and energy (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development and Lampreys: Environmental Physiology). In addition, barriers can drastically alter the physical and chemical characteristics of a stream, and, thus, may reduce the abundance and quality of suitable stream habitat.

Toxicants and other chemical contaminants can also directly impact the migratory success of fishes. Contaminants may mask the odors that some fishes use to identify the home stream (**see also Toxicology**: The Effects of Toxicants on Olfaction in Fishes). Moreover, some toxicants cause physical damage to the sensory cells that mediate orientation. For instance, the olfactory and lateral line organs are particularly susceptible to heavy metals. Contaminants can also interfere with metabolism. Many toxicants have been shown to reduce swimming performance in fishes by limiting oxygen uptake and shuttling energy away from the swimming muscles. This increased metabolic load can also lead to premature mortality.

The final anthropogenic impact we will discuss is climate change. It is clear that the Earth is undergoing a relatively rapid change in its temperature regime and this will have an impact on migration success. First, higher temperatures, especially in temperate regions, are reducing the abundance of suitable habitat for many species, limiting the range over which migration can occur. Second, populations whose migrations are synchronized by photoperiod, rather than temperature, will experience higher temperatures throughout their migration. These higher temperatures will put greater metabolic demands on stored energy reserves and increase disease prevalence, resulting in a greater incidence of en-route migration mortality. Indeed, there is already evidence of this occurring in populations of Pacific salmon (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle). Third, higher temperatures could impact the reproductive success of spawning phase migrants. Embryonic and larval development is exquisitely sensitive to temperature. Even slight deviations from optimal temperatures can have drastic effects on development, including physical deformations and a reduction in the proportion of embryos that develop into juveniles. There is a paucity of information available on the long-term effects of small-increment increases in temperature on fishes, so it is difficult to predict to what extent individual species will be able to adapt their migration strategies to the new temperature regime. It appears, however, that species that undergo long-distance migrations may be most at risk (**see also Temperature**: Effects of Climate Change).
